Peptidoglycan structure varies considerably among different gram-positive groups. Most gram-negative bacteria have a peptidoglycan structure in which *meso*-diaminopimelic acid in position 3 is directly linked through its free amino group with the free carboxyl of the terminal D-alanine of an adjacent peptide chain (**figure 23.4*a***; *see also figure 3.18*). This same peptidoglycan structure is present in many gram-positive genera, for example, *Bacillus, Clostridium, Lactobacillus, Corynebacterium, Mycobacterium,* and *Nocardia.* In other gram-positive bacteria, lysine is substituted for diaminopimelic acid in position 3, and the peptide subunits of the glycan chains are cross-linked by interpeptide bridges containing monocarboxylic L-amino acids or glycine, or both (figure 23.4*b*). Many genera including *Staphylococcus, Streptococcus, Micrococcus, Lactobacillus,* and *Leuconostoc* have this type of peptidoglycan. The genus *Streptomyces* and several other actinobacterial genera have replaced *meso*-diaminopimelic acid with L,L-diaminopimelic acid in position 3 and have one glycine residue as the interpeptide bridge. The plant pathogenic corynebacteria provide another example of peptidoglycan variation. In some of these bacteria, the interpeptide bridge connects positions 2 and 4 of the peptide subunits rather than 3 and 4 (figure 23.4*c*). Because the interpeptide bridge connects the carboxyl groups of glutamic acid and alanine, a diamino acid such as ornithine is used in the bridge. Many other variations in peptidoglycan structure are found, including other interbridge structures and large differences in the frequency of cross-linking between glycan chains. Bacilli and most gram-negative bacteria have fewer cross-links between chains than do gram-positive bacteria such as *Staphylococcus aureus* in which almost every muramic acid is cross-linked to another. These structural variants are often characteristic of particular groups and are therefore taxonomically useful.

Bacterial endospores are round or oval intracellular objects that have a complex structure with a spore coat, cortex, and

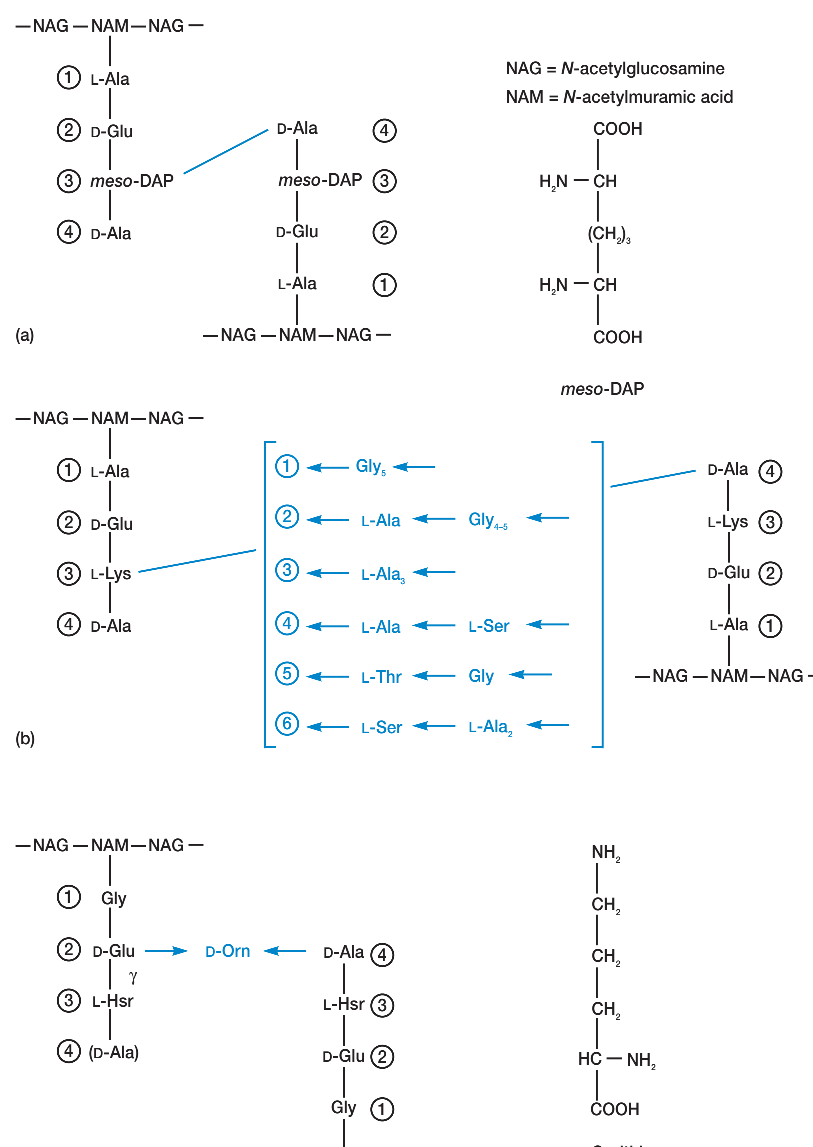

Figure 23.4 Representative Examples of Peptidoglycan Structure. (**a**) The peptidoglycan with a direct cross-linkage between positions 3 and 4 of the peptide subunits, which is present in most gram-negative and many gram-positive bacteria. (**b**) Peptidoglycan with lysin in position 3 and an interpeptide bridge. The bracket contains six typical bridges: (**1**) *Staphylococcus aureus,* (**2**) *S. epidermidis,* (**3**) *Micrococcus roseus* and *Streptococcus thermophilus,* (**4**) *Lactobacillus viridescens,* (**5**) *Streptococcus salvarius,* and (**6**) *Leuconostoc cremoris.* The arrows indicate the polarity of peptide bonds running in the C to N direction. (**c**) An example of the cross-bridge extending between positions 2 and 4 from *Corynebacterium poinsettiae.* The interbridge contains an L-diamino acid like ornithine, and L-homoserine (L-Hsr) is in position 3. The abbreviations and structures of amino acids in the figure are found in appendix I. See text for more detail.

inner spore membrane surrounding the protoplast (**figure 23.5**). They contain dipicolinic acid, are very heat resistant, and can remain dormant and viable for very long periods (**Box 23.1**). In one well-documented experiment, endospores remained viable for about 70 years. A recent research article reports that viable endospores have been recovered from Dominican bees that were encased in 25- to 40-million-year-old amber. If this result is confirmed, endospores from an ancestor of *Bacillus sphaericus* have survived for more than 25 million years! Similar reports have been made subsequently; all these studies will have to be reconfirmed. Usually endospores are observed either in the light microscope after spore staining or by phase-contrast microscopy of unstained cells (*see sections 2.2 and 2.3*). They also can be detected by heating a culture at 70 to 80°C for 10 minutes followed by incubation in the proper growth medium. Because only endospores and some thermophiles would survive such heating, bacterial growth tentatively confirms their presence. Bacterial endospore structure (pp. 68–71)

Although endospore-forming bacteria are distributed widely, they are primarily soil inhabitants. Soil conditions are often extremely variable, and endospores are an obvious advantage in surviving periods of dryness or nutrient deprivation.

The second edition takes a phylogenetic approach primarily based on 16S rRNA data rather than phenotypic similarity. The traditional low G + C gram-positive bacteria are divided into two classes: *Clostridia* (the clostridia and relatives), and *Bacilli* (the bacilli and lactobacilli) (figure 23.1). Each class has endospore-forming bacteria and both rods and cocci. Thus the new group-

Box 23.1

Spores in Space

During the nineteenth-century argument over the question of the evolution of life, the panspermia hypothesis became popular. According to this hypothesis, life did not evolve from inorganic matter on earth but arrived as viable bacterial spores that had escaped from another planet. More recently, the British astronomer Fred Hoyle has revived the hypothesis based on his study of the absorption of radiation by interstellar dust. Hoyle maintains that dust grains were initially viable bacterial cells that have been degraded, and that the beginning of life on earth was due to the arrival of bacterial endospores that had survived their trip through space.

Even more recently Peter Weber and J. Mayo Greenberg from the University of Leiden in the Netherlands have studied the effect of very high vacuum, low temperature, and UV radiation on the survival of *Bacillus subtilis* endospores. Their data suggest that endospores within an interstellar molecular cloud might be able to survive between 4.5 to 45 million years. Molecular clouds move through space at speeds sufficient to transport spores between solar systems in this length of time. Although these results do not prove the panspermia hypothesis, they are consistent with the possibility that bacteria might be able to travel between planets capable of supporting life.

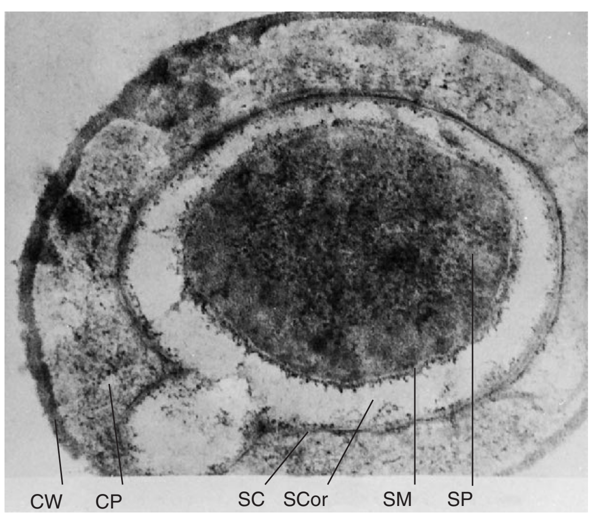

Figure 23.5 Bacterial Endospores. A cross section of *Bacillus megaterium* and its endospore within the vegetative cell wall, CW; cell protoplast, CP; spore coat, SC; spore cortex, SCor; spore membrane, SM; and spore protoplast, SP (×120,000).

ings of gram-positive bacteria do not at all resemble those in the first edition. Phylogenetically coherent groups do not necessarily contain bacteria that closely resemble one another phenotypically. The following survey of low G + C gram-positive bacteria will follow the general organization of the second edition, but will refer to the first edition where appropriate.

23.3 Class *Clostridia*

The class *Clostridia* has a very wide variety of gram-positive bacteria distributed into three orders and 11 families. The characteristics of some of the more important genera are summarized in **table 23.2.** Phylogenetic relationships are shown in figure 23.1.

By far the largest genus is *Clostridium.* It includes obligately anaerobic, gram-positive bacteria that form endospores and do not carry out dissimilatory sulfate reduction. The genus contains well over 100 species in several distinct phylogenetic clusters. It is quite likely that the *Clostridium* will be subdivided into several genera in the future.

Members of the genus *Clostridium* have great practical impact. Because they are anaerobic and form heat-resistant endospores, they are responsible for many cases of food spoilage, even in canned foods. *C. botulinum* (**figure 23.6*a*;** *see also figure 2.8*d) is the causative agent of botulism (*see section 39.4*). Clostridia often can ferment amino acids to produce ATP by oxidizing one amino acid and using another as an electron acceptor in a process called the Stickland reaction (*see figure 9.11*).

This reaction generates ammonia, hydrogen sulfide, fatty acids, and amines during the anaerobic decomposition of proteins. These products are responsible for many unpleasant odors arising during putrefaction. Several clostridia produce toxins and are major disease agents. *C. tetani* (figure 23.6*b*) is the causative agent of tetanus, and *C. perfringens* (*see figure 2.15*a), of gas gangrene and food poisoning. Clostridia also are industrially valuable; for example, *C. acetobutylicum* is used to manufacture butanol in some countries. Microbiology of food (chapter 41)

In addition to the genus *Clostridium,* this section has several other genera of interest. *Desulfotomaculum* is an anaerobic, endospore-forming genus that reduces sulfate and sulfite to hydrogen sulfide during anaerobic respiration (**figure 23.7**). Although it stains gram negative, electron microscopic studies have shown that *Desulfotomaculum* has a gram-positive type cell wall despite its staining characteristics and really is a member of the low G + C gram positives. An excellent example of the diversity in this section are the heliobacteria. The heliobacteria, genera *Heliobacterium* and *Heliophilum,* are a group of unusual anaerobic photosynthetic bacteria characterized by the presence of bacteriochlorophyll *g.* They have a photosystem I type reaction center like the green sulfur bacteria, but have no intracytoplasmic photosynthetic membranes; pigments are contained in the plasma membrane. Like *Desulfotomaculum,* they have a gram-positive

Table 23.2 Characteristics of Clostridia and Relatives

Genus	Dimensions (μm) and Morphology	G + C Content (mol%)	Oxygen Requirement	Other Distinctive Characteristics
Clostridium	0.3–2.0 × 1.5–20; rod-shaped, often pleomorphic, nonmotile or peritrichous	22–55	Anaerobic	Does not carry out dissimilatory sulfate reduction; usually chemoorganotrophic, fermentative, and catalase negative; forms oval or spherical endospores
Desulfotomaculum	0.3–1.5 × 3–9; straight or curved rods, peritrichous or polar flagella	37–50	Anaerobic	Reduces sulfate to H_2S, forms subterminal to terminal endospores; stains gram negative but has gram-positive wall, catalase negative
Heliobacterium	1.0 × 4–10; rods that are frequently bent, gliding motility	52–55	Anaerobic	Photoheterotrophic with bacteriochlorophyll *g;* stains gram negative but has gram-positive wall, some form endospores
Veillonella	0.3–0.5; cocci in pairs, short chains, and masses; nonmotile	36–43	Anaerobic	Gram negative; pyruvate and lactate fermented, but not carbohydrates; acetate, propionate, CO_2, and H_2 produced from lactate; parasitic in mouths, intestines, and respiratory tracts of animals

type cell wall with lower than normal peptidoglycan content, and they stain gram negative. Some heliobacteria form endospores.

The genus *Veillonella* provides another good example of the difference between the first and second editions with respect to placement of genera. The second edition of *Bergey's Manual* locates the genus in the low G + C gram positives. In the first edition *Veillonella* is placed with other anaerobic gram-negative cocci in section 8 and assigned to the family *Veillonellaceae.* The family *Veillonellaceae* contains anaerobic, chemoheterotrophic cocci ranging in diameter from about

0.3 to 2.5 µm. Usually they are diplococci (often with their adjacent sides flattened), but they may exist as single cells, clusters, or chains. All have complex nutritional requirements and ferment substances such as carbohydrates, lactate and other organic acids, and amino acids to produce gas (CO_2 and often H_2) plus a mixture of volatile fatty acids. They are parasites of homeothermic (warm-blooded) animals.

Like many groups of anaerobic bacteria, members of this family have not been thoroughly studied. Some species are part of the normal biota of the mouth, the gastrointestinal tract, and the urogenital tract of humans and other animals. For example, *Veillonella* is plentiful on the tongue surface and dental plaque of humans (*see figure 39.25*) and it can be isolated about 10 to 20% of the time from the vagina. *Veillonella* is unusual in growing well on organic acids such as lactate, pyruvate, and malate while normally being unable to ferment glucose and other carbohydrates. It is well adapted to the oral environment because it can use the lactic acid produced from carbohydrates by the streptococci and other oral bacteria. Gram-negative, anaerobic cocci are found in infections of the head, lungs, and the female genital tract, but their precise role in such infections is unclear.

1. Briefly discuss the ways in which low G + C bacteria are treated differently in the first and second editions of *Bergey's Manual.*
2. Describe, in a diagram, the chemical composition and structure of the peptidoglycan found in gram-negative bacteria and many gram-positive genera.
3. Briefly discuss the ways in which three other peptidoglycan types differ from the gram-negative peptidoglycan.
4. How do bacilli and most gram-negative bacteria differ from gram-positive bacteria such as *S. aureus* with respect to cross-linking frequency?
5. What is a bacterial endospore? Give its most important properties and two ways to demonstrate its presence.
6. Give the general characteristics of *Clostridium, Desulfotomaculum,* the heliobacteria, and *Veillonella.* Briefly discuss why each is interesting or of practical importance.

23.4 Class *Bacilli*

The second edition of *Bergey's Manual* gathers a large variety of gram-positive bacteria into one class, *Bacilli,* and two orders, *Bacillales* and *Lactobacillales.* Within these orders are 16 families and around 59 gram-positive genera representing cocci, endospore-forming rods and cocci, and nonsporing rods. The biology of some members of the order *Bacillales* will be described first; then important representatives of the order *Lactobacillales* will be considered. The phylogenetic relationships between some of these organisms are pictured in figure 23.1, and the characteristics of selected genera are summarized in **table 23.3.**

Order Bacillales

The genus *Bacillus,* family *Bacillaceae,* is the largest in the order (**figure 23.8;** *see also figures 3.1*c *and 3.11*). The genus contains gram-positive, endospore-forming, chemoheterotrophic rods that are usually motile and peritrichously flagellated. It is aerobic, or sometimes facultative, and catalase positive. In the first edition the genus is clearly diverse phenotypically and genotypically. More recently, rRNA sequence data have been used to divide the genus *Bacillus* into at least five separate lines. Several species already have been moved to two new genera. The genus *Alicyclobacillus* contains acidophilic, sporing, gram-positive or gram-variable rods that have ω-alicyclic fatty acids with 6- or 7-carbon rings in their membranes. Members are aerobic or facultative and have a G + C content of about 51 to 60%. The second new genus is *Paenibacillus* [Latin *paene,* almost, and bacillus]. This genus contains gram-positive rods from rRNA group 3 that are facultative, motile by peritrichous flagella, have ellipsoidal endospores and swollen sporangia, produce acid and sometimes gas from glucose and various sugars, and have a G + C content of 40 to 54%. Some examples of organisms that were formerly in the genus *Bacillus* are *Paenibacillus alvei, P. macerans,* and *P. polymyxa.*

The 4.2 million base pair genome of *Bacillus subtilis,* the type species of the genus *Bacillus,* has been sequenced. Several families of genes have been expanded by gene duplication; the largest such family encodes ABC transporters (*see p. 101*), which are the most frequent type of protein in *B. subtilis.* The genome contains genes for the catabolism of many diverse carbon sources, and for protein secretion and antibiotic synthesis. There are at least 10 integrated prophages or remnants of prophages.

Many species of *Bacillus* are of considerable importance. For example, members of the genus *Bacillus* produce the antibiotics bacitracin, gramicidin, and polymyxin. *B. cereus* (figure 23.8*c*) causes some forms of food poisoning and can infect humans. *B. anthracis* is the causative agent of the disease anthrax, which can affect both farm animals and humans (*see section 39.3*). Several species are used as insecticides. For example, *B. thuringiensis* and *B. sphaericus* form a solid protein crystal, the **parasporal body,** next to their spores during endospore formation (**figure 23.9**). The *B. thuringiensis* parasporal body contains protein toxins that will kill over 100 species of moths by dissolving in the alkaline gut contents of caterpillars and destroying their gut epithelium (*see section 42.6*). The solubilized toxin proteins are cleaved by midgut proteases to smaller toxic polypeptides that attack the epithelial cells. The alkaline gut contents escape into the blood, causing paralysis and death. One of these toxins has been isolated and shown to form pores in the plasma membrane. These channels allow monovalent cations such as potassium to pass through. Most of these *B. thuringiensis* toxin genes are carried on large plasmids. The *B. sphaericus* parasporal body contains proteins toxic for mosquito larvae and may be useful in controlling the mosquitos that carry the malaria parasite *Plasmodium.* Microbial insecticides (chapter 42)

The genus *Thermoactinomyces* is placed with the actinomycetes in the first edition of *Bergey's Manual.* The second edition moves the genus to the family *Thermoactinomycetaceae* in

Table 23.3 Characteristics of Members of the Class *Bacilli*

Genus	Dimensions (µm) and Morphology	G + C Content (mol%)	Oxygen Requirement	Other Distinctive Characteristics
Bacillus	0.5–2.5 × 1.2–10; straight rods, peritrichous	32–69	Aerobic or facultative	Forms endospores; catalase positive; chemoorganotrophic
Caryophanon	1.5–3.0 × 10–20; multicellular rods with rounded ends, peritrichous	41–46	Aerobic	Acetate only major carbon source; catalase positive; trichome cells have greater width than length, trichomes can be in short chains
Enterococcus	0.6–2.0 × 0.6–2.5; spherical or ovoid cells in pairs or short chains, nonsporing, sometimes motile	34–42	Facultative	Ferments carbohydrates to lactate with no gas; complex nutritional requirements; catalase negative; occurs widely, particularly in fecal material
Lactobacillus	0.5–1.2 × 1.0–10; usually long, regular rods, nonsporing, rarely motile	32–53	Facultative or microaerophilic	Fermentative, at least half the end-product is lactate; requires rich, complex media; catalase and cytochrome negative
Lactococcus	0.5–1.2 × 0.5–1.5; spherical or ovoid cells in pairs or short chains, nonsporing, nonmotile	38–40	Facultative	Chemoorganotrophic with fermentative metabolism; lactate and no gas produced; catalase negative; complex nutritional requirements; in dairy and plant products
Leuconostoc	0.5–0.7 × 0.7–1.2; cells spherical or ovoid, in pairs or chains; nonmotile and nonsporing	38–44	Facultative	Requires fermentable carbohydrate and nutritionally rich medium for growth; fermentation produces lactate, ethanol, and gas; catalase and cytochrome negative
Staphylococcus	0.9–1.3; spherical cells occurring singly and in irregular clusters, nonmotile and nonsporing	30–39	Facultative	Chemoorganotrophic with both respiratory and fermentative metabolism, usually catalase positive, associated with skin and mucous membranes of vertebrates
Streptococcus	0.5–2.0; spherical or ovoid cells in pairs or chains, nonmotile and nonsporing	34–46	Facultative	Fermentative, producing mainly lactate and no gas; catalase negative; commonly attack red blood cells (α- or β-hemolysis); complex nutritional requirements; commensals or parasites on animals
Thermoactinomyces	0.4–1.0 in diameter; branched, septate mycelium typical of actinomycetes	52.0–54.8	Aerobic	Usually thermophilic; true endospores form singly on hyphae; numerous in decaying hay, vegetable matter, and compost

the order *Bacillales.* This genus is thermophilic and grows between 45 and 60°C; it forms single spores on both its aerial and substrate mycelia (**figure 23.10**). Its G + C content is lower than that of the actinobacteria (52 to 55 mol%), and its 16S rRNA sequence suggests a relationship with the genus *Bacillus. Thermoactinomyces* is commonly found in damp haystacks, compost piles, and other high-temperature habitats. *Thermoactinomyces* spores (figure 23.10*b,c*) are true endospores and very heat resistant; they can survive at 90°C for 30 minutes. They are formed within hyphae and appear to have typical endospore structure, including the presence of calcium and dipicolinic acid. *Thermoactinomyces vulgaris* (figure 23.10*a*) from haystacks, grain storage silos, and compost piles is a causative agent of farmer's lung, an allergic disease of the respiratory system in agricultural workers. Recently spores from *Thermoactinomyces vulgaris* were recovered from the mud of a Minnesota lake and found to be viable after about 7,500 years of dormancy.

One of the more unusual genera in this order is *Caryophanon.* This gram-positive bacterium is strictly aerobic, catalase positive, and motile by peritrichous flagella. Its normal habitat is cow dung. *Caryophanon* morphology is distinctive. Individual cells are disk-shaped (1.5 to 2.0 μm wide by 0.5 to 1.0 μm long) and joined to form rods about 10 to 20 μm long (**figure 23.11**).

The family *Staphylococcaceae* contains four genera, the most important of which is the genus *Staphylococcus.* Members of this genus are facultatively anaerobic, nonmotile, gram-positive cocci that usually form irregular clusters (**figure 23.12,** *see also figure 3.1*a). They are catalase positive, oxidase negative, ferment glucose, and have teichoic acid in their cell walls. Staphylococci are normally associated with the skin, skin glands, and mucous membranes of warm-blooded animals.

Staphylococci are responsible for many human diseases. *S. epidermidis* is a common skin resident that is sometimes responsible for endocarditis and infections of patients with lowered resistance (e.g., wound infections, surgical infections, urinary tract infections). *S. aureus* is the most important human staphylococcal pathogen and causes boils, abscesses, wound infections, pneumonia, toxic shock syndrome, and other diseases. Recently strains of multiple drug resistant *S. aureus* have appeared and proven very difficult to treat medically (*see section 35.7*).

It also is a major cause of food poisoning as the following case illustrates. In March 1986 an outbreak of acute gastrointestinal illness occurred following a buffet supper served to 855 people at a New Mexico country club. At least 67 people were ill with diarrhea, nausea, or vomiting, and 24 required emergency medical treatment or hospitalization. The problem was *S. aureus* growing in the turkey and dressing served at the buffet. One or more of the food handlers carried *S. aureus* and had contaminated the food. Because the turkey was cooled for 3 hours after cooking, there was sufficient time for the bacterium to grow and produce toxins (*see sections 39.4 and 41.4*). This case is not uncommon. Turkey accounts for 10 to 21% of all bacterial food poisoning cases in which the source of poisoning is known, and it must be cooked and handled carefully.

Unlike other common staphylococci, *S. aureus* produces the enzyme **coagulase,** which causes blood plasma to clot. Growth and hemolysis patterns on blood agar are also useful in identifying these staphylococci (figure 23.17). Recently the structure of staphylococcal α-hemolysin has been determined. The toxin lyses a cell by forming solvent-filled channels in its plasma membrane. Water-soluble toxin monomers bind to the cell surface and associate with each other to form pores. The hydrophilic channels then allow free passage of water, ions, and small molecules. *S. aureus* usually grows on the nasal membranes and skin; it also is found in the gastrointestinal and urinary tracts of warm-blooded animals. Staphylococcal diseases (pp. 919–23)

Listeria, family *Listeriaceae,* is another medically important genus in this order. The genus contains short rods that are aerobic or facultative, catalase positive, and motile by peritrichous flagella. It is widely distributed in nature, particularly in decaying matter. *Listeria monocytogenes* is a pathogen of humans and other animals and causes listeriosis, an important food infection (*p. 931*).

Order *Lactobacillales*

Many members of the order *Lactobacillales* produce lactic acid as their major or sole fermentation product and are sometimes collectively called **lactic acid bacteria.** *Streptococcus, Enterococcus, Lactococcus, Lactobacillus,* and *Leuconostoc* are all members of this group. Lactic acid bacteria are nonsporing and usually nonmotile. They lack cytochromes and obtain energy by substrate-level phosphorylation rather than by electron transport and oxidative phosphorylation. They normally depend on sugar fermentation for energy. Nutritionally they are fastidious and many vitamins, amino acids, purines, and pyrimidines must be supplied because of their limited biosynthetic capabilities. Lactic acid bacteria usually are categorized as facultative anaerobes, but some classify them as aerotolerant anaerobes. Oxygen relationships (pp. 127–29).

The largest genus in this order is *Lactobacillus* with almost 80 species. *Lactobacillus* contains nonsporing rods and sometimes coccobacilli that lack catalase and cytochromes, are usually facultative or microaerophilic, produce lactic acid as their main or sole fermentation product, and have complex nutritional requirements (**figure 23.13**). Lactobacilli carry out either a homolactic fermentation using the Embden-Meyerhof pathway or a heterolactic fermentation with the pentose phosphate pathway (*see section 9.2*). They grow optimally under slightly acidic conditions, when the pH is between 4.5 to 6.4. The genus is found on plant surfaces and in dairy products, meat, water, sewage, beer, fruits, and many other materials. Lactobacilli also are part of the normal flora of the human body in the mouth, intestinal tract, and vagina. They usually are not pathogenic.

Lactobacillus is indispensable to the food and dairy industry (*see chapter 41*). Lactobacilli are used in the production of fermented vegetable foods (sauerkraut, pickles, silage), beverages (beer, wine, juices), sour dough, Swiss cheese and other hard cheeses, yogurt, and sausage. Yogurt is probably the most popular fermented milk product in the United States and is produced

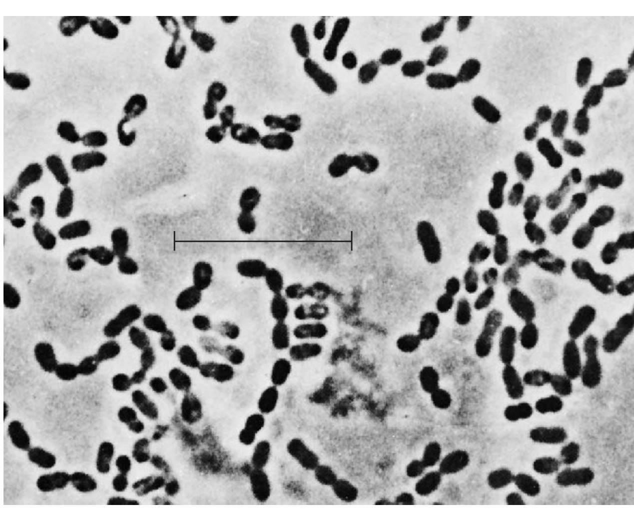

Figure 23.14 ***Leuconostoc.*** *Leuconostoc mesenteroides;* phase-contrast micrograph. Bar = 10 μm.

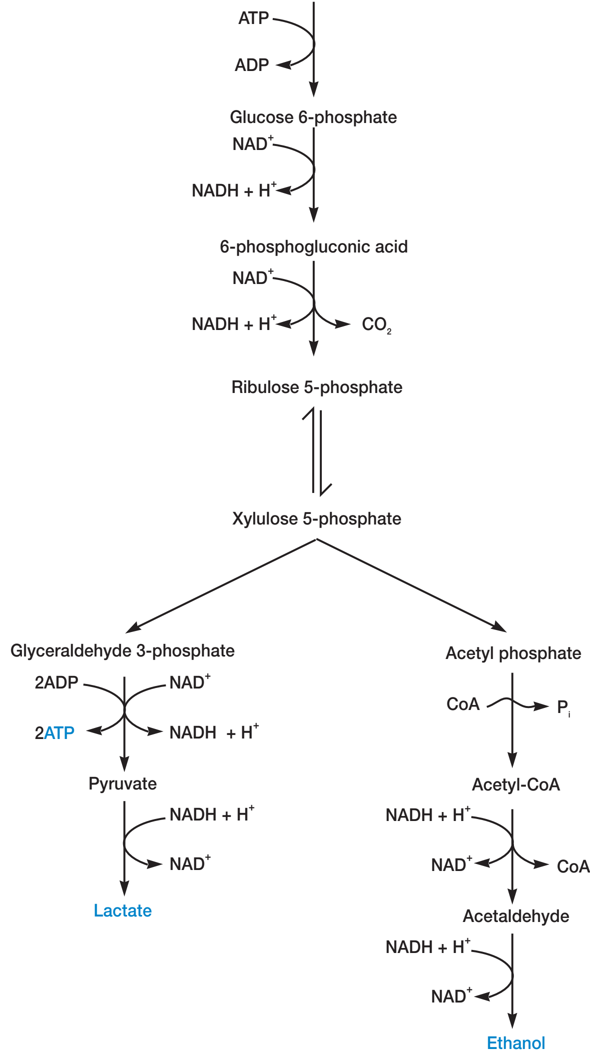

Figure 23.15 **Heterolactic Fermentation and the Phosphoketolase Pathway.** The phosphoketolase pathway converts glucose to lactate, ethanol, and CO_2.

commercially and by individuals using yogurt-making kits. In commercial production, nonfat or low-fat milk is pasteurized, cooled to 43°C or lower, inoculated with *Streptococcus thermophilus* and *Lactobacillus bulgaricus. S. thermophilus* grows more rapidly at first and renders the milk anaerobic and weakly acidic. *L. bulgaricus* then acidifies the milk even more. Acting together, the two species ferment almost all the lactose to lactic acid and flavor the yogurt with diacetyl (*S. thermophilus*) and acetaldehyde (*L. bulgaricus*). Fruits or fruit flavors to be added are pasteurized separately and then combined with the yogurt.

Lactobacilli also create problems. They sometimes are responsible for spoilage of beer, milk, and meat because their metabolic end products contribute undesirable flavors and odors.

Leuconostoc, family *Leuconostocaceae,* contains facultative gram-positive cocci, which may be elongated or elliptical and arranged in pairs or chains (**figure 23.14**). Leuconostocs lack catalase and cytochromes and carry out **heterolactic fermentation** (*see section 9.3*) by converting glucose to D-lactate and ethanol or acetic acid by means of the phosphoketolase pathway (**figure 23.15**). They can be isolated from plants, silage, and milk. The genus is used in wine production, in the fermentation of vegetables such as cabbage (sauerkraut; *see figure 41.23*) and cucumbers (pickles), and in the manufacture of buttermilk, butter, and cheese. *L. mesenteroides* synthesizes dextrans from sucrose and is important in industrial dextran production. *Leuconostoc* species are involved in food spoilage and tolerate high sugar concentrations so well that they grow in syrup and are a major problem in sugar refineries.

Several important genera have chemoheterotrophic, mesophilic, nonsporing, gram-positive cocci and are placed in the families *Enterococcaceae (Enterococcus)* and *Streptococcaceae (Streptococcus, Lactococcus).* In practice, they are often distinguished primarily based on phenotypic properties such as oxygen relationships, cell arrangement, the presence of catalase and cytochromes, and peptidoglycan structure. The most important of these genera is *Streptococcus,* which is facultatively anaerobic and catalase negative. The streptococci and their close relatives, the enterococci and lactococci, occur in pairs or chains when grown in liquid media (**figure 23.16;** *see also figure 3.1*b), do not form endospores, and usually are nonmotile. They are all chemoheterotrophs that ferment sugars with lactic acid, but no gas, as the major product—that is, they carry out homolactic fermentation (*see section 9.3*). A few species are anaerobic rather that facultative.

The genus *Streptococcus* is large and complex. The first edition of *Bergey's Manual* lists 38 species clustered in four groups; pyogenic streptococci, oral streptococci, anaerobic streptococci, and other streptococci. Many bacteria that were placed within the

genus have been moved to two new genera, *Enterococcus* and *Lactococcus.* Undoubtedly the second edition will still have many streptococcal species. Some major characteristics of these three closely related genera are summarized in **table 23.4. Table 23.5** lists a few properties of selected genera.

Many characteristics are used to identify these cocci. One of their most important taxonomic characteristics is the ability to lyse erythrocytes when growing on blood agar, an agar medium containing 5% sheep or horse blood (**figure 23.17**). In **α-hemolysis** a 1 to 3 mm greenish zone of incomplete hemolysis forms around the

(**b**) *Streptococcus pneumoniae* on blood agar, illustrating α-hemolysis. (**c**) *Staphylococcus aureus* on blood agar, illustrating β-hemolysis. (**d**) *Staphylococcus epidermidis* on blood agar with no hemolysis.

streptococcal colony; **β-hemolysis** is characterized by a zone of clearing or complete lysis without a marked color change. In addition, other hemolytic patterns are sometimes seen. Serological studies (*see chapters 33 and 36*) are also very important in identification because streptococci often have distinctive cell wall antigens. Polysaccharide and teichoic acid antigens found in the wall or between the wall and the plasma membrane are used to identify these cocci, particularly pathogenic β-hemolytic streptococci, by the **Lancefield grouping system** (*see Box 33.3*). Biochemical and physiological tests are essential in identification (e.g., growth tem-

perature preferences, carbohydrate fermentation patterns, acetoin production, reduction of litmus milk, sodium chloride and bile salt tolerance, and the ability to hydrolyze arginine, esculin, hippurate, and starch). Sensitivity to bacitracin, sulfa drugs, and optochin (ethylhydrocuprein) also are used to identify particular species.

Members of the three genera have considerable practical importance. Pyogenic streptococci usually are pathogens and associated with pus formation (pyogenic means pus producing). Most species produce β-hemolysis on blood agar and form chains of cells. The major human pathogen in this group is *S. pyogenes* (streptococcal sore throat, acute glomerulonephritis, rheumatic fever). The normal habitat of oral streptococci is the oral cavity and upper respiratory tract of humans and other animals. In other respects oral streptococci are not necessarily similar. *S. pneumoniae* is α-hemolytic and grows as pairs of cocci (figures 23.16*c* and 23.17*b*). It is associated with lobar pneumonia and otitis media (inflammation of the middle ear). *S. mutans* is associated with the formation of dental caries (*see section 39.6*). The enterococci such as *E. faecalis* are normal residents of the intestinal tracts of humans and most other animals. *E. faecalis* is an opportunistic pathogen that can cause urinary tract infections and endocarditis. Unlike the streptococci the enterococci will grow in 6.5% sodium chloride. The lactococci ferment sugars to lactic acid and can grow at 10°C but not at 45°C. *L. lactis* is widely used in the production of buttermilk and cheese (*see section 41.6*) because it can curdle milk and add flavor through the synthesis of diacetyl and other products. Streptococcal diseases (pp. 903–6)

1. List the major properties of the genus *Bacillus.* What practical impacts does it have on society? Define parasporal body and Strickland reaction.
2. Briefly describe the genus *Thermoactinomyces,* with particular emphasis on its unique features. What disease does it cause?
3. What is distinctive about the morphology of *Caryophanon?*
4. Describe the genus *Staphylococcus.* How does the pathogen *S. aureus* differ from the common skin resident *S. epidermidis,* and where is it normally found?
5. List the major properties of the genus *Lactobacillus.* Why is it important in the food and dairy industries?
6. Describe the major distinguishing characteristics of the following taxa: *Streptococcus, Enterococcus, Lactococcus,* and *Leuconostoc.*
7. Of what practical importance is *Leuconostoc?* What are lactic acid bacteria?
8. What are α-hemolysis, β-hemolysis, and the Lancefield grouping system?
9. Give a representative species and its importance for *Streptococcus, Enterococcus,* and *Lactococcus.* Distinguish between pyogenic and oral streptococci.

Summary

1. Bacteria are placed in sections of volume 2 of the first edition of *Bergey's Manual* according to characteristics such as general shape, the possession of endospores, and their response to acid-fast staining.
2. Based on 16S rRNA analysis, gram-positive bacteria are divided into low G + C and high G + C groups; this system is used in the second edition of *Bergey's Manual.*
3. The second edition of *Bergey's Manual* places the low G + C gram positives in the phylum *Firmicutes,* which contains three classes: *Clostridia, Mollicutes,* and *Bacilli* (**tables 23.1–23.3** and **figure 23.1**).
4. Mycoplasmas are gram-negative bacteria that lack cells walls and cannot synthesize peptidoglycan precursors. Many species require sterols for growth. They are the smallest bacteria capable of self-reproduction and usually grow on agar to give colonies a "fried-egg" appearance (**figure 23.3**).
5. Peptidoglycan structure often differs between groups in taxonomically useful ways. Most variations are in amino acid 3 of the peptide subunit or in the interpeptide bridge (**figure 23.4**).
6. Endospores resist desiccation and heat; they are used by bacteria to survive harsh conditions, especially in the soil.
7. Members of the genus *Clostridium* are anaerobic gram-positive rods that form endospores and don't carry out dissimilatory sulfate reduction (**figure 23.6**). They are responsible for botulism, tetanus, food spoilage, and putrefaction.
8. *Desulfotomaculum* is an anaerobic, endospore-forming genus that reduces sulfate to sulfide during anaerobic respiration.
9. The heliobacteria are gram-positive, anaerobic, photosynthetic bacteria with bacteriochlorophyll *g.* Some form endospores.
10. The family *Veillonellaceae* contains anaerobic, gram-negative cocci, some of which are parasites of vertebrates.
11. The class *Bacilli* is divided into two orders: *Bacillales* and *Lactobacillales.*
12. The genus *Bacillus* contains aerobic and facultative, catalase-positive, endospore-forming, chemoheterotrophic, gram-positive rods that are usually motile and peritrichous (**figure 23.8**). *Bacillus* synthesizes antibiotics and insecticides, and causes food poisoning and anthrax.
13. *Thermoactinomyces* is a gram-positive thermophile that forms a mycelium and true endospores (**figure 23.10**). It causes allergic reactions and leads to farmer's lung.
14. Members of the genus *Staphylococcus* are facultatively anaerobic, nonmotile, gram-positive cocci that form irregular clusters (**figure 23.12**). They grow on the skin and mucous membranes of warm-blood animals, and some are important human pathogens.
15. Several important genera such as *Lactobacillus, Listeria,* and *Caryophanon* contain regular, nonsporing, gram-positive rods. *Lactobacillus* carries out lactic acid fermentation and is extensively used in the food and dairy industries.
16. *Leuconostoc* carries out heterolactic fermentation using the phosphoketolase pathway (**figure 23.15**) and is involved in the production of fermented vegetable products, buttermilk, butter, and cheese.
17. The genera *Streptococcus, Enterococcus,* and *Lactococcus* contain gram-positive cocci arranged in pairs and chains that are usually facultative and carry out homolactic fermentation (**tables 23.4** and **23.5**). Some important species are the pyogenic coccus *S. pyogenes,* the oral streptococci *S. pneumoniae* and *S. mutans,* the enterococcus *E. faecalis* and lactococcus *L. lactis* (**figure 23.16**).

α-hemolysis *531*
β-hemolysis *532*
coagulase *529*
heterolactic fermentation *530*
lactic acid bacteria *529*
Lancefield grouping system *532*
mycoplasmas *520*
parasporal body *525*

Questions for Thought and Review

1. On the basis of the treatment of gram-positive bacteria given in volume 2 of the first edition of *Bergey's Manual,* is it best to consider the volume as an identification guide, a description of phylogenetic relationships, or some of both? Explain your reasoning and conclusion.
2. Draw a diagram illustrating how gram-positive cocci might divide to produce the various clustering patterns observed (chains, tetrads, cubical packets, grapelike clusters).
3. Describe the characteristics most important in distinguishing between members of the following groups of genera: *Staphylococcus* and *Streptococcus, Bacillus* and *Clostridium.*
4. Which genera are noted for each of the following: coagulase, pathogenicity for insects, production of fermented foods and cheeses, use of the phosphoketolase pathway, causing allergic respiratory ailments, destruction of red blood cells, colonization of the tongue and teeth, and the generation of odors during putrefaction?
5. How might one go about determining whether the genome of *M. genitalium* is the smallest one compatible with a free-living existence?
6. Account for the ease with which anaerobic clostridia can be isolated from soil and other generally aerobic niches.

Critical Thinking Questions

1. Many low G + C bacteria are parasitic. The dependence on a host might be a consequence of the low G + C content. Elaborate on this concept.
2. The idea that *Bacillus* spores could be recovered from the intestines of bees preserved in amber is a bit *Jurassic Park*–like. Nevertheless, what types of controls would you wish to see performed in order to conclude that the spores were genuine and not contaminants from the current environment? (Assume the identification of the spore species was by PCR of rRNA sequences.)

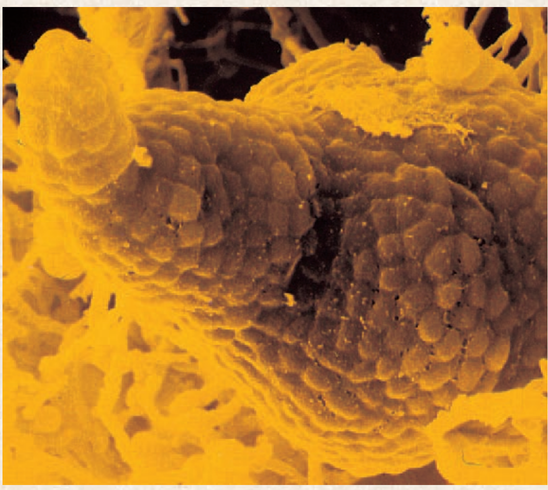
CHAPTER 24

Bacteria: The High G + C Gram Positives



Frankia forms nonmotile spores and is symbiotic with a number of higher plants such as alder trees.

Outline

24.1 General Properties of the Actinomycetes 537
24.2 High G + C Gram-Positive Bacteria in *Bergey's Manual* 539
24.3 Suborder *Actinomycineae* 542
24.4 Suborder *Micrococcineae* 542
24.5 Suborder *Corynebacterineae* 543
24.6 Suborder *Micromonosporineae* 544
24.7 Suborder *Propionibacterineae* 546
24.8 Suborder *Streptomycineae* 546
24.9 Suborder *Streptosporangineae* 548
24.10 Suborder *Frankineae* 548
24.11 Order *Bifidobacteriales* 549

Concepts

1. Volume 4 of the first edition of *Bergey's Manual* contains aerobic, gram-positive bacteria—the actinomycetes—that form branching hyphae and asexual spores.
2. The morphology and arrangement of spores, cell wall chemistry, and the types of sugars present in cell extracts are particularly important in actinomycete taxonomy and are used to divide these bacteria into different groups.
3. The second edition of *Bergey's Manual* classifies high G + C gram-positive bacteria using 16S rRNA data. They are placed in the phylum *Actinobacteria,* which contains the actinomycetes in volume 4 of the first edition plus gram-positive bacteria from sections 12, 15, 16, and 17 of volume 2.
4. Actinomycetes have considerable practical impact because they play a major role in the mineralization of organic matter in the soil and are the primary source of most naturally synthesized antibiotics. The genera *Corynebacterium* and *Mycobacterium* contain important human pathogens.

© The McGraw–Hill Companies, 2002

Actinomycetes are very important from a medical point of view. . . . They may be a nuisance, as when they decompose rubber products, grow in aviation fuel, produce odorous substances that pollute water supplies, or grow in sewage-treatment plants where they form thick clogging foams. . . . In contrast, actinomycetes are the producers of most of the antibiotics.

H. A. Lechevalier and M. P. Lechevalier

Chapter 24, the last of the survey chapters on bacteria, describes the high G + C gram-positive bacteria (see dendrogram on the right). These are located in volume 4 and part of volume 2 in the first edition of *Bergey's Manual of Systematic Bacteriology;* they will be in volume 4 of the second edition. The bacteria in volume 4 of the first edition are commonly called actinomycetes. Actinomycetes are gram positive like the bacteria in volume 2, but are distinctive because they have filamentous hyphae that do not normally undergo fragmentation and produce asexual spores. They closely resemble fungi in overall morphology. Presumably this resemblance results partly from adaptation to the same habitats. First, the general characteristics of the actinomycetes are summarized. Then the treatment of high G + C bacteria, essentially the actinomycetes and their relatives, by the two editions will be compared. Finally, representatives are described, with emphasis on morphology, taxonomy, reproduction, and general importance. This survey of representative high G + C gram positives will follow the organization of the second edition.

The **actinomycetes** [s., actinomycete] are aerobic, gram-positive bacteria that form branching filaments or hyphae and asexual spores. Although they are a diverse group, the actinomycetes do share many properties.

24.1 General Properties of the Actinomycetes

When growing on a solid substratum such as agar, the branching network of hyphae developed by actinomycetes grows both on the surface of the substratum and into it to form a substrate mycelium. Septa usually divide the hyphae into long cells (20 μm and longer) containing several nucleoids. Sometimes a tissuelike mass results and may be called a **thallus.** Many actinomycetes also have an aerial mycelium that extends above the substratum and forms asexual, thin-walled spores called **conidia** [s., conidium] or **conidiospores** on the ends of filaments (**figure 24.1**). If the spores are located in a

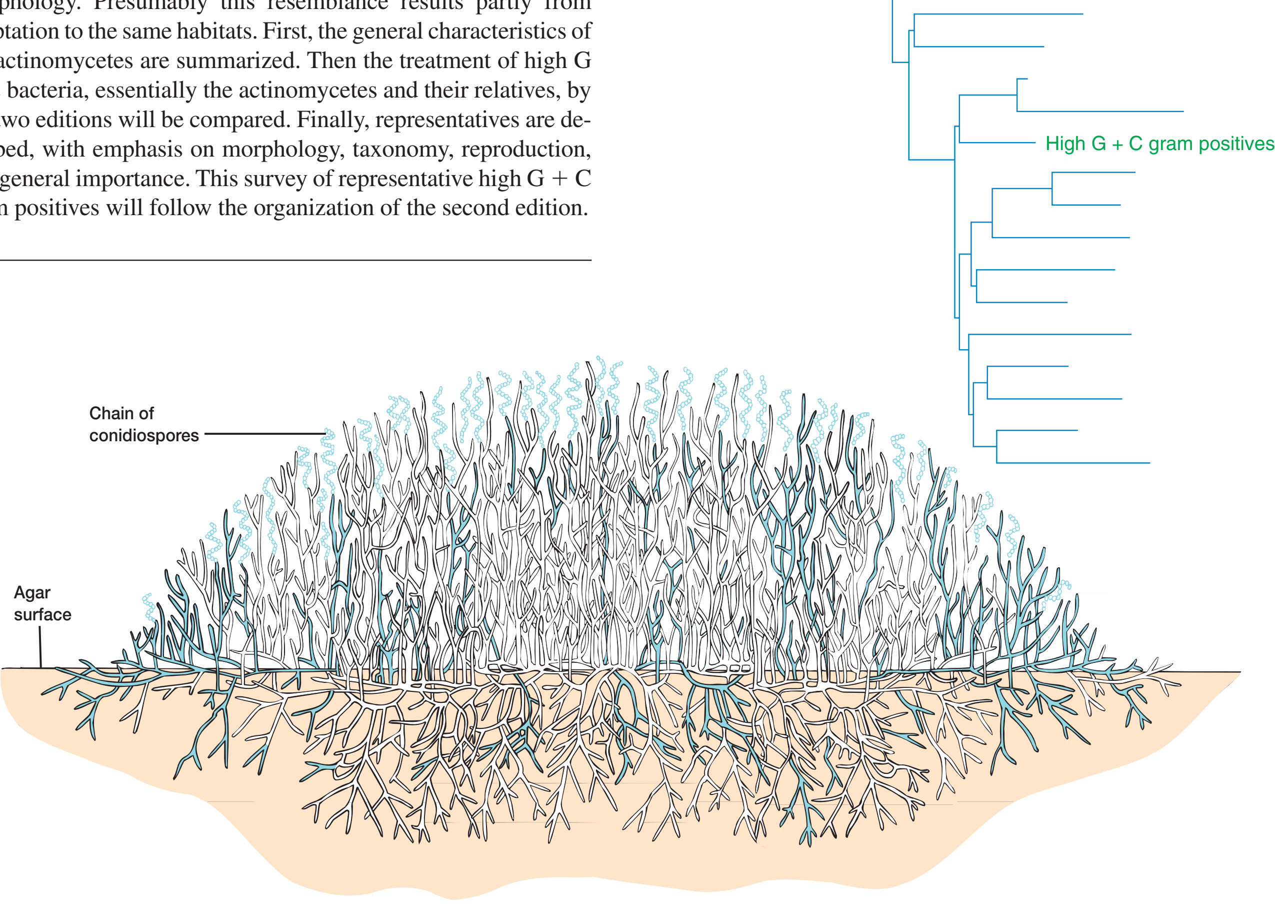


Figure 24.1 **An Actinomycete Colony.** The cross section of an actinomycete colony with living (blue-green) and dead (white) hyphae. The substrate mycelium and aerial mycelium with chains of conidiospores are shown.

Table 24.1 Actinomycete Cell Wall Types

Cell Wall Type	Diaminopimelic Acid Isomer	Glycine in Interpeptide Bridge	Characteristic Sugars[a]	Representative Genera
I	L, L	+	NA	*Nocardioides, Streptomyces,*
II	*meso*	+	NA	*Micromonospora, Pilimelia, Actinoplanes*
III	*meso*	–	NA	*Actinomadura, Frankia*
IV	*meso*	–	Arabinose, galactose	*Saccharomonospora, Nocardia*

[a]NA, either not applicable or no diagnostic sugars.

sporangium, they are called **sporangiospores.** The spores can vary greatly in shape (**figure 24.2**). Actinomycete spores develop by septal formation at filament tips, usually in response to nutrient deprivation. Most are not particularly heat resistant but do withstand desiccation well and thus have considerable adaptive value.

Most actinomycetes are not motile. When motility is present, it is confined to flagellated spores.

Actinomycete cell wall composition varies greatly among different groups and is of considerable taxonomic importance. Four major cell wall types can be distinguished according to three features of peptidoglycan composition and structure: the amino acid in tetrapeptide side chain position 3, the presence of glycine in interpeptide bridges, and peptidoglycan sugar content (**table 24.1**). Cell extracts of actinomycetes with wall types II, III, and IV also contain characteristic sugars that are useful in identification (**table 24.2**). Some other taxonomically valuable properties are the morphology and color of mycelia and sporangia, the surface features and arrangement of conidiospores, the percent G + C in DNA, the phospholipid composition of cell membranes, and spore heat resistance. Newer techniques are being applied to actinomycete taxonomy. Comparison of 16S rRNA sequences has proven valuable as we shall see. Another useful technique is the production of large DNA fragments by restriction enzyme digestion and their separation and comparison using pulsed-field electrophoresis. Gram-positive peptidoglycan structure and chemistry (pp. 521–22)

Actinomycetes have considerable practical significance. They are primarily soil inhabitants and are very widely distributed. They can degrade an enormous number and variety of organic compounds and are extremely important in the mineralization of organic matter. Actinomycetes produce most of the medically useful natural antibiotics. Although most actinomycetes are free-living microorganisms, a few are pathogens of humans, other animals, and some plants.

Table 24.2 Actinomycete Whole Cell Sugar Patterns

Sugar Pattern Types[a]	Characteristic Sugars	Representative Genera
A	Arabinose, galactose	*Nocardia, Rhodococcus, Saccharomonospora*
B	Madurose[b]	*Actinomadura, Streptosporangium, Dermatophilus*
C	None	*Thermomonospora, Actinosynnema, Geodermatophilus*
D	Arabinose, xylose	*Micromonospora, Actinoplanes*

[a]Characteristic sugar patterns are present only in wall types II–IV, those actinomycetes with *meso*-diaminopimelic acid.

[b]Madurose is 3-*O*-methyl-D-galactose

24.2 High G + C Gram-Positive Bacteria in *Bergey's Manual*

The first edition of *Bergey's Manual* divides the actinomycetes into seven sections, primarily based on properties such as cell wall type, conidia arrangement, and the presence or absence of a sporangium (**table 24.3**).

It has been clear for some time that the sections in volume 4 of the first edition are not homogeneous and do not always fit with 16S rRNA sequence data. The second edition of *Bergey's Manual*

Table 24.3 Some Characteristics of Actinomycete Groups in the First Edition of *Bergey's Manual*

Group	Wall Type	Sugar Pattern	Mol% G + C	Spore Arrangement	Presence of Sporangia	Selected Genera
Nocardioform actinomycetes[a]	I, IV, VI[b]	A	59–79	Varies	–	*Nocardia, Rhodococcus, Nocardioides, Saccharomonospora*
Actinomycetes with multilocular sporangia	III	B, C, D	57–75	Clusters of spores	+(–)[c]	*Geodermatophilus, Dermatophilus, Frankia*
Actinoplanetes	II	D	71–73	Varies	Usually +	*Actinoplanes, Pilimelia, Dactylosporangium, Micromonospora*
Streptomyces and related genera	I	Not of taxonomic value	69–78	Chains of 5 to more than 50 spores	–	*Streptomyces, Sporichthya*
Maduromycetes	III	B, C	64–74	Varies	+ or –	*Actinomadura, Microbispora, Planomonospora, Streptosporangium*
Thermomonospora and related genera	III	C (sometimes B)	64–73	Varies	–	*Thermomonospora, Actinosynnema, Nocardiopsis*

[a]Several genera have mycolic acid. Filaments readily fragment into rods and coccoid elements.

[b]Type VI cell wall has lysine instead of diaminopimelic acid.

[c]Members have clusters of spores that may not always be surrounded by a sporangial wall.

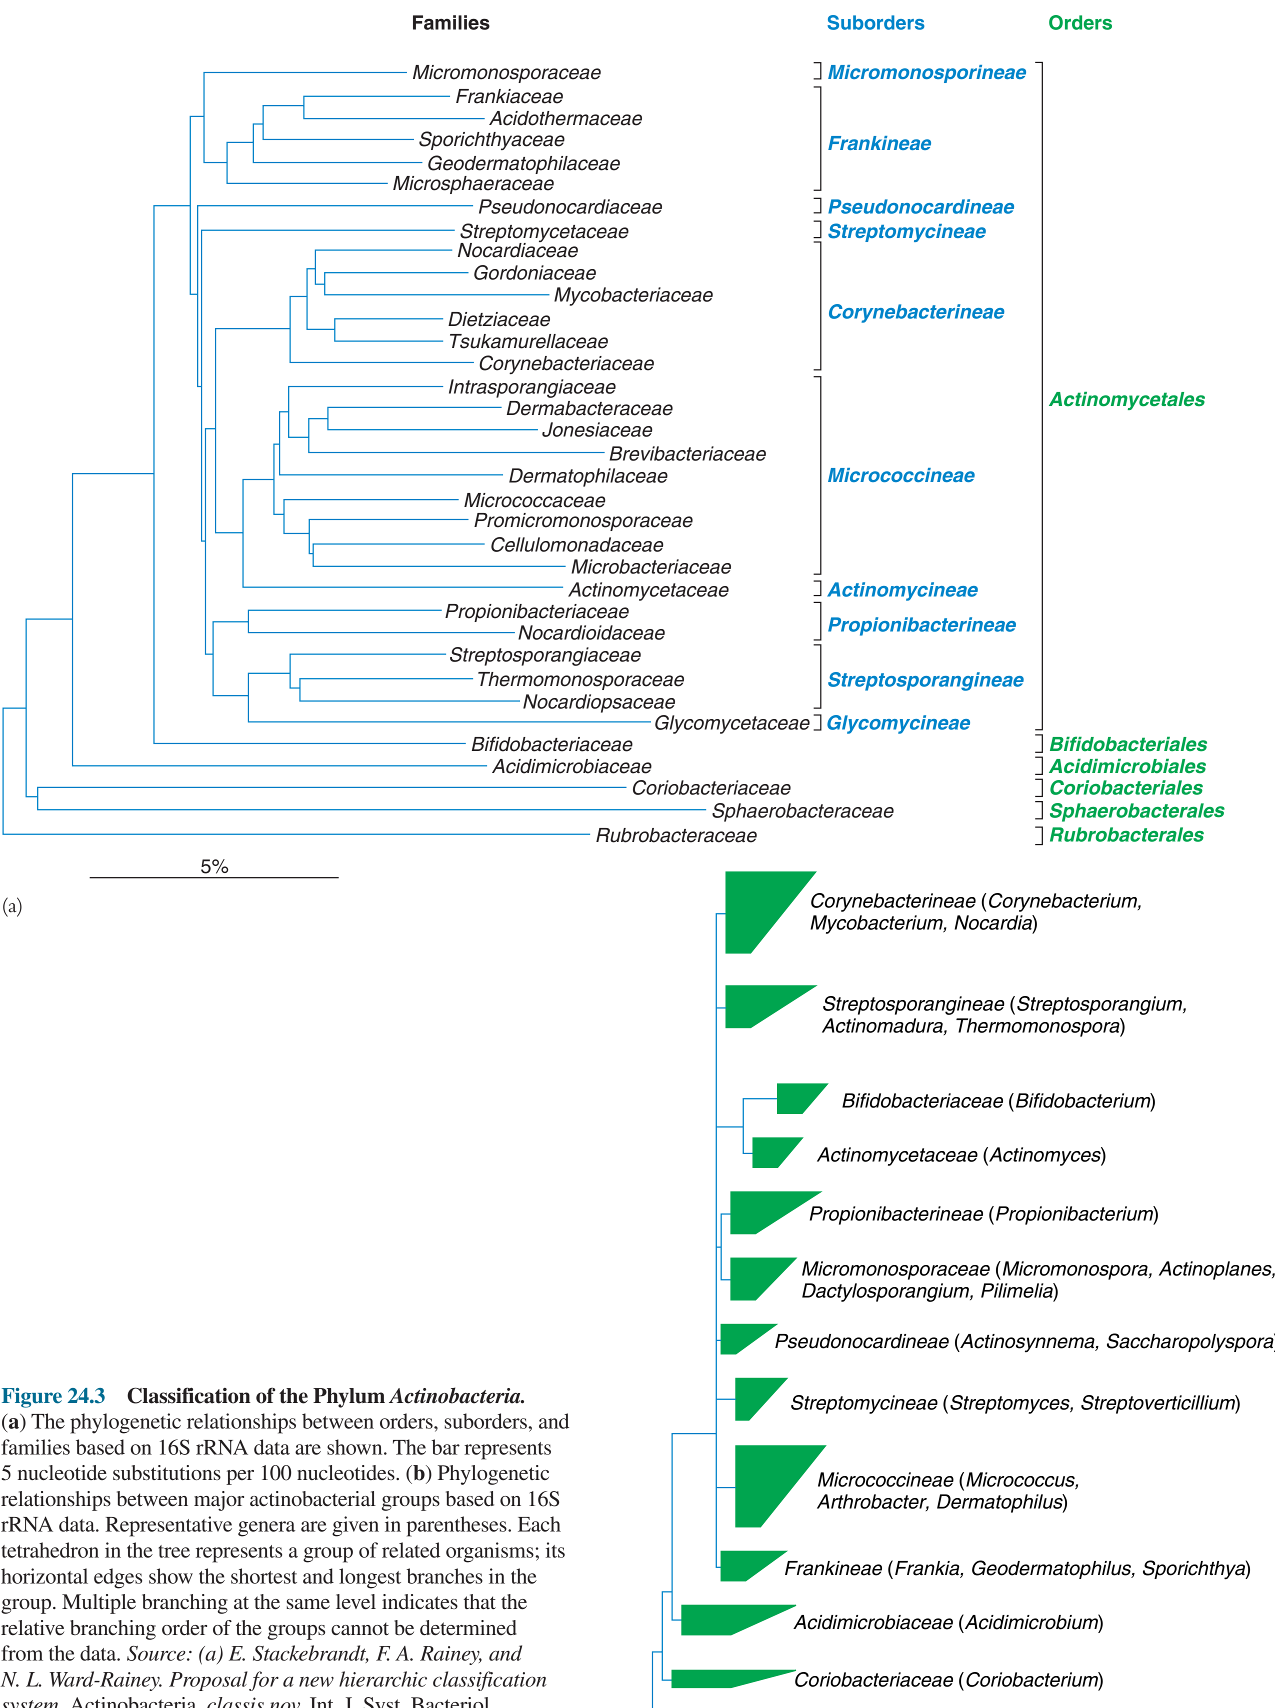

Figure 24.3 Classification of the Phylum *Actinobacteria*. (**a**) The phylogenetic relationships between orders, suborders, and families based on 16S rRNA data are shown. The bar represents 5 nucleotide substitutions per 100 nucleotides. (**b**) Phylogenetic relationships between major actinobacterial groups based on 16S rRNA data. Representative genera are given in parentheses. Each tetrahedron in the tree represents a group of related organisms; its horizontal edges show the shortest and longest branches in the group. Multiple branching at the same level indicates that the relative branching order of the groups cannot be determined from the data. *Source: (a) E. Stackebrandt, F. A. Rainey, and N. L. Ward-Rainey. Proposal for a new hierarchic classification system,* Actinobacteria, *classis nov.* Int. J. Syst. Bacteriol. *47(2):479–491, 1997. Figure 3, p. 482.*

uses 16S rRNA sequences to classify the high G + C gram positives, gram-positive bacteria with a DNA base composition above approximately 50 mol% G + C. Many of the genera from the first edition's sections 15 (irregular, nonsporing, gram-positive rods), 16 (the mycobacteria), and 17 (nocardioforms) are high G + C gram positives and are grouped with the actinomycetes in the second edition. Some members of the family *Micrococcaceae* (section 12) such as *Micrococcus* and *Stomatococcus* also are high G + C gram positives. All these bacteria are placed in the phylum *Actinobacteria* and classified as shown in **figure 24.3.** The phylum is large and very complex; it contains one class (*Actinobacteria*), five subclasses, six orders, 14 suborders, and 40 families. In this system the **actinobacteria** are composed of the actinomycetes and their high G + C relatives. The orders, suborders, and families are defined based on 16S rRNA sequences and distinctive signature nucleotides (*see p. 434*). **Figure 24.4** shows the phylogenetic relationships between selected representatives of the high G + C gram positives, and **table 24.4** summarizes the characteristics of some of the genera discussed in this chapter.

Most of the genera to be discussed in the following survey are in the subclass *Actinobacteridae* and order *Actinomycetales*

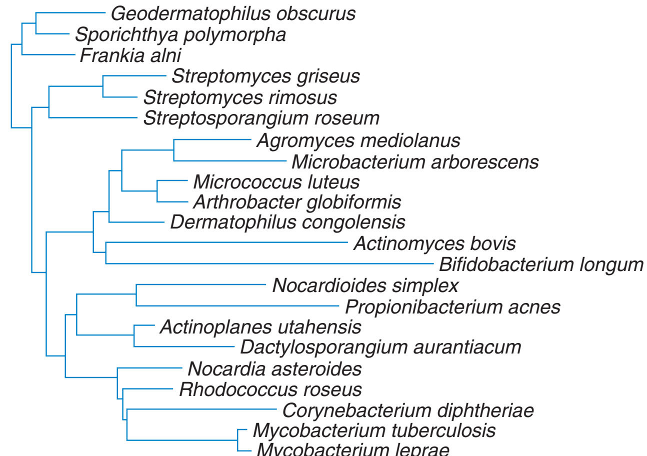

Figure 24.4 Phylogenetic Relationships Among Selected High G + C Gram-Positive Bacteria. The relationships of a few species based on 16S rRNA sequence data are shown. *Source: The Ribosomal Database Project.*

Table 24.4 Characteristics of Actinobacteria

Genus	Dimensions (μm) and Morphology	G + C Content (mol%)	Oxygen Requirement	Other Distinctive Characteristics
Actinoplanes	Nonfragmenting, branching mycelium with little aerial growth; sporangia formed; motile spores with polar flagella	72–73	Aerobic	Hyphae often in palisade arrangement; highly colored; type II cell walls; found in soil and decaying plant material
Arthrobacter	0.8–1.2 × 1.0–8.0; young cells are irregular rods, older cells are small cocci; usually nonmotile	about 59–70	Aerobic	Have rod-coccus growth cycle; metabolism respiratory; catalase positive; mainly in soil
Bifidobacterium	0.5–1.3 × 1.5–8; rods of varied shape, usually curved; nonmotile	55–67	Anaerobic	Cells can be clubbed or branched, pairs often in V arrangement; ferment carbohydrates to acetate and lactate, but no CO_2; catalase negative
Corynebacterium	0.3–0.8 × 1.5–8.0; straight or slightly curved rods with tapered or clubbed ends; nonmotile	51–63	Facultatively anaerobic	Cells often arranged in a V formation or in palisades of parallel cells; catalase positive and fermentative; metachromatic granules
Frankia	0.5–2.0 in diameter; vegetative hyphae with limited to extensive branching and no aerial mycelium; multilocular sporangia formed	66–71	Aerobic to microaerophilic	Sporangiospores nonmotile; usually fixes nitrogen; type III cell walls; most strains are symbiotic with angiosperm plants and induce nodules
Micrococcus	0.5–2.0 diameter; cocci in pairs, tetrads, or irregular clusters; usually nonmotile	64–75	Aerobic	Colonies usually yellow or red; catalase positive with respiratory metabolism; primarily on mammalian skin and in soil
Mycobacterium	0.2–0.6 × 1.0–10; straight or slightly curved rods, sometimes branched; acid-fast; nonmotile and nonsporing	62–70	Aerobic	Catalase positive; can form filaments that are readily fragmented; walls have high lipid content; in soil and water; some parasitic
Nocardia	0.5–1.2 in diameter; rudimentary to extensive vegetative hyphae that can fragment into rod-shaped and coccoid forms	64–72	Aerobic	Aerial hyphae formed; catalase positive; type IV cell wall; widely distributed in soil
Propionibacterium	0.5–0.8 × 1–5; pleomorphic nonmotile rods, may be bifid or branched; nonsporing	53–67	Anaerobic to aerotolerant	Fermentation produces propionate and acetate, and often gas; catalase positive
Streptomyces	0.5–2.0 in diameter; vegetative mycelium extensively branched; aerial mycelium forms chains of three to many spores	69–78	Aerobic	Form discrete lichenoid, leathery, or butyrous colonies that often are pigmented; use many different organic compounds as nutrients; soil organisms

Figure 24.5 Representatives of the Genus *Actinomyces.* (**a**) *A. naeslundii;* Gram stain (×1,000). (**b**) *Actinomyces;* scanning electron micrograph (×18,000). Note filamentous nature of the colony.

that is divided into 10 suborders. The following survey will focus on several of these suborders. The order *Bifidobacteriales* also will be briefly described.

24.3 Suborder *Actinomycineae*

Most genera have irregularly shaped, nonsporing, gram-positive rods with aerobic or faculative metabolism. The rods may be straight or slightly curved and usually have swellings, club shapes, or other deviations from normal rod morphology. *Actinomyces, Arcanobacterium,* and *Mobiluncus* are located in the suborder *Actinomycineae.*

Members of the genus *Actinomyces* are straight or slightly curved rods that vary considerably in shape and slender filaments with true branching (**figure 24.5**). The rods and filaments may have swollen, clubbed, or clavate ends. They are either facultative or strict anaerobes that require CO_2 for best growth. The cell walls contain lysine but not diaminopimelic acid or glycine. *Actinomyces* species are normal inhabitants of mucosal surfaces of humans and other warm-blooded animals; the oral cavity is their preferred habitat. *A. bovis* causes lumpy jaw in cattle. *Actinomyces* is responsible for actinomycoses, ocular infections, and periodontal disease in humans. The most important human pathogen is *A. israelii.*

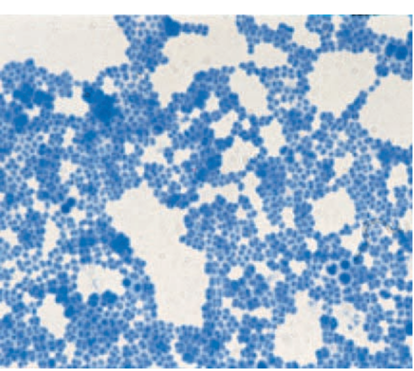

Figure 24.6 *Micrococcus.* *Micrococcus luteus,* methylene blue stain (×1,000).

24.4 Suborder *Micrococcineae*

The suborder *Micrococcineae* has 10 families and a wide variety of genera. Two of the best-known genera are *Micrococcus* and *Arthrobacter.*

The genus *Micrococcus* contains aerobic, catalase-positive cocci that occur mainly in pairs, tetrads, or irregular clusters and are usually nonmotile (**figure 24.6**). Micrococci often are yellow, orange, or red in color. They are widespread in soil, water, and on mammalian skin; the last habitat may be their normal one. Despite their frequent presence on the skin, micrococci do not seem particularly pathogenic.

The genus *Arthrobacter* contains aerobic, catalase-positive rods with respiratory metabolism and lysine in its peptidoglycan. Its most distinctive feature is a rod-coccus growth cycle (**figure 24.7**). When *Arthrobacter* grows in exponential phase, the bacteria are irregular, branched rods that may reproduce by snapping division (see below). As they enter stationary phase, the cells change to a coccoid form. Upon transfer to fresh medium, the coccoid cells produce outgrowths and again form actively growing rods. Although arthrobacters often are isolated from fish, sewage, and plant surfaces, their most important habitat is the soil, where they constitute a significant component of the microbial flora. They are well adapted to this niche because they are very resistant to desiccation and nutrient deprivation. This genus is unusually flexible nutritionally and can even degrade some herbicides and pesticides; it is probably important in the mineralization of complex organic molecules.

The mechanism of **snapping division** has been studied in *Arthrobacter.* These bacteria have a two-layered cell wall, and only the inner layer grows inward to generate a transverse wall di-

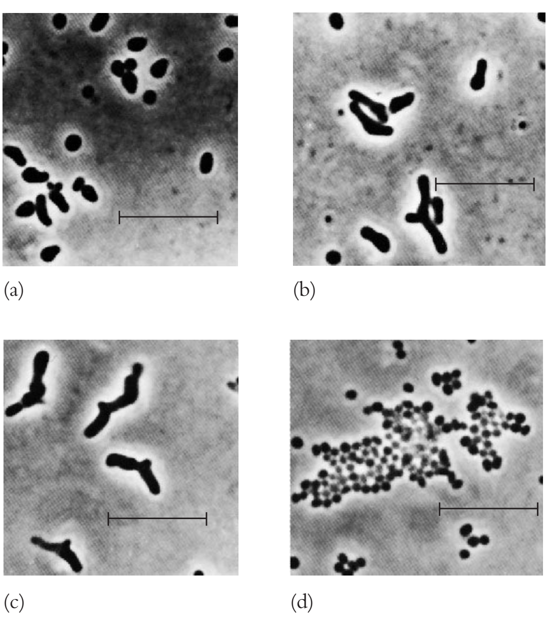

Figure 24.7 **The Rod-Coccus Growth Cycle.** The rod-coccus cycle of *Arthrobacter globiformis* when grown at 25°C. (**a**) Rods are outgrowing from cocci 6 hours after inoculation. (**b**) Rods after 12 hours of incubation.(**c**) Bacteria after 24 hours. (**d**) Cells after reaching stationary phase (3 days' incubation). The cells used for inoculation resembled these stationary-phase cocci. Bars = 10 μm.

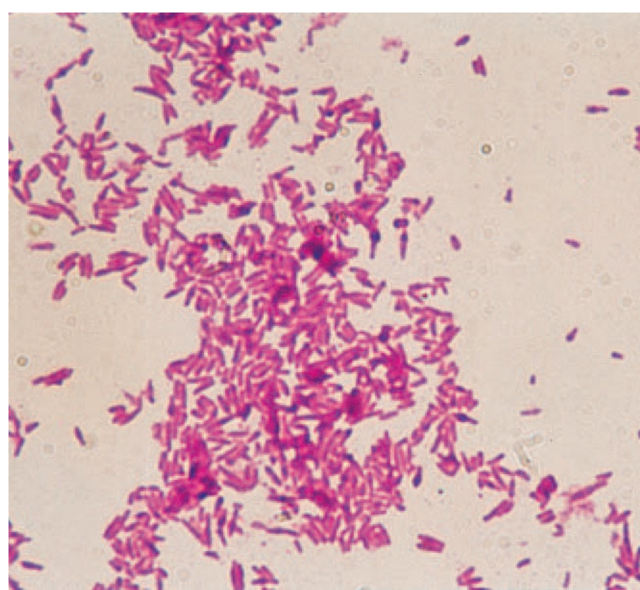

Figure 24.8 ***Corynebacterium diphtheriae.*** Note the irregular shapes of individual cells, the angular associations of pairs of cells, and palisade arrangements (×1,000). These gram-positive rods do not form endospores.

viding the new cells. The completed transverse wall or septum next thickens and puts tension on the outer wall layer, which still holds the two cells together. Eventually, increasing tension ruptures the outer layer at its weakest point, and a snapping movement tears the outer layer apart around most of its circumference. The new cells now rest at an angle to each other and are held together by the remaining portion of the outer layer that acts as a hinge.

A third genus in this suborder is *Dermatophilus. Dermatophilus* (cell wall type IIIB) also forms packets of motile spores with tufts of flagella, but it is a facultative anaerobe and a parasite of mammals responsible for the skin infection streptothrichosis.

24.5 Suborder *Corynebacterineae*

This suborder contains seven families with several well-known genera. Three of the most important genera are *Corynebacterium, Mycobacterium,* and *Nocardia.*

The family *Corynebacteriaceae* contains one genus, *Corynebacterium,* which contains aerobic and facultative, catalase-positive, straight to slightly curved rods, often with tapered ends. Club-shaped forms are also seen. The bacteria often remain partially attached after snapping division, resulting in angular arrangements of the cells, somewhat like Chinese letters, or a palisade arrangement in which rows of cells are lined up side by side (**figure 24.8**). Corynebacteria form metachromatic granules, and their walls have *meso*-diaminopimelic acid. Although some species are harmless oil and water saprophytes, many corynebacteria are plant or animal pathogens. For example, *C. diphtheriae* is the causative agent of diphtheria in humans (*see section 39.1*).

The family *Mycobacteriaceae* contains the genus *Mycobacterium,* which is composed of slightly curved or straight rods that sometimes branch or form filaments (**figure 24.9**). Mycobacterial filaments differ from those of actinomycetes in readily fragmenting into rods and coccoid bodies when distributed. They are aerobic and catalase positive. Mycobacteria grow very slowly and must be incubated for 2 to 40 days after inoculation of a solidified complex medium to form a visible colony. Their cell walls have a very high lipid content and contain waxes with 60 to 90 carbon **mycolic acids.** These are complex fatty acids with a hydroxyl group on the β-carbon and an aliphatic chain attached to the α-carbon. The presence of mycolic acids and other lipids outside the peptidoglycan layer makes mycobacteria **acid-fast** (basic fuchsin dye cannot be removed from the cell by acid alcohol treatment). Extraction of wall lipid with alkaline ethanol destroys acid-fastness. Actinomycete morphology (pp. 537–39); Acid-fast staining (p. 28)

Although some mycobacteria are free-living saprophytes, they are best known as animal pathogens. *M. bovis* causes tuberculosis in cattle, other ruminants, and primates. Because this bacterium can produce tuberculosis in humans, dairy cattle are tested for the disease yearly; milk pasteurization kills the pathogen and affords further protection against disease transmission. Thus *M. tuberculosis* is the chief source of tuberculosis in humans. The

other major mycobacterial human disease is leprosy, caused by *M. leprae.* Tuberculosis (pp. 906–8); Leprosy (pp. 916–17); The genome sequences of *M. tuberculosis* and *M. leprae* (pp. 351–52)

The family *Nocardiaceae* is composed of two genera, *Nocardia* and *Rhodococcus.* Because these and related genera resemble members of the genus *Nocardia* (named after Edmond Nocard [1850–1903], French bacteriologist and veterinary pathologist), they are collectively called **nocardioforms.** These bacteria develop a substrate mycelium that readily breaks into rods and coccoid elements (**figure 24.10**). Several genera also form an aerial mycelium that rises above the substratum and may produce conidia. All genera have a high G + C content like other actinomycetes, and almost all are strict aerobes. Most species have peptidoclycan with *meso*-diaminopimelic acid and no peptide interbridge. The wall usually contains a carbohydrate composed of arabinose and galactose; mycolic acids are present in *Nocardia* and *Rhodococcus.*

Nocardia is distributed worldwide in soil and also is found in aquatic habitats. Nocardiae are involved in the degradation of hydrocarbons and waxes and can contribute to the biodeterioration of rubber joints in water and sewage pipes. Although most are free-living saprophytes, some species, particularly *N. asteroides,* are opportunistic pathogens that cause nocardiosis in humans and other animals. People with low-resistance due to other health problems are most at risk. The lungs are most often infected, but the central nervous system and other organs may be invaded. *Rhodococcus* also is widely distributed in soils and aquatic habitats. It is of considerable interest because members of the genus can degrade an enormous variety of molecules such as petroleum hydrocarbons, detergents, benzene, polychlorinated biphenyls (PCBs), and various pesticides. It may be possible to use rhodococci to remove sulfur from fuels, thus reducing air pollution by sulfur oxide emissions.

1. Define actinomycete, thallus, substrate mycelium, aerial mycelium, conidium, conidiospore, and sporangiospore.
2. Describe how cell wall structure and sugar content are used to classify the actinomycetes. Include a brief description of the four major wall types.
3. Why are the actinomycetes of such practical interest?
4. How do the first and second editions of *Bergey's Manual* differ in their treatment of the high G + C gram-positive bacteria?
5. Give the major distinguishing characteristics of the actinomycetes in the first edition of *Bergey's Manual.* Describe the phylum *Actinobacteria* and its relationship to the actinomycetes.
6. Describe the major characteristics of the following genera: *Actinomyces, Micrococcus, Arthrobacter,* and *Corynebacterium.* Include comments on their normal habitat and importance.
7. What is snapping division? The rod-coccus growth cycle?
8. Give the distinctive properties of the genus *Mycobacterium,* and indicate how mycobacteria differ from actinomycetes.
9. Define mycolic acid and acid-fast.
10. List two human mycobacterial diseases and their causative agents. Which pathogen causes tuberculosis in cattle?
11. What is a noncardioform, and how can the group be distinguished from other actinomycetes?
12. Where is *Nocardia* found, and what problems may it cause? Consider both environmental and public health concerns.

24.6 Suborder *Micromonosporineae*

The suborder *Micromonosporineae* contains only one family, *Micromonosporaceae.* Many of the genera in this family are placed among the actinoplanetes in the first edition of *Bergey's Manual.* Actinoplanetes [Greek *actinos,* a ray or beam, and *planes,* a wan-

derer] have an extensive substrate mycelium and are wall type IID. Often the hyphae are highly colored and diffusible pigments may be produced. Normally an aerial mycelium is absent or rudimentary. Conidiospores are usually formed within a sporangium raised above the surface of the substratum at the end of a special hypha called a sporangiophore. The spores can be either motile or nonmotile. These bacteria vary in the arrangement and development of their spores. Some genera (*Actinoplanes, Pilimelia*) have spherical, cylindrical, or irregular sporangia with a few to several thousand spores per sporangium (figure 24.2*b* and **figure 24.11**). The sporangium develops above the substratum at the tip of a sporangiophore; the spores are arranged in coiled or parallel chains (**figure 24.12**). *Dactylosporangium* forms club-shaped, fingerlike, or pyriform sporangia with one to six spores (figure 24.11*d,e*). *Micromonospora* bears single spores, which often occur in branched clusters of sporophores (figure 24.2*c*).

Actinoplanetes [s., actinoplanete] grow in almost all soil habitats, ranging from forest litter to beach sand. They also flourish in freshwater, particularly in streams and rivers (probably because of abundant oxygen and plant debris). Some have been isolated from

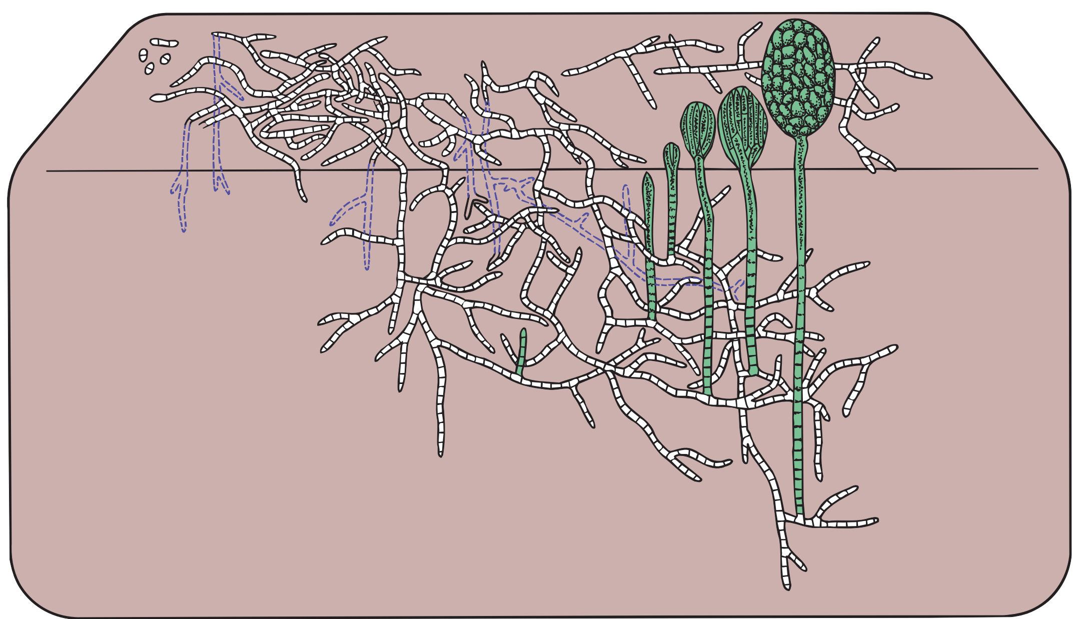

Figure 24.12 Sporangium Development in an Actinoplanete. The developing sporangium is shown in green.

the ocean. The soil-dwelling species may have an important role in the decomposition of plant and animal material. *Pilmelia* grows in association with keratin. *Micromonospora* actively degrades chitin and cellulose, and it can produce antibiotics such as gentamicin.

24.7 Suborder *Propionibacterineae*

This suborder contains two families and 10 genera. The genus *Propionibacterium* will be placed in the family *Propionibacteriaceae* in the second edition. The genus contains pleomorphic, nonmotile, nonsporing rods that are often club-shaped with one end tapered and the other end rounded. Cells also may be coccoid or even branched. They can be single, in short chains, or in clumps. The genus is facultatively anaerobic or aerotolerant; lactate and sugars are fermented to produce large quantities of propionic and acetic acids, and often carbon dioxide. *Propionibacterium* is usually catalase positive. The genus is found growing on the skin and in the digestive tract of animals, and in dairy products such as cheese. *Propionibacterium* contributes substantially to the production of Swiss cheese (*see p. 982*). *P. acnes* is involved with the development of body odor and acne vulgaris (*see p. 701*).

24.8 Suborder *Streptomycineae*

The suborder *Streptomycineae* has only one family, *Streptomycetaceae,* and three genera, the most important of which is *Streptomyces.* The first edition of *Bergey's Manual* places *Streptomyces* in section 29 with genera whose aerial hyphae divide in a single plane to form chains of 3 to 50 or more nonmotile conidiospores with surface texture ranging from smooth to spiny and warty (figure 24.2*d;* **figures 24.13** and **24.14**). All have a type I cell wall and a G + C content of around 69 to 78%. The substrate mycelium, when present, does not undergo fragmentation. Members of the section are often called **streptomycetes** [Greek *streptos,* bent or twisted, and *myces,* fungus].

Streptomyces is an enormous genus; there are around 500 species. Members of the genus are strict aerobes, are wall type I, and form chains of nonmotile spores within a thin, fibrous sheath (figure 24.14). The three to many conidia in each chain are often pigmented and can be smooth, hairy, or spiny in texture. *Streptomyces* species are determined by means of a mixture of morphological and physiological characteristics, including the following: the color of the aerial and substrate mycelia, spore arrangement, surface features of individual spores, carbohydrate use, antibiotic production, melanin synthesis, nitrate reduction, and the hydrolysis of urea and hippuric acid.

Streptomycetes are very important, both ecologically and medically. The natural habitat of most streptomycetes is the soil, where they may constitute from 1 to 20% of the culturable population. In fact, the odor of moist earth is largely the result of streptomycete production of volatile substances such as **geosmin.** Streptomycetes play a major role in mineralization. They are flexible nutritionally and can aerobically degrade resistant substances such as pectin, lignin, chitin, keratin, latex, and aromatic compounds. Streptomycetes are best known for their synthesis of a vast array of antibiotics, some of which are useful in medicine and biological research. Examples include amphotericin B, chloramphenicol, erythromycin, neomycin, nystatin, streptomycin,

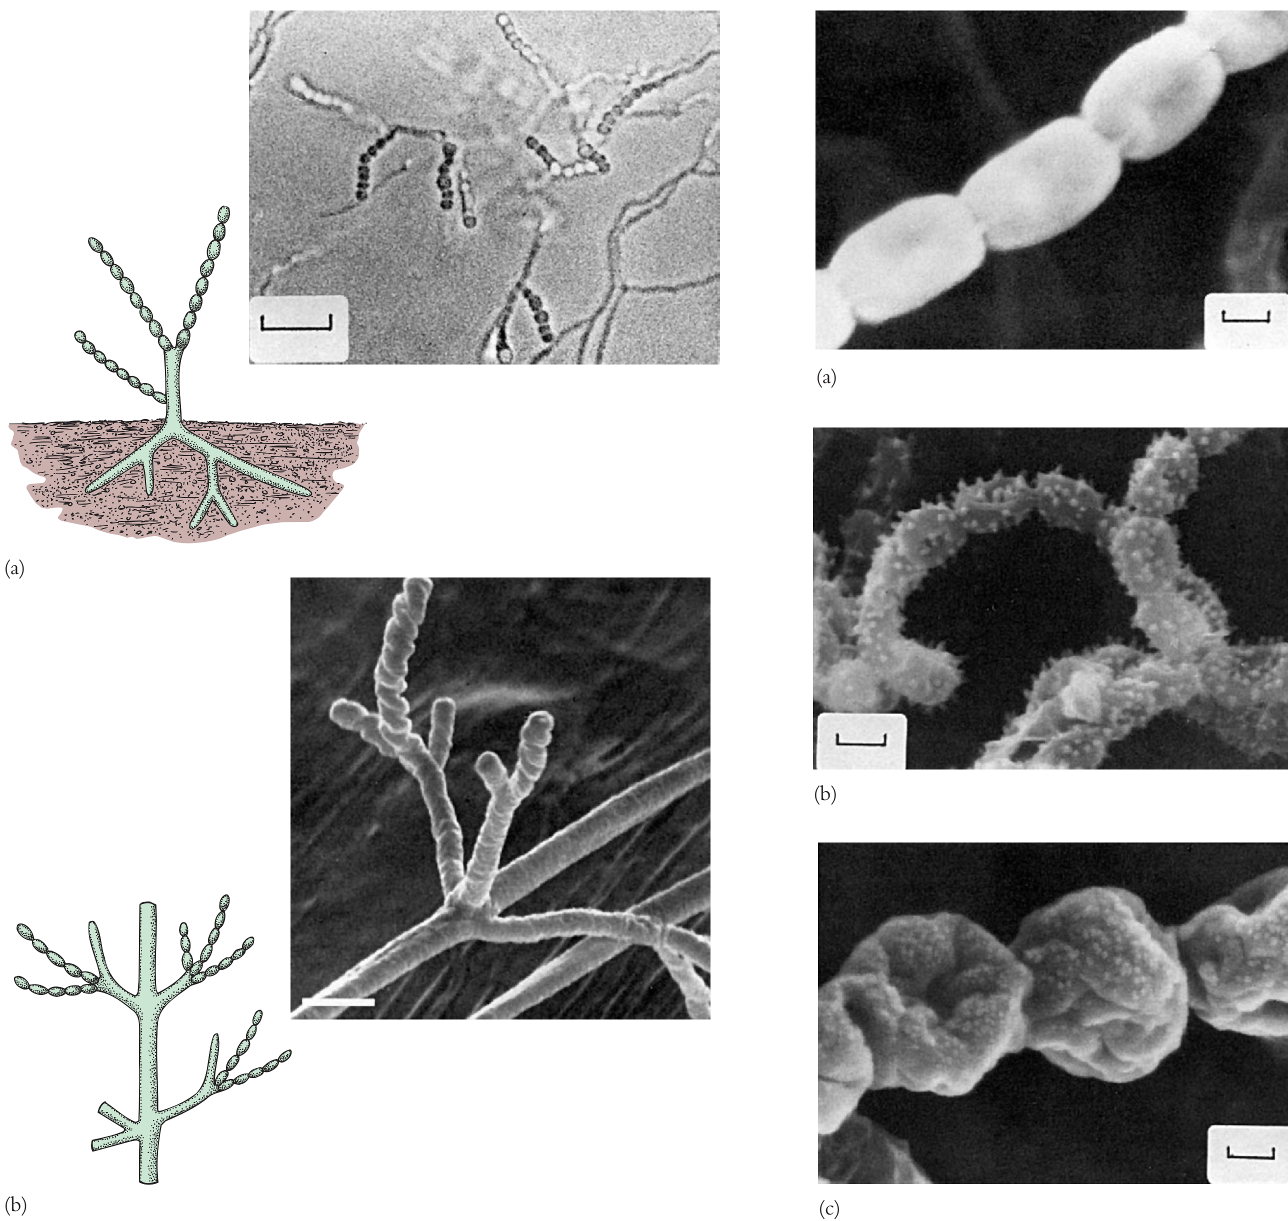

Figure 24.13 ***Streptomyces* and Related Genera.** Streptomycete conidia arrangement. tetracycline, and so forth (**figure 24.15*a***). Although most streptomycetes are nonpathogenic saprophytes, a few are associated with plant and animal diseases. *Streptomyces scabies* causes scab disease in potatoes and beets (figure 24.15*b*). *S. somaliensis* is the only streptomycete known to be pathogenic for humans. It is associated with **actinomycetoma,** an infection of subcutaneous tissues that produces lesions and leads to swelling, abscesses, and even bone destruction if untreated. *S. albus* and other species have been isolated from patients with various ailments and may be pathogenic. Antibiotics and their properties (chapter 35)

Streptoverticillium, another genus in the family, has an aerial mycelium with a whorl of three to six short branches that are produced at fairly regular intervals. These branches have secondary branches bearing chains of spores (figure 24.13*b*).

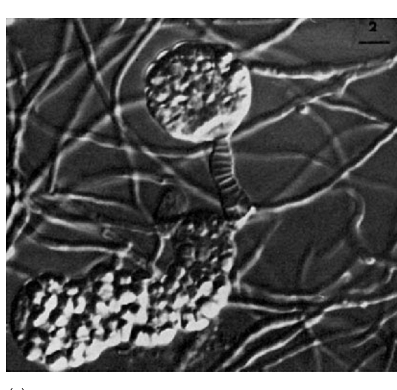
24.9 Suborder *Streptosporangineae*

The suborder *Streptosporangineae* contains three families and 14 genera. The genera in this suborder are found in section 30 (maduromycetes) and section 31 (*Thermomonospora* and related genera) of the first edition of *Bergey's Manual.* All genera of the maduromycetes have type III cell walls and the sugar derivative **madurose** (3-*O*-methyl-D-galactose) in whole cell homogenates. Their G + C content is 64 to 74 mol%. Aerial mycelia bear pairs or short chains of spores, and the substrate mycelium is branched (figure 24.2*e* and **figure 24.16**). Some genera form sporangia; spores are not heat resistant. Maduromycete genera such as *Streptosporangium, Microbispora,* and *Planomonospora* will be placed in the family *Streptosporangiaceae* in the second edition. *Thermomonospora, Actinomadura* and *Spirillospora* will be in the family *Thermomonosporaceae. Actinomadura* is another actinomycete associated with the disease actinomycetoma. *Thermomonospora* produces single spores on the aerial mycelium or on both the aerial and substrate mycelia. It has been isolated from high-temperature habitats such as compost piles and hay; it can grow at 40 to 48°C.

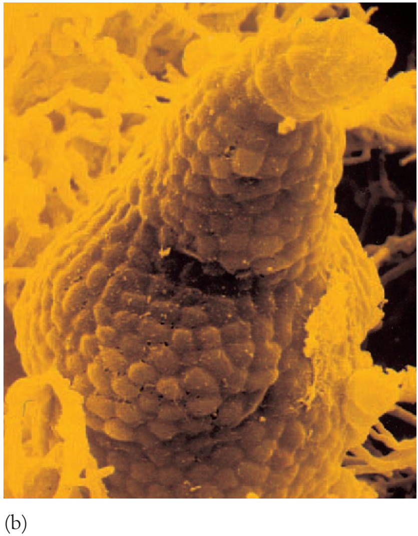
24.10 Suborder *Frankineae*

Like the suborder *Streptosporangineae, Frankineae* contains genera from different parts of the first edition. Two of the genera, *Frankia* and *Geodermatophilus,* come from section 27 (actinomycetes with mutilocular sporangia). These genera form clusters of spores when a hypha divides both transversely and longitudinally. (Multilocular means having many cells or compartments.) They have type III cell walls (table 24.1), although the cell extract sugar patterns differ. The G + C content varies from 57 to 75 mol%. *Geodermatophilus* (type IIIC) has motile spores and is an aerobic soil organism. *Frankia* (type IIID) forms nonmotile sporangiospores in a sporogenous body (**figure 24.17**). It grows in symbiotic association with the roots of at least eight families of higher nonleguminous plants (e.g., alder trees) and is a microaerophile able to fix atmospheric nitrogen (*see section 30.4*).

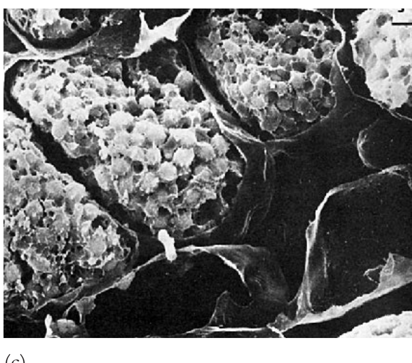
The roots of infected plants develop nodules that fix nitrogen so efficiently that a plant such as an alder can grow in the absence of combined nitrogen when nodulated. Within the nodule cells, *Frankia* forms branching hyphae with globular vesicles at their ends (figure 24.17*c*). These vesicles may be the sites of nitrogen fixation. The nitrogen-fixation process resembles that of *Rhizobium* in that it is oxygen sensitive and requires molybdenum and cobalt.



(a)



(b)



(c)

Figure 24.17 ***Frankia.*** (**a**) An interference contrast micrograph showing hyphae, multilocular sporangia, and spores. Bar = 5 μm. (**b**) A scanning electron micrograph of a sporangium surrounded by hyphae. (**c**) A nodule of the alder *Alnus rubra* showing cells filled with vesicles of *Frankia.* Scanning electron microscopy. Bar = 5 μm.

Another genus in this suborder, *Sporichthya,* has been transferred from section 29 (streptomycetes and related genera) of the first edition. *Sporichthya* is one of the strangest of the actinomycetes. It lacks a substrate mycelium. The hyphae remain attached to the substratum by holdfasts and grow upward to form aerial mycelia that release motile, flagellate conidia in the presence of water.

24.11 Order *Bifidobacteriales*

The order *Bifidobacteriales* has one true family, *Bifidobacteriaceae,* and eight genera (five of which have unknown affiliation). *Falcivibrio* and *Gardnerella* are found in the human genital/urinary tract; *Gardnerella* is thought to be a major cause of bacterial vaginitis. *Bifidobacterium* probably is the best-studied genus. Bifidobacteria are nonmotile, nonsporing, gram-positive rods of varied shapes that are slightly curved and clubbed; often they are branched (**figure 24.18**). The rods can be single or in clusters and V-shaped pairs. *Bifidobacterium* is anaerobic and actively ferments carbohydrates to produce acetic and lactic acids, but no carbon dioxide. It is found in the mouth and intestinal tract of warm-blooded vertebrates, in sewage, and in insects. *B. bifidus* is a pioneer colonizer of the human intestinal tract, particularly when babies are breast fed. A few *Bifidobacterium* infections have been reported in humans, but the genus does not appear to be a major cause of disease.

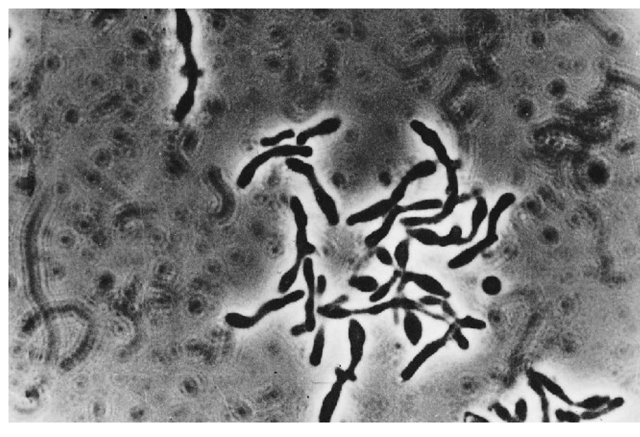


Figure 24.18 ***Bifidobacterium.*** *Bifidobacterium bifidum;* phase-contrast photomicrograph (×1,500).

1. Give the distinguishing properties of the actinoplanetes.
2. Briefly describe the variations in sporangia and sporophore organization of the actinoplanetes.
3. Describe the genus *Propionibacterium* and comment on its practical importance.
4. What characteristics do streptomycetes have in common?
5. Describe the major properties of the genus *Streptomyces.*
6. Give three ways in which *Streptomyces* is of ecological and medical importance.
7. Briefly describe the genera of the suborder *Streptosporangineae.* What is madurose? Why is *Actinomadura* important?
8. Describe *Frankia* and discuss its importance.
9. Characterize the genus *Bifidobacterium.* Where is it found and why is it significant?

Summary

1. Actinomycetes are aerobic, gram-positive bacteria that form branching, usually nonfragmenting, hyphae and asexual spores (**figure 24.1**).
2. The asexual spores borne on aerial mycelia are called conidiospores or conidia if they are at the tip of hyphae and sporangiospores when they are within sporangia.
3. Actinomycetes have several distinctively different types of cell walls and often also vary in terms of the sugars present in cell extracts. Properties such as color and morphology are also taxonomically useful.
4. The first edition of *Bergey's Manual* classifies the actinomycetes based on such properties as conidial arrangement, the presence of a sporangium, cell wall type, and cell extract sugars (**tables 24.1–24.3**).
5. The second edition of *Bergey's Manual* classifies the high G + C bacteria phylogenetically using 16S rRNA data. The phylum *Actinobacteria* contains one class, five subclasses, six orders, 14 suborders, and 40 families (**figure 24.3**).
6. The suborder *Actinomycineae* contains the genus *Actinomyces,* members of which are irregularly shaped, nonsporing rods that can cause disease in cattle and humans.
7. The suborder *Micrococcineae* has the genera *Micrococcus, Arthrobacter,* and *Dermatophilus. Arthrobacter* has an unusual rod-coccus growth cycle and carries out snapping division (**figure 24.7**).
8. The genera *Corynebacterium, Mycobacterium,* and *Nocardia* will be placed in the suborder *Corynebacterineae.* Mycobacteria form either rods or filaments that readily fragment. Their cell walls have a high lipid content and mycolic acids; the presence of these lipids makes them acid-fast. The genera *Corynebacterium* and *Mycobacterium* contain several very important human pathogens.
9. Nocardioform actinomycetes have hyphae that readily fragment into rods and coccoid elements, and often form aerial mycelia with spores.
10. The suborder *Micromonosporineae* has genera that are classified as actinoplanetes in section 28 of the first edition. These actinomycetes have an extensive substrate mycelium and form special aerial sporangia (**figure 24.12**). They are present in soil, fresh water, and the ocean. The soil forms are probably important in decomposition.
11. The genus *Propionibacterium* has been placed in the suborder *Propionibacterineae* in the second edition. Members of this genus are common skin and intestinal inhabitants and are important in cheese manufacture and the development of acne vulgaris.
12. The suborder *Streptomycineae* of the second edition contain the genus *Streptomyces.* Members of this genus have type I cell walls and aerial hyphae bearing chains of 3 to 50 or more nonmotile conidiospores within a thin sheath (**figure 24.13**).
13. Streptomycetes are important in the degradation of more resistant organic material in the soil and produce many useful antibiotics. A few cause diseases in plants and animals.
14. The suborder *Streptosporangineae* contains several genera that the first edition places in section 30 (the maduromycetes) and section 31 (*Thermomonospora* and related genera). Many of these organisms have the sugar derivative madurose and type III cell walls.
15. The genera *Frankia* and *Geodermatophilus* are placed in the suborder *Frankineae.* They produce clusters of spores at hyphal tips and have type III cell walls. *Frankia* grows in symbiotic association with higher nonleguminous plants and fixes nitrogen.
16. The genus *Bifidobacterium* is placed in the order *Bifidobacteriales* in the second edition. This irregular, anaerobic rod is one of the first colonizers of the intestinal tract in nursing babies.

Key Terms

acid-fast *543*
actinobacteria *541*
actinomycete *537*
actinomycetoma *547*
conidia *537*
conidiospores *537*
geosmin *546*
madurose *548*
mycolic acids *543*
nocardioforms *544*
snapping division *542*
sporangiospores *539*
streptomycetes *546*
thallus *537*

Questions for Thought and Review

1. Suppose that you discovered a nodulated plant that could fix atmospheric nitrogen. How might you show that a bacterial symbiont was involved and that *Frankia* rather than *Rhizobium* was responsible?
2. How could one decide whether a newly isolated spore-forming bacterium was producing conidiospores or true endospores?
3. List the properties that are most useful in actinomycete taxonomy and give some indication of their relative importance. How does the second edition of *Bergey's Manual* differ in its approach to classification of actinomycetes?
4. Which bacteria are noted for each of the following: the rod-coccus growth cycle, early colonization of the human intestine, metachromatic granules and snapping division, 60 to 90 carbon mycolic acids and acid fastness, the synthesis of antibiotics, the production of substrate mycelia that readily break into rods and cocci, and the production of large amounts of propionic and acetic acids.
5. Propose an explanation for the observation that mycobacteria are normally only weakly gram positive.
6. Which characteristics might be most important in distinguishing between the genera *Corynebacterium, Arthrobacter, Actinomyces, Propionibacterium, Mycobacterium,* and *Bifidobacterium?*

Critical Thinking Questions

1. Even though these are "high G + C" organisms, there are regions of the genome that must be more AT-rich. Suggest a few such regions and explain why they must be more AT-rich.
2. Choose two different species in the phylum *Actinobacteria* and investigate their physiology and ecology. Compare and contrast these two organisms. Can you determine why having a high G + C genomic content might confer an evolutionary advantage?
3. *Streptomyces coelicolor* has a developmental program for differentiation. Some of the genes involved in sporulation contain a rare codon, not used in vegetative genes. Suggest how *Streptomyces* might turn on sporulation, in response to starvation.

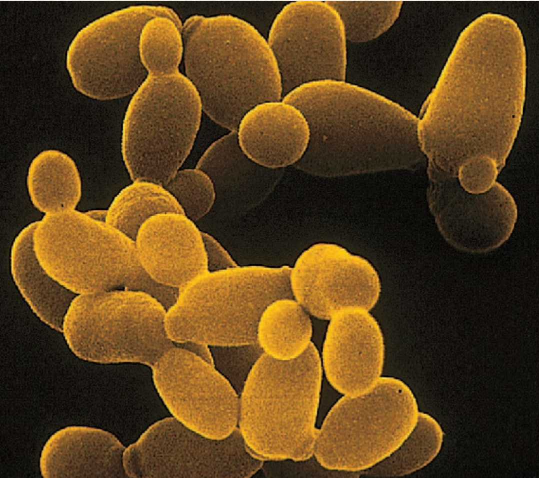
CHAPTER 25

The Fungi (Eumycota), Slime Molds, and Water Molds



This is a scanning electron micrograph of the microscopic, unicellular yeast, *Saccharomycetes cerevisiae* (×21,000). *S. cerevisiae* is the most thoroughly investigated eucaryotic microorganism in the world. This has led to a better understanding of the biology of the eucaryotic cell. Today it serves as a widely used biotechnological production organism as well as a eucaryotic model system.

Outline

25.1 Distribution 554
25.2 Importance 554
25.3 Structure 554
25.4 Nutrition and Metabolism 557
25.5 Reproduction 557
25.6 Characteristics of the Fungal Divisions 559
Division *Zygomycota* 560
Division *Ascomycota* 560
Division *Basidiomycota* 561
Division *Deuteromycota* 564
Division *Chytridiomycota* 564

Division *Myxomycota* (Acellular Slime Molds) 564
Division *Acrasiomycota* (Cellular Slime Molds) 565
Division *Oomycota* 565

Concepts

1. Fungi are widely distributed and are found wherever moisture is present. They are of great importance to humans in both beneficial and harmful ways.
2. Fungi exist primarily as filamentous hyphae. A mass of hyphae is called a mycelium.
3. Like some bacteria, fungi digest insoluble organic matter by secreting exoenzymes, then absorbing the solubilized nutrients.
4. Two reproductive structures occur in the fungi: (1) sporangia form asexual spores, and (2) gametangia form sexual gametes.
5. The zygomycetes are characterized by resting structures called zygospores—cells in which zygotes are formed.
6. The ascomycetes form zygotes within a characteristic saclike structure, the ascus. The ascus contains two or more ascospores.
7. Yeasts are unicellular fungi—mainly ascomycetes.
8. Basidiomycetes possess dikaryotic hyphae with two nuclei, one of each mating type. The hyphae divide uniquely, forming basidiocarps within which club-shaped basidia can be found. The basidia bear two or more basidiospores.

Concepts *(continued)*

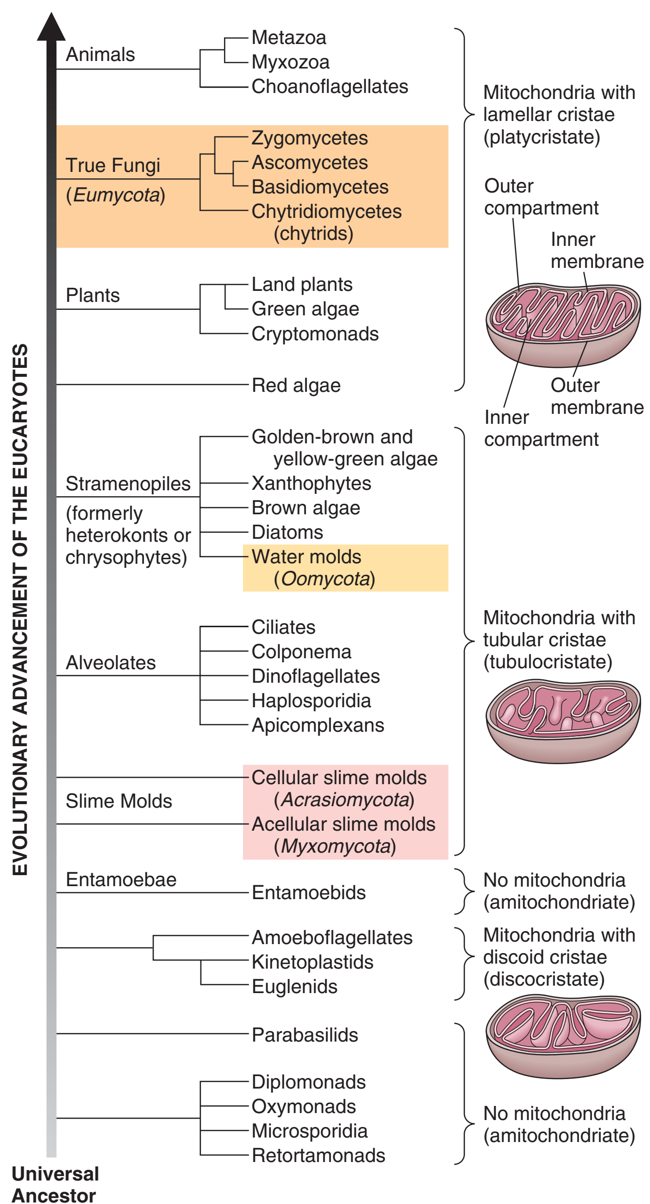
9. The deuteromycetes (Fungi Imperfecti) have either lost the capacity for sexual reproduction, or it has never been observed.
10. The chytrids are a group of terrestrial and aquatic fungi that reproduce by motile zoospores with single, posterior, whiplash flagella, and represent a link between the true fungi and protists.
11. The slime and water molds resemble the fungi only in appearance and lifestyle. In their cellular organization, reproduction, and life cycles, they are phylogenetically distinct.

Yeasts, molds, mushrooms, mildews, and the other fungi pervade our world. They work great good and terrible evil. Upon them, indeed, hangs the balance of life; for without their presence in the cycle of decay and regeneration, neither man nor any other living thing could survive.

—*Lucy Kavaler*

This chapter is an introduction to the true fungi. It surveys their diversity, discusses their ecological and commercial impact, and presents some of their typical life cycles. A brief overview is also given of the eucaryotes that resemble the fungi—the slime molds and water molds.

Microbiologists use the term **fungus** [pl., fungi; Latin *fungus,* mushroom] to include eucaryotic, spore-bearing organisms with absorptive nutrition, no chlorophyll, and that reproduce sexually and asexually. Scientists who study fungi are **mycologists** [Greek *mykes,* mushroom, and *logos,* discourse], and the scientific discipline dealing with fungi is called **mycology.** The study of fungal toxins and their effects is called **mycotoxicology,** and the diseases caused by fungi in animals are known as **mycoses** [s., mycosis]. The five-kingdom system places the fungi in the kingdom *Fungi* (*see figure 19.12*a). According to the universal phylogenetic tree, fungi are members of the domain *Eucarya* (*see figure 19.3*). As presently deliminated, the kingdom *Fungi* is believed to constitute a monophyletic group (**Phylogenetic Diagram 25**) referred to as the true fungi or ***Eumycota*** (Greek *eu,* true, and *mykes,* fungus).



Phylogenetic Diagram 25 Tentative Phylogeny of the True Fungi (*Eumycota*), Slime Molds, and Water Molds Based on 18S rRNA Sequence Comparisons. Using molecular systematics, organisms are grouped together based on the molecular phylogeny of their nuclear SSU rRNA genes and the type of mitochondrial cristae present. According to this tentative phylogeny, the true fungi, slime molds, and water molds form three distinct monophyletic branches (highlighted by three different colors). Accordingly, the four major groups of fungi (Zygomycetes, Ascomycetes, Basidiomycetes, and Chytridiomycetes) form a phylogenetically coherent group. Molecular characters have been essential for phylogenetic analysis in cases when morphological characters are convergent, reduced, or missing. This is especially true for species that never reproduce sexually (e.g., the Fungi Imperfecti or *Deuteromycota*), because characters of sexual reproduction traditionally have been the basis for classifying fungi. The use of molecular characters allows the asexual fungi (*Deuteromycota*) to be placed among their closest relatives in the *Eumycota* and not in a separate division.

25.1 Distribution

Fungi are primarily terrestrial organisms, although a few are freshwater or marine. Many are pathogenic and infect plants and animals. Fungi also form beneficial relationships with other organisms. For example, about three-fourths of all vascular plants form associations (called mycorrhizae) between their roots and fungi. Fungi also are found in the upper portions of many plants. These endophytic fungi affect plant reproduction and palatability to herbivores. Lichens are associations of fungi and either algae or cyanobacteria. Mycorrhizae (pp. 679–82); Endophytic fungi (p. 679); Lichens (pp. 598–99)

25.2 Importance

About 90,000 fungal species have been described; however, some estimates of total numbers suggest that 1.5 million species may exist.

Fungi are important to humans in both beneficial and harmful ways. With bacteria and a few other groups of heterotrophic organisms, fungi act as decomposers, a role of enormous significance. They degrade complex organic materials in the environment to simple organic compounds and inorganic molecules. In this way carbon, nitrogen, phosphorus, and other critical constituents of dead organisms are released and made available for living organisms (*see section 28.3*).

However, fungi are the major cause of plant diseases (**figure 25.1*a***). Over 5,000 species attack economically valuable crops and garden plants and also many wild plants. In like manner many diseases of animals (figure 25.1*b* and **table 25.1**) and humans (*see section 40.1*) are caused by fungi.

Fungi, especially the yeasts, are essential to many industrial processes involving fermentation (*see chapter 41*). Examples include the making of bread, wine, and beer. Fungi also play a major role in the preparation of some cheeses, soy sauce, and sufu; in the commercial production of many organic acids (citric, gallic) and certain drugs (ergometrine, cortisone); and in the manufacture of many antibiotics (penicillin, griseofulvin) and the immunosuppressive drug cyclosporine.

In addition, fungi are important research tools in the study of fundamental biological processes. Cytologists, geneticists, biochemists, biophysicists, and microbiologists regularly use fungi in their research. Based on this research the yeast *Saccharomyces cerevisiae* is the best understood eucaryotic cell.

25.3 Structure

The body or vegetative structure of a fungus is called a **thallus** [pl., thalli]. It varies in complexity and size, ranging from the single-cell microscopic yeasts to multicellular molds, macroscopic puffballs, and mushrooms (**figure 25.2**). The fungal cell usually is encased in a cell wall of **chitin.** Chitin is a strong but flexible nitrogen-containing polysaccharide consisting of *N*-acetylglucosamine residues.

A **yeast** is a unicellular fungus that has a single nucleus and reproduces either asexually by budding and transverse division or sexually through spore formation. Each bud that separates can grow into a new yeast, and some group together to form colonies. Generally yeast cells are larger than bacteria, vary considerably in size, and are commonly spherical to egg shaped. They have no flagella but do possess most of the other eucaryotic organelles (**figure 25.3**).

Table 25.1 Some Mycotoxicoses[a] Produced by Fungal Mycotoxins in Domestic Animals

Disease	Fungus	Mycotoxin	Contaminated Foodstuff	Animals Affected
Aflatoxicosis	*Aspergillus flavus*	Aflatoxins	Rice, corn, sorghum, cereals, peanuts, soybeans	Poultry, swine, cattle, sheep, dogs
Ergotism	*Claviceps purpurea*	Ergot alkaloids	Seedheads of many grasses, grains	Cattle, horses, swine, poultry
Mushroom poisoning	*Amanita verna*	Amanitins	Eaten from pastures	Cattle
Poultry hemorrhagic syndrome	*Aspergillus flavus* and others	Aflatoxins	Toxic grain and meal	Chickens
Slobbers	*Rhizoctonia*	Alkaloid slaframine	Red clover	Sheep, cattle
Tall fescue toxicosis	*Acremonium coenophialum* (an endophytic fungus)	Ergot alkaloids	Endophyte-infected tall fescue plants	Cattle, horses

[a]A mycotoxicosis [pl., mycotoxicoses] is a poisoning caused by a fungal toxin.

(d)

Figure 25.5 Hyphae. Drawings of (**a**) coenocytic hyphae and (**b**) hyphae divided into cells by septa. (**c**) Electron micrograph (×40,000) of a section of *Drechslera sorokiniana* showing wall differentiation and a single pore. (**d**) Drawing of a multiperforate septal wall structure.

A **mold** (figure 25.2*a*) consists of long, branched, threadlike filaments of cells called **hyphae** [s., hypha; Greek *hyphe,* web] that form a **mycelium** [pl., mycelia], a tangled mass or tissuelike aggregation (**figure 25.4**). In some fungi, protoplasm streams through hyphae, uninterrupted by cross walls. These hyphae are called **coenocytic** (**figure 25.5*a***). The hyphae of other fungi (figure 25.5*b*) have cross walls called **septa** [s., septum] with either a single pore (figure 25.5*c*) or multiple pores (figure 25.5*d*) that permit cytoplasmic streaming. These hyphae are termed **septate.**

Hyphae are composed of an outer cell wall and an inner lumen, which contains the cytosol and organelles (**figure 25.6**). A plasma membrane surrounds the cytoplasm and lies next to the cell wall.

Many fungi, especially those that cause diseases in humans and animals, are dimorphic (**table 25.2**)—that is, they have two forms. Dimorphic fungi can change from (1) the yeast (Y) form in the animal to (2) the mold or mycelial form (M) in the external environment in response to changes in various environmental factors (nutrients, CO_2 tension, oxidation-reduction potentials, temperature). This shift is called the **YM shift.** In plant-associated fungi the opposite type of dimorphism exists: the mycelial form occurs in the plant and the yeast form in the external environment.

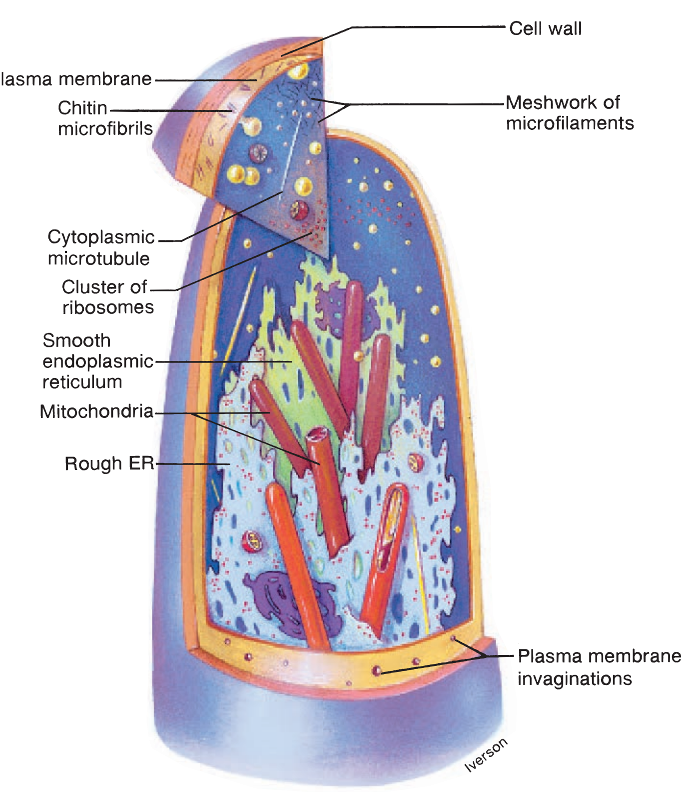

Figure 25.6 Hyphal Morphology. Diagrammatic representation of hyphal tip showing typical organelles and other structures.

Table 25.2 Some Medically Important Dimorphic Fungi

Fungus	Disease[a]
Blastomyces dermatitidis	Blastomycosis
Candida albicans	Candidiasis
Coccidioides capsulatum	Coccidioidomycosis
Histoplasma capsulatum	Histoplasmosis
Sporothrix schenckii	Sporotrichosis
Paracoccidioides brasiliensis	Paracoccidioidomycosis

[a]See chapter 40 for a discussion of each of these diseases.

1. How can a fungus be defined?
2. Where are fungi found?
3. Why are fungi important as decomposers?
4. What are some forms represented by different fungal thalli?
5. What organelles would you expect to find in the cytoplasm of a typical fungus?
6. Describe a typical yeast; a typical mold.

25.4 Nutrition and Metabolism

Fungi grow best in dark, moist habitats, but they are found wherever organic material is available. Most fungi are **saprophytes,** securing their nutrients from dead organic material. Like many bacteria, fungi release hydrolytic exoenzymes that digest external substrates. They then absorb the soluble products. They are chemoorganoheterotrophs and use organic compounds as a source of carbon, electrons, and energy.

Glycogen is the primary storage polysaccharide in fungi. Most fungi use carbohydrates (preferably glucose or maltose) and nitrogenous compounds to synthesize their own amino acids and proteins.

Fungi usually are aerobic. Some yeasts, however, are facultatively anaerobic and can obtain energy by fermentation, such as in the production of ethyl alcohol from glucose. Obligately anaerobic fungi are found in the rumen of cattle.

25.5 Reproduction

Reproduction in fungi can be either asexual or sexual. Asexual reproduction is accomplished in several ways:

1. A parent cell can divide into two daughter cells by central constriction and formation of a new cell wall (**figure 25.7*a***).
2. Somatic vegetative cells may bud to produce new organisms. This is very common in the yeasts.
3. The most common method of asexual reproduction is spore production. Asexual spore formation occurs in an individual fungus through mitosis and subsequent cell division. There are several types of asexual spores:
   a. A hypha can fragment (by the separation of hyphae through splitting of the cell wall or septum) to form cells that behave as spores. These cells are called **arthroconidia** or **arthrospores** (figure 25.7*b*).
   b. If the cells are surrounded by a thick wall before separation, they are called **chlamydospores** (figure 25.7*c*).
   c. If the spores develop within a sac [**sporangium;** pl., sporangia] at a hyphal tip, they are called **sporangiospores** (figure 25.7*d*).
   d. If the spores are not enclosed in a sac but produced at the tips or sides of the hypha, they are termed **conidiospores** (figures 25.7*e* and 25.11).
   e. Spores produced from a vegetative mother cell by budding (figure 25.7*f*) are called **blastospores.**

Sexual reproduction in fungi involves the union of compatible nuclei. Some fungal species are self-fertilizing and produce sexually compatible gametes on the same mycelium (homothallic). Other species require outcrossing between different but sexually compatible mycelia (heterothallic). Depending on the species, sexual fusion may occur between haploid gametes, gamete-producing bodies called **gametangia,** or hyphae. Sometimes both the cytoplasm and haploid nuclei fuse immediately to produce the diploid zygote. Usually, however, there is a delay between cytoplasmic and nuclear fusion. This produces a **dikaryotic stage** in which cells contain two

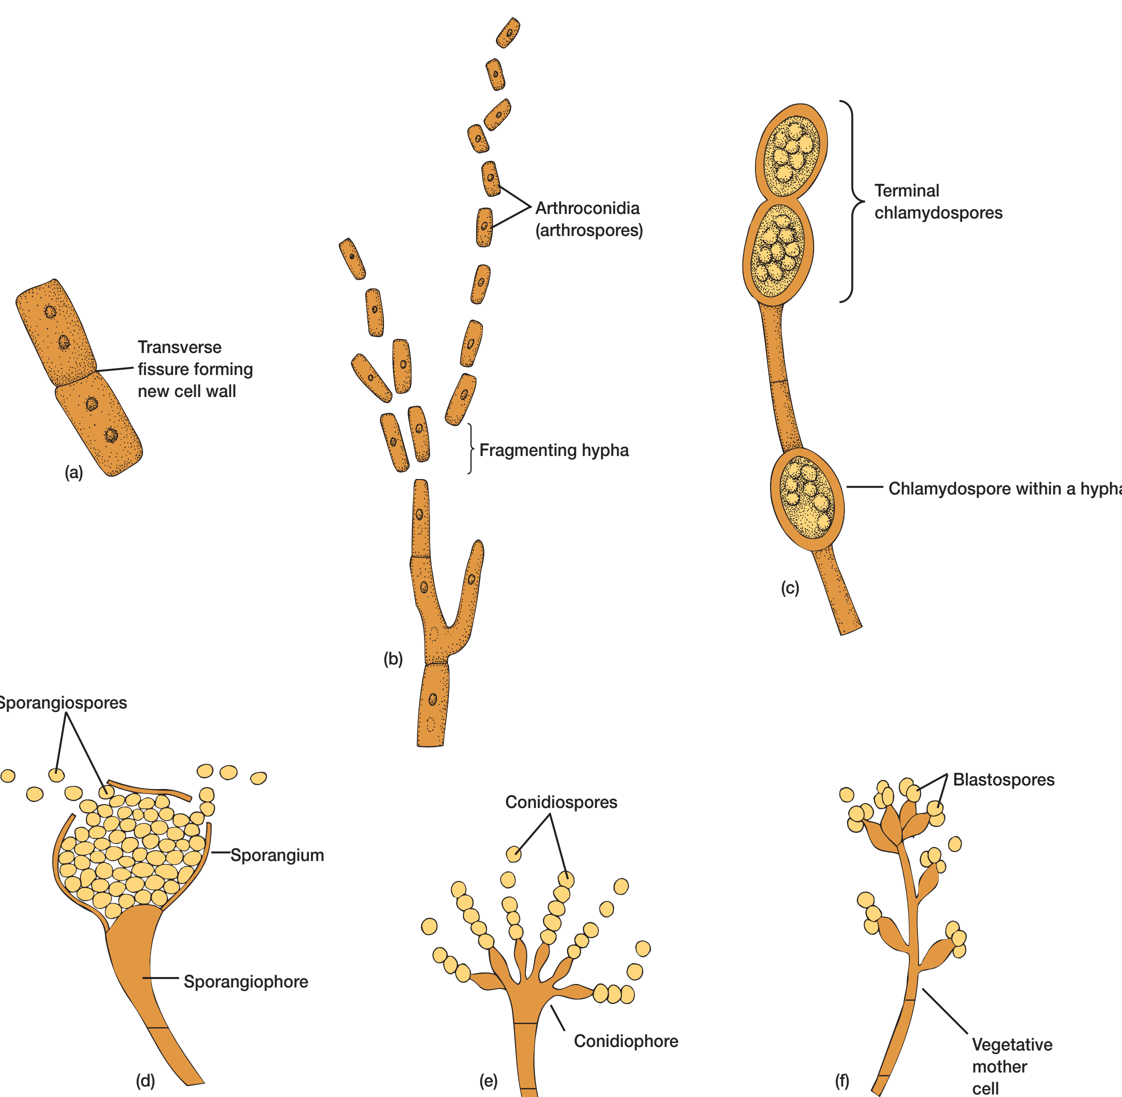

Figure 25.7 Diagrammatic Representation of Asexual Reproduction in the Fungi and Some Representative Spores. (**a**) Transverse fission. (**b**) Hyphal fragmentation resulting in arthroconidia (arthrospores) and (**c**) chlamydospores. (**d**) Sporangiospores in a sporangium. (**e**) Conidiospores arranged in chains at the end of a conidiophore. (**f**) Blastospores are formed from buds off of the parent cell.

separate haploid nuclei, one from each parent (**figure 25.8**). After a period of dikaryotic existence, the two nuclei fuse. This sexual reproduction yields spores. For example, in the zygomycetes the zygote develops into a **zygospore** (**figure 25.9**); in the ascomycetes, an **ascospore** (figure 25.12); and in the basidomycetes; a **basidiospore** (figure 25.14).

Fungal spores are important for several reasons. The size, shape, color, and number of spores are useful in the identification of fungal species. The spores are often small and light; they can remain suspended in air for long periods. Thus they frequently aid in fungal dissemination, a significant factor that explains the wide distribution of many fungi. Fungal spores often spread by adhering to the bodies of insects and other animals. The bright colors and fluffy textures of many molds often are due to their aerial hyphae and spores.

1. What generally governs the ecological distribution of fungi?
2. How is asexual reproduction accomplished in the fungi? Sexual reproduction?
3. Describe each of the following types of asexual fungal spores: sporangiospore, conidiospore, and blastospore.

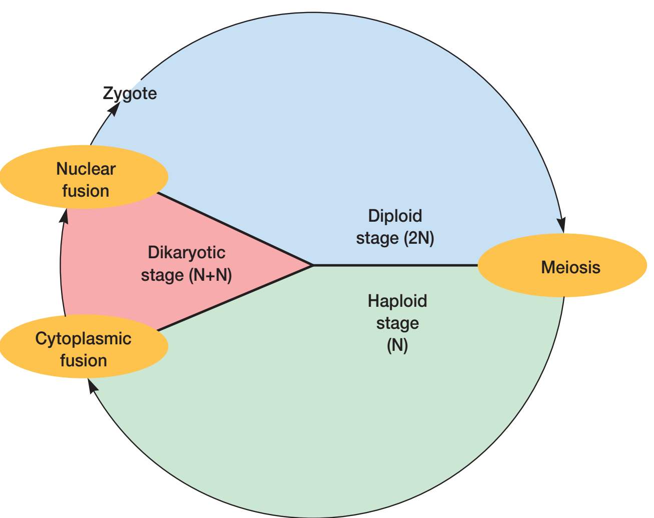

Figure 25.8 Reproduction in Fungi. A drawing of the generalized life cycle for fungi showing the alternation of haploid and diploid stages. Some fungal species do not pass through the dikaryotic stage indicated in this drawing. The asexual (haploid) stage is used to produce spores that aid in the dissemination of the species. The sexual (diploid) stage involves the formation of spores that survive adverse environmental conditions (e.g., cold, dryness, heat).

25.6 Characteristics of the Fungal Divisions

The traditional taxonomic scheme used by mycologists classifies the fungi into four divisions (**table 25.3**), based primarily on variations in sexual reproduction. (In mycology a division is equivalent to a phylum in animal classification schemes.) Based on 18S rRNA studies, molecular microbiologists place the *Deuteromycota* (Fungi Imperfecti) among their closest relatives in either the *Zygomycota, Ascomycota,* or *Basidiomycota* and add the class *Chytridiomycetes* (Phylogenetic Diagram 25).

Table 25.3 Divisions of Fungi*

Division	Common Name	Approximate Number of Species
Zygomycota	Zygomycetes	600
Ascomycota	Sac fungi	35,000
Basidiomycota	Club fungi	30,000
Deuteromycota[a]	Fungi Imperfecti	30,000

[a]According to the traditional system often followed by mycologists.

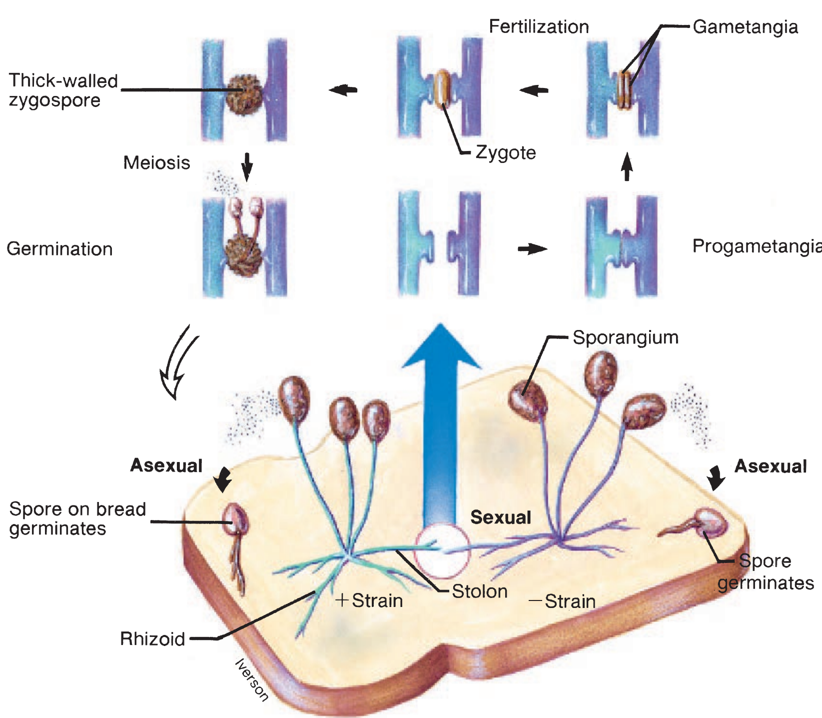

Figure 25.9 Division *Zygomycota*. Diagrammatic representation of the life cycle of *Rhizopus stolonifer.* Both the sexual and asexual phases are illustrated.

(a)

(b)

(c)

Figure 25.10 **Division *Ascomycota.*** (**a**) The common morel, *Morchella esculenta,* is one of the choicest edible fungi. It fruits in the spring. (**b**) Scarlet cups, *Sarcoscypha coccinea,* with open ascocarps (apothecia). (**c**) The black truffle, *Tuber brumale,* is highly prized for its flavor by gourmet cooks. Technically truffles are mycorrhizal associations on oak trees.

Division *Zygomycota*

The division *Zygomycota* contains the fungi called **zygomycetes.** Most live on decaying plant and animal matter in the soil; a few are parasites of plants, insects, animals, and humans. The hyphae of zygomycetes are coenocytic, with many haploid nuclei. Asexual spores, usually wind dispersed, develop in sporangia at the tips of aerial hyphae. Sexual reproduction produces tough, thick-walled zygotes called zygospores that can remain dormant when the environment is too harsh for growth of the fungus.

The bread mold, *Rhizopus stolonifer,* is a very common member of this division. This fungus grows on the surface of moist, carbohydrate-rich foods, such as breads, fruits, and vegetables. On breads, for example, *Rhizopus's* hyphae rapidly cover the surface. Special hyphae called rhizoids extend into the bread, and absorb nutrients (figure 25.9). Other hyphae (stolons) become erect, then arch back into the substratum forming new rhizoids. Still others remain erect and produce at their tips asexual sporangia filled with the black spores, giving the mold its characteristic color. Each spore, when liberated, can start a new mycelium.

Rhizopus usually reproduces asexually, but if food becomes scarce or environmental conditions unfavorable, it begins sexual reproduction. Sexual reproduction requires compatible strains of opposite mating types (figure 25.9). These have traditionally been labeled + and − strains because they are not morphologically distinguishable as male and female. When the two mating strains are close, hormones are produced that cause their hyphae to form projections called **progametangia** [Greek *pro,* before], and then mature gametangia. After fusion of the gametangia, the nuclei of the two gametes fuse, forming a zygote. The zygote develops a thick, rough, black coat and becomes a dormant zygospore. Meiosis often occurs at the time of germination; the zygospore then splits open and produces a hypha that bears an asexual sporangium and the cycle begins anew.

The zygomycetes also contribute to human welfare. For example, *Rhizopus* is used in Indonesia to produce a food called tempeh from boiled, skinless soybeans. Another zygomycete (*Mucor* spp.) is used with soybeans in the Orient to make a cheese called sufu. Others are employed in the commercial preparation of some anesthetics, birth control agents, industrial alcohols, meat tenderizers, and the yellow coloring used in margarine and butter substitutes.

Division *Ascomycota*

The division *Ascomycota* contains the fungi called **ascomycetes,** commonly known as the sac fungi. Many species are quite familiar and economically important (**figure 25.10**). For example, most of the red, brown, and blue-green molds that cause food spoilage are ascomycetes. The powdery mildews that attack plant leaves and the fungi that cause chestnut blight and Dutch elm disease are ascomycetes. Many yeasts as well as edible morels and truffles are ascomycetes. The pink bread mold *Neurospora crassa,* also an ascomycete, has been a most important research tool in genetics and biochemistry.

Figure 25.11 Asexual Reproduction in Ascomycetes. Characteristic conidiospores of *Aspergillus* as viewed with the electron microscope (×1,200).

Many ascomycetes are parasites on higher plants. *Claviceps purpurea* parasitizes rye and other grasses, causing the disease **ergot. Ergotism,** the toxic condition in humans and animals who eat grain infected with the fungus, is often accompanied by gangrene, psychotic delusions, nervous spasms, abortion, and convulsions. During the Middle Ages ergotism, then known as St. Anthony's fire, killed thousands of people. For example, over 40,000 deaths from ergot poisoning were recorded in France in the year 943. It has been suggested that the widespread accusations of witchcraft in Salem Village (now Danvers) and other Massachusetts communities in the late 1690s may have resulted from outbreaks of ergotism. The pharmacological activities of ergot are due to its active ingredient, lysergic acid diethylamide (LSD). In controlled dosages ergot can be used to induce labor, lower blood pressure, and ease migraine headaches.

The ascomycetes are named for their characteristic reproductive structure, the saclike **ascus** [pl., asci; Greek *askos,* sac]. The mycelium of the ascomycetes is composed of septate hyphae. Asexual reproduction is common in the ascomycetes and takes place by way of conidiospores (**figure 25.11**).

Sexual reproduction in the ascomycetes always involves the formation of an ascus containing two or more haploid ascospores (**figure 25.12*a***). In the more complex ascomycetes, ascus formation is preceded by the development of special **ascogenous hyphae** into which pairs of nuclei migrate (figure 25.12*b*). One nucleus of each pair originates from a "male" mycelium (**antheridium**) or cell and the other from a "female" organ or cell (**ascogonium**) that has fused with it. As the ascogenous hyphae grow, the paired nuclei divide so that there is one pair of nuclei in each cell. After the ascogenous hyphae have matured, nuclear fusion occurs at the hyphal tips in the ascus mother cells. The diploid zygote nucleus then undergoes meiosis, and the resulting four haploid nuclei divide mitotically again to produce a row of eight nuclei in each developing ascus. These nuclei are walled off from one another. Thousands of asci may be packed together in a cup- or flask-shaped **ascocarp** (figure 25.10*b*). When the ascospores mature, they often are released from the asci with great force. If, perchance, the mature ascocarp is jarred, it may appear to belch puffs of "smoke" consisting of thousands of ascospores. Upon reaching a suitable environment, the ascospores germinate and start the cycle anew.

Although the term yeast is used in a general sense to refer to all unicellular fungi that reproduce asexually by either budding or binary fission (figure 25.13*a,b*), many yeast genera are classified specifically within the ascomycetes because of their sexual reproduction (figure 25.13*c,d*). Yeasts are present in both terrestrial and aquatic habitats in which a suitable carbon source is available.

Division *Basidiomycota*

The division *Basidiomycota* contains the **basidiomycetes,** commonly known as the club fungi. Examples include the smuts, jelly fungi, rusts, shelf fungi, stinkhorns, puffballs, toadstools, mushrooms, and bird's nest fungi.

Basidiomycetes are named for their characteristic structure or cell, the **basidium,** that is involved in sexual reproduction (**figure 25.14**). A basidium [Greek *basidion,* small base] is produced at the tip of hyphae and normally is club shaped. Two or more basidiospores are produced by the basidium, and basidia may be held within fruiting bodies called **basidiocarps.**

The basidiomycetes affect humans in many ways. Most are saprophytes that decompose plant debris, especially cellulose and lignin. Many mushrooms are used as food throughout the world. The cultivation of *Agaricus campestris* is a multimillion-dollar business (*see figure 41.24*).

Many mushrooms produce specific alkaloids that act as either poisons or hallucinogens. One such example is the "destroying angel" mushroom, *Amanita phalloides.* Two toxins isolated from this species are phalloidin and α-amanitin. Phalloidin primarily attacks liver cells where it binds to plasma membranes, causing them to rupture and leak their contents. Alpha-amanitin attacks the cells lining the stomach and small intestine and is responsible for the severe gastrointestinal symptoms associated with mushroom poisoning.

The basidiomycete *Cryptococcus neoformans* is an important human pathogen. It produces the disease called **cryptococcosis,** a systemic infection primarily involving the lungs and central nervous system. Other basidiomycetes, the smuts and rusts, are virulent plant pathogens that cause extensive damage to cereal crops; millions of dollars worth of crops are destroyed annually. In these fungi, large basidiocarps are not formed. Instead the small basidia arise from hyphae at the surface of the host plant. The mycelia grow either intra- or extracellularly in plant tissue.

Figure 25.12 The Life Cycle of Ascomycetes. Sexual reproduction involves the formation of asci and ascospores. Within the ascus, karyogamy is followed by meiosis to produce the ascospores. (**a**) Sexual reproduction and ascocarp morphology of a cup fungus. (**b**) The details of sexual reproduction in ascogenous hyphae. The nuclei of the two mating types are represented by unfilled and filled circles. See text for details.

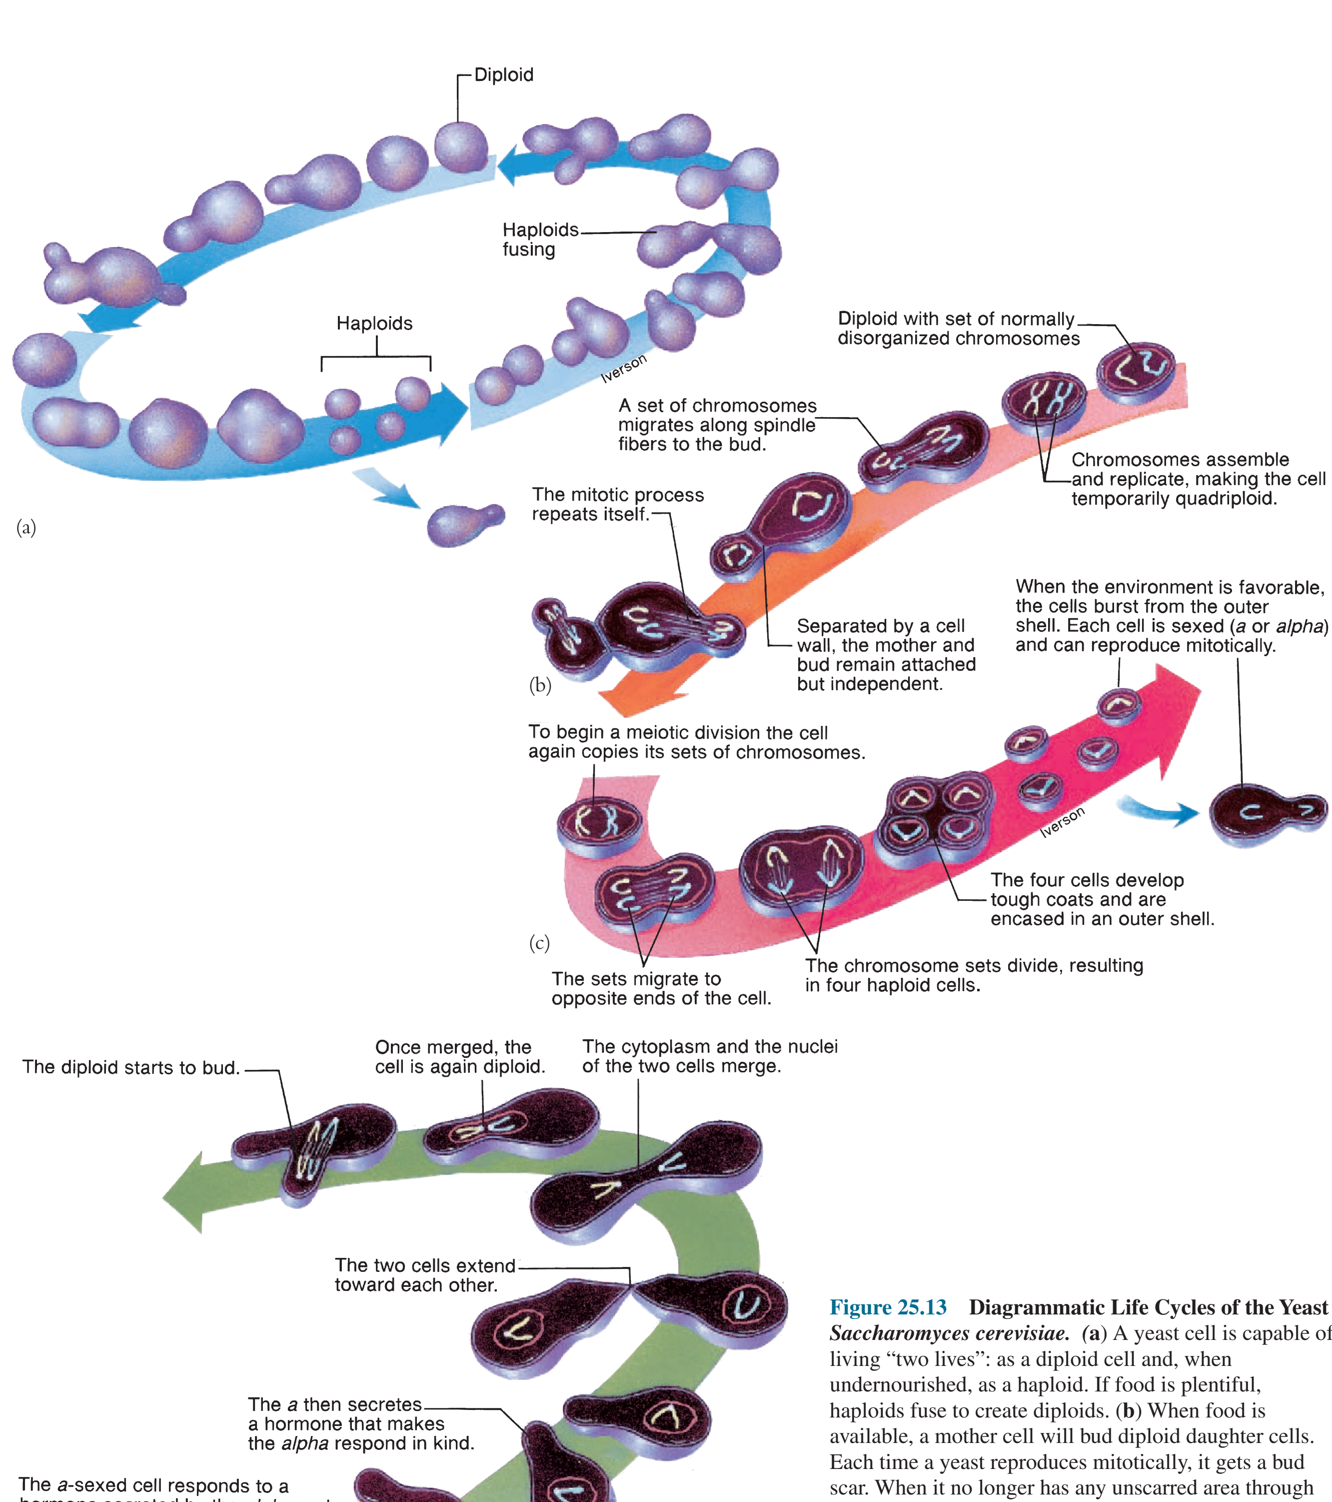

Figure 25.13 Diagrammatic Life Cycles of the Yeast *Saccharomyces cerevisiae*. (**a**) A yeast cell is capable of living “two lives”: as a diploid cell and, when undernourished, as a haploid. If food is plentiful, haploids fuse to create diploids. (**b**) When food is available, a mother cell will bud diploid daughter cells. Each time a yeast reproduces mitotically, it gets a bud scar. When it no longer has any unscarred area through which to bud, it dies. (**c**) When starved, a yeast cell undergoes meiosis. In this process four cells develop within the mother cell as a unit and remain in their rugged cell walls until food is available once more. (**d**) Two haploids in proximity can fuse and produce a diploid. Once formed, it buds even before it attains its final shape. (*See section 4.9 and figure 4.19 for a discussion of mitosis.*)

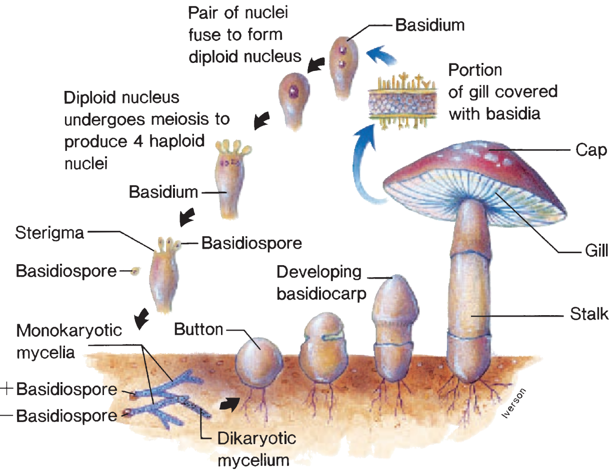

Figure 25.14 Division *Basidiomycota.* The life cycle of a typical soil basidiomycete starts with a basidiospore germinating to produce a monokaryotic mycelium (one with a single nucleus in each septate cell). The mycelium quickly grows and spreads throughout the soil. When this primary mycelium meets another monokaryotic mycelium of a different mating type, the two fuse to initiate a new dikaryotic secondary mycelium. The secondary mycelium is divided by septa into cells, each of which contains two nuclei, one of each mating type. This dikaryotic mycelium is eventually stimulated to produce basidiocarps. A solid mass of hyphae forms a button that pushes through the soil, elongates, and develops a cap. The cap contains many platelike gills, each of which is coated with basidia. The two nuclei in the tip of each basidium fuse to form a diploid zygote nucleus, which immediately undergoes meiosis to form four haploid nuclei. These nuclei push their way into the developing basidiospores, which are then released at maturity.

Division *Deuteromycota*

To a large degree, classical fungal taxonomy is based on specific patterns of sexual reproduction. When a fungus lacks the sexual phase (perfect stage), or if this phase has not been observed, it is placed within the division *Deuteromycota,* commonly called the Fungi Imperfecti or **deuteromycetes** (“secondary fungi”). Once a perfect stage is observed, the fungus is transferred to its proper division. Molecular systematics places the *Deuteromycota* among their closest relatives in the *Eumycota* (Phylogenetic Diagram 25).

Most Fungi Imperfecti are terrestrial, with only a few being reported from freshwater and marine habitats. The majority are either saprophytes or parasites of plants. A few are parasitic on other fungi.

Many imperfect fungi directly affect human welfare. Several are human pathogens, causing such diseases as athlete’s foot, ringworm, and histoplasmosis (*see section 40.1*). The chemical activities of many Fungi Imperfecti are important industrially. For example, some species of *Penicillium* (*see figure 4.1*c,d) synthesize the well-known antibiotics penicillin and griseofulvin. Other species give characteristic aromas to cheeses such as Gorgonzola, Camembert, and Roquefort. Different species of *Aspergillus* are used to ferment soy sauce and to manufacture citric, gluconic, and gallic acids. *Aspergillus flavus* and *A. parasiticus* produce secondary metabolites, called aflatoxins, that are highly toxic and carcinogenic to animals and humans (*see section 41.2*). Another group of fungal toxins, the trichothecenes, are strong inhibitors of protein synthesis in eucaryotic cells.

Division *Chytridiomycota*

The simplest of the true fungi belong to the division *Chytridiomycota.* This division contains one class, *Chytridiomycetes,* and its members are known familiarly as the **chytrids.** These are simple terrestrial and aquatic fungi that reproduce asexually by forming motile zoospores with single, posterior, whiplash flagella. The entire organism is microscopic in size and may consist of a single cell, a small multinucleate mass, or a true mycelium. Usually chitin is the major constituent of chytrid cell walls. Chytrids are thought to have been derived from a protozoan ancestor having similar flagellation. They are likely to be ancestral to the remaining groups of true fungi (Phylogenetic Diagram, page 553). Chytrids have a variety of life cycles. When sexual reproduction occurs, it results in a zygote that generally becomes a resting spore or sporangium. Some can grow saprophytically on dead organic matter; others are parasites of algae (*see figure 29.7*), other true fungi, and terrestrial and aquatic plants. Species such as *Allomyces* are used in the study of morphogenesis.

1. Describe how a typical zygomycete reproduces.
2. Give some beneficial uses for zygomycetes.
3. Describe the ascomycete life cycle. How are the ascomycetes important to humans?
4. How do yeasts reproduce sexually? Asexually?
5. Describe the life cycle of a typical basidiomycete.
6. How do some Fungi Imperfecti affect humans?
7. What are chytrids? Discuss their importance.

25.7 Slime Molds and Water Molds

The **slime molds** and **water molds** resemble fungi in only appearance and life-style. In their cellular organization, reproduction, and life cycles, they are phylogenetically distinct (Phylogenetic Diagram 25).

Division *Myxomycota* (Acellular Slime Molds)

Under appropriate conditions **plasmodial (acellular) slime molds** exist as streaming masses of colorful protoplasm that creep along in an amoeboid fashion over moist, rotting logs, leaves, and other organic matter. Feeding is by phagocytosis. Be-

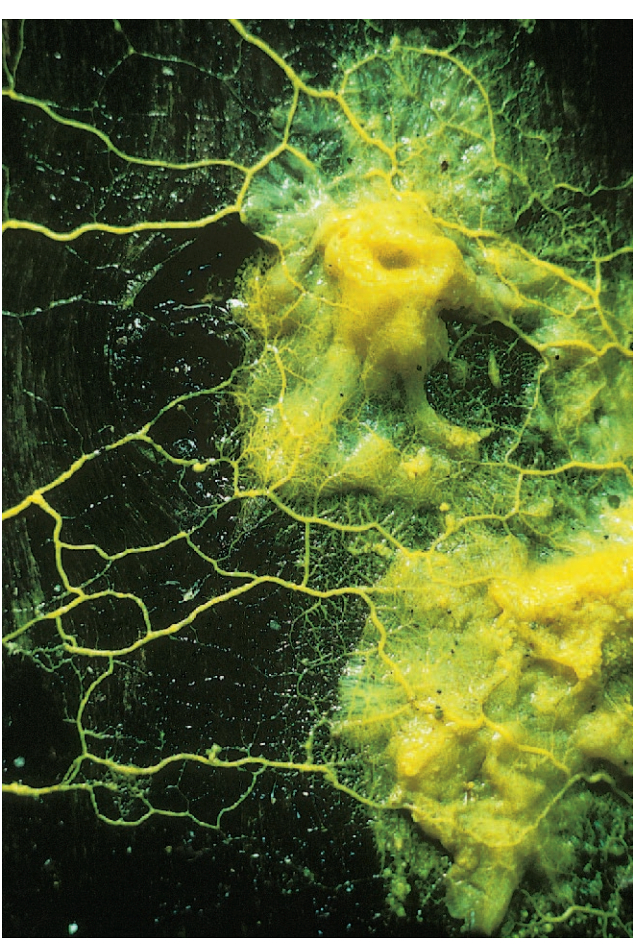

Figure 25.15 Slime Molds. Plasmodium of the slime mold *Physarum;* light micrograph (×175).

cause this streaming mass lacks cell walls, it is called a **plasmodium** (**figures 25.15** and **25.16*a***). The plasmodium contains many nuclei, and as the organism grows, the diploid nuclei divide repeatedly.

When the plasmodium matures or when food and/or moisture are scarce, it moves into a lighted area and develops delicate ornate fruiting bodies (figure 25.16*b–e*). As the fruiting bodies mature, they form spores with cellulose walls that are resistant to environmental extremes. The spores germinate in the presence of adequate moisture to release either nonflagellated amoeboid **myxamoebae** or flagellated **swarm cells.** Initially the myxamoebae or swarm cells feed and are haploid (figure 25.16*a*); eventually they fuse to form a diploid zygote. The zygote feeds, grows, and multiplies its nuclei through synchronous mitotic division to form the multinucleate plasmodium.

Division *Acrasiomycota* (Cellular Slime Molds)

The vegetative stage of **cellular slime molds** consists of individual amoeboid cells termed myxamoebae (**figure 25.17*a***). The myxamoebae feed phagocytically on bacteria and yeasts. When food is plentiful, they divide repeatedly by mitosis and cytokinesis, producing new daughter myxamoebae. As their food supply is exhausted, the myxamoebae begin to secrete cyclic adenosine monophosphate (cAMP). This attracts other myxamoebae that move toward the cAMP chemotactic source and in turn secrete more cAMP. When the individual myxamoebae aggregate (figure 25.17*b*), they form a sluglike **pseudoplasmodium** (figure 25.17*c*). The pseudoplasmodium may move around as a unit for a while, leaving a slime trail, but it eventually becomes sedentary. In the culmination of the asexual phase, pseudoplasmodial cells begin to differentiate into prestalk cells and prespore cells (figure 25.17*b*). A fruiting body called a **sorus** or **sorocarp** forms and matures (figure 25.17*d*) and then produces spores (figure 25.17*e*). The spores are eventually released, and when conditions become favorable, they germinate to release haploid amoebae and repeat the cycle.

Division *Oomycota*

Members of the division *Oomycota* are collectively known as **oomycetes** or water molds. Oomycetes resemble true fungi only in appearance, consisting of finely branched filaments called hyphae. However, oomycetes have cell walls of cellulose, whereas the walls of most fungi are made of chitin. Oomycetes are also unlike the true fungi in that they have tubular mitochondrial cristae.

Oomycota means "egg fungi," a reference to the mode of sexual reproduction in water molds. A relatively large egg cell (oogonium) is fertilized by either a sperm cell or a smaller antheridium to produce a zygote. When the zygote germinates, it forms asexual zoospores that bear flagella.

Water molds such as *Saprolegnia* and *Achlya* are saprophytes that grow as cottony masses on dead algae and small animals, mainly in freshwater environments. They are important decomposers in aquatic ecosystems. Some water molds are parasitic on the gills of fish. The water mold *Peronospora hyoscyami* is currently responsible for the troublesome "blue mold" of tobacco plants throughout the world. In the United States alone, blue mold produces millions of dollars of damage yearly to tobacco crops. Other oomycetes cause late blight of potatoes (*Phytophthora infestans*) and grape downy mildew (*Plasmopara viticola*).

1. What is a plasmodium?
2. How do the plasmodial slime molds reproduce? Describe the cellular slime mold life cycle.
3. Where would you look for an oomycete?

(**a**) Aggregating myxamoebae become polar and begin to move in an oriented direction due to the influence of cAMP. (**b**) Diagrammatic drawing of cell migration involved in the formation of the sorocarp from (**c**) an initial pseudoplasmodium. (**d**) Light micrograph of a mature fruiting body (sorocarp). (**e**) Electron micrograph of a sorus showing spores (×1,800).

Summary

1. Fungi are omnipresent in the environment, being found wherever water, suitable organic nutrients, and an appropriate temperature occur. They secrete enzymes outside their body structure and absorb the digested food.
2. Fungi are important decomposers that break down organic matter; live as parasites on animals, humans, and plants; play a role in many industrial processes; and are used as research tools in the study of fundamental biological processes.
3. The body or vegetative structure of a fungus is called a thallus (**figure 25.2**). Fungi may be grouped into molds or yeasts based on the development of the thallus.
4. A fungus is a eucaryotic, spore-bearing organism that has absorptive nutrition and lacks chlorophyll; that reproduces asexually, sexually, or by both methods; and that normally has filamentous hyphae surrounded by cell walls, which usually contain chitin.
5. Yeasts are unicellular fungi that have a single nucleus and reproduce either asexually by budding and transverse division or sexually through spore formation (**figure 25.3**).
6. A mold consists of long, branched, threadlike filaments of cells, the hyphae, that form a tangled mass called a mycelium (**figure 25.4**). Hyphae may be either septate or coenocytic (nonseptate). The mycelium can produce reproductive structures.
7. Some fungi are dimorphic—they alternate between a yeast and a mold form (**table 25.2**).
8. Asexual reproduction often occurs in the fungi by the production of specific types of spores that are easily dispersed (**figure 25.7**).
9. Sexual reproduction is initiated in the fungi by the fusion of hyphae of different mating strains. In some fungi the nuclei in the fused hyphae immediately combine to form a zygote. In others the two genetically distinct nuclei remain separate, forming pairs that divide synchronously. Eventually some nuclei fuse (**figure 25.8**).
10. The zygomycetes are coenocytic. Most are saprophytic. One example is the common bread mold, *Rhizopus stolonifer*. Sexual reproduction occurs through a form of conjugation involving + and − strains (**figure 25.9**).
11. The ascomycetes are known as the sac fungi because they form a sac-shaped reproductive structure called an ascus (**figure 25.10**). In asexual reproduction they produce characteristic conidia (**figure 25.11**). Sexual reproduction involves + and − strains (**figure 25.12**).
12. The basidiomycetes are the club fungi. They are named after their basidium that produces basidiospores (**figure 25.14**).
13. The deuteromycetes (Fungi Imperfecti) are fungi with no known sexual (perfect) phase.
14. The plasmodial (acellular) slime molds move about as a multinucleate plasmodium (**figure 25.15**). When food or moisture is scarce, these slime molds form sporangia within which spores are produced (**figure 25.16**).
15. The cellular slime molds consist of a vegetative stage called a myxamoeba (**figure 25.17**). The myxamoebae feed until their nutrients are exhausted, then the cells come together to form a moldlike multicellular structure called a sorus or sorocarp. The sorocarp produces haploid spores that germinate when conditions are favorable to form new myxamoebae.
16. The chytrids are a group of terrestrial and aquatic fungi that produce motile zoospores with single, posterior, whiplash flagella.
17. The *Oomycota* (water molds) are characterized by the production of motile spores (zoospores, gametes) and production of resistant sexual spores (oospores).

Questions for Thought and Review

1. Some fungi can reproduce both sexually and asexually. What are the advantages and disadvantages of each?
2. Why is nutrition in the fungi a property of membrane function?
3. Why are most fungi confined to a specific ecological niche?
4. Some authorities believe that the slime molds and water molds should be placed in the kingdom *Fungi,* whereas others believe that they should be placed in the kingdom *Protista.* What are the characteristics that these organisms share with both the fungi and protists that have led to this ambiguity?
5. At the present time those fungi that have no sexual reproduction cannot be classified with their sexually reproducing relatives. Why? Do you think that this is likely to change in the future?
6. Because asexual spores are such a rapid way of reproducing for some fungi, what adaptive "use" is there for an additional sexual phase?
7. Some fungi can be viewed as coenocytic organisms that exhibit little differentiation. When differentiation does occur, such as in the formation of reproductive structures, it is preceded by septum formation. Why does this occur?
8. The term mushrooming is a proverbial description for expanding rapidly. Why is this an accurate metaphor?
9. Both bacteria and fungi are major environmental decomposers. Obviously competition exists in a given environment, but fungi usually have an advantage. What is this advantage?
10. Very few antibiotics can control fungi, while there are many for bacterial control. Why is this so?

Critical Thinking Questions

1. What are some logical targets to exploit in treating animals or plants suffering from fungal infections? Are they different from the targets you would use when treating infections caused by bacteria? By viruses? Explain.
2. Fungi tend to reproduce asexually when nutrients are plentiful and conditions are favorable for growth, but reproduce sexually when environmental or nutrient conditions are not favorable. Why is this an evolutionarily important and successful strategy?
3. Compare and contrast the development of fruiting bodies by cellular slime molds and by myxobacteria.

- *Pyrrhophyta* (Dinoflagellates) 579

Concepts

1. Most algae are found in freshwater and marine environments; a few grow in terrestrial habitats.
2. The algae are not a single, closely related taxonomic group but, instead, are a diverse, polyphyletic assemblage of unicellular, colonial, and multicellular eucaryotic organisms.
3. Although algae can be autotrophic or heterotrophic, most are photoautotrophs. They store carbon in a variety of forms, including starch, oils, and various sugars.
4. The body of an alga is called the thallus. Algal thalli range from small solitary cells to large, complex multicellular structures.
5. Algae reproduce asexually and sexually.
6. The following classical divisions of the algae are discussed: *Chlorophyta* (green algae), *Charophyta* (stoneworts/brittleworts), *Euglenophyta* (euglenoids), *Chrysophyta* (golden-brown and yellow-green algae; diatoms), *Phaeophyta* (brown algae), *Rhodophyta* (red algae), and *Pyrrhophyta* (dinoflagellates).

The term algae means different things to different people, and even the professional botanist and biologist find algae embarrassingly elusive of definition. Thus, laymen have given such names as "pond scums," "frog spittle," "water mosses," and "seaweeds," while some professionals shrink from defining them.

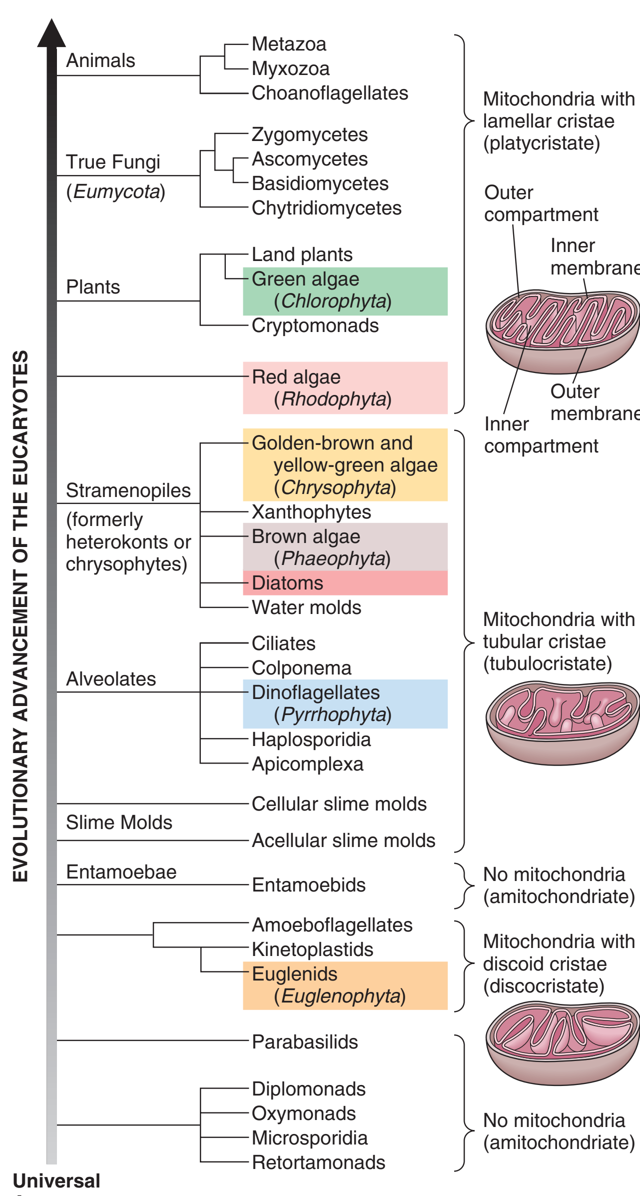
—*Harold C. Bold and Michael J. Wynne*

Chapter 26 presents some general features of algae. Because 18S rRNA analysis has shown that these organisms arose independently on different occasions, the algae do not represent a monophyletic group (**Phylogenetic Diagram 26**). Accordingly, the taxa "algae" should not be used in molecular taxonomy schemes. The term algae can still be used (as it is in this chapter) to denote a group of related eucaryotic organisms that share some morphological, reproductive, ecological, and biochemical characteristics.

Phycology or **algology** is the study of algae. The word phycology is derived from the Greek *phykos,* meaning seaweed. The term **algae** [s., alga] was originally used to define simple "aquatic plants." As noted above, it no longer has any formal significance in classification schemes. Instead the algae can be described as eucaryotic organisms that have chlorophyll *a* and carry out oxygen-producing photosynthesis. They differ from other photosynthetic eucaryotes in lacking a well-organized vascular conducting system and in having very simple reproductive structures. In sexual reproduction the whole organism may serve as a gamete; unicellular structures (gametangia) may produce gametes; or gametes can be formed by multicellular gametangia in which every cell is fertile. Unlike the case with plants, algal gametangia do not have nonfertile cells.

26.1 Distribution of Algae

Algae most commonly occur in water (fresh, marine, or brackish) in which they may be suspended (**planktonic**) or attached and living on the bottom (**benthic**). A few algae live at the water-atmosphere interface and are termed **neustonic. Plankton** [Greek *plankos,* wandering] consists of free-floating, mostly microscopic aquatic organisms. **Phytoplankton** is made up of algae and small plants, whereas **zooplankton** consists of animals and nonphotosynthetic protists. Some algae grow on moist rocks, wood, trees, and on the surface of moist soil. Algae also live as endosymbionts in various protozoa, mollusks, worms, and corals. Several algae grow as endosymbionts within plants, some are attached to the surface of various structures, and a few lead a parasitic existence. Algae also associate with fungi to form lichens. Zooxanthella symbiosis (p. 599); Lichen symbiosis (pp. 598–99)



Phylogenetic Diagram 26 Tentative Phylogeny of the Algae-like Eucaryotes Based on 18S rRNA Sequence Comparisons. Using molecular systematics, organisms are grouped together based on the molecular phylogeny of their nuclear SSU rRNA genes and the type of mitochondrial cristae present. Accordingly, the algae-like eucaryotic organisms have arisen independently on five different occasions and are polyphyletic (highlighted by different colors).

26.2 Classification of Algae

According to the five-kingdom system of Whittaker, the algae belong to seven divisions distributed between two different kingdoms (**table 26.1**). This classical classification is based on

cellular, not organismal, properties. Some more important properties include: (1) cell wall (if present) chemistry and morphology; (2) form in which food or assimilatory products of photosynthesis are stored; (3) chlorophyll molecules and accessory pigments that contribute to photosynthesis; (4) flagella number and the location of their insertion in motile cells; (5) morphology of the cells and/or body (thallus); (6) habitat; (7) reproductive structures; and (8) life history patterns. Based on these properties the algae are arranged by divisions in **table 26.2,** which summarizes their more significant characteristics.

Table 26.1 Classical Classification of Algae[a]

Division (Common Name)	Kingdom
Chrysophyta (yellow-green and golden-brown algae; diatoms)	*Protista* (single cell or colonial; eucaryotic)
Euglenophyta (photosynthetic euglenoid flagellates)	*Protista*
Pyrrhophyta (dinoflagellates)	*Protista*
Charophyta (stoneworts)	*Protista*
Chlorophyta (green algae)	*Protista*
Phaeophyta (brown algae)	*Plantae* (multicellular; eucaryotic)
Rhodophyta (red algae)	*Plantae*

[a]Five-kingdom system.

Molecular systems (Phylogenetic Diagram 26) have placed some of the classical algae with plants (green algae); some as a separate lineage (red algae); some with the stramenopiles (golden-brown and yellow-green algae, brown algae, and diatoms); some with the alveolates (dinoflagellates); and still others with some protozoa (euglenoids). Two of these groups, the alveolates and stramenopiles, have been created recently as a result of rRNA comparisons and ultrastructural studies. The alveolates have mitochondria with tubular cristae and subsurface alveoli or sacs that abut the surface. Dinoflagellates, ciliate protozoa, and the apicomplexan protozoa are alveolates (Phylogenetic Diagram 26). The stramenopiles have mitochondria with tubular cristae and hollow hairs that give rise to a small number of fine hairs (tripartite tubular hairs). These hairs are usually on their flagella. Photosynthetic forms often have chlorophylls a and c. Some common stramenopiles are the opalinid protozoa, oomycetes, diatoms, brown algae or phaeophytes, chrysophytes, and xanthophytes. Although a few groups such as the diatoms have lost their hairs, they are still considered stramenopiles based on the rRNA data, mitochondrial characteristics, and other properties.

26.3 Ultrastructure of the Algal Cell

The eucaryotic algal cell (**figure 26.1**) is surrounded by a thin, rigid cell wall. Some algae have an outer matrix lying outside the cell wall. This usually is flexible and gelatinous, similar to bacterial capsules. When present, the flagella are the locomotor organelles. The nucleus

Table 26.2 Comparative Summary of Some Algal Characteristics

			Pigments			
Division	**Approximate Number of Species**	**Common Name and Representative**	**Chlorophylls**	**Phycobilins (Phycobiliproteins)**	**Carotenoids**	**Thylakoids per Stack in Chloroplast**
Chlorophyta	7,500	Green algae (*Chlamydomonas*)	*a, b*	–	β-carotene, ± α-carotene, xanthophylls	3–6
Charophyta	250	Stoneworts or brittleworts (*Chara*)	*a, b*	–	α-, β-, τ-carotene, xanthophylls	Many
Euglenophyta	700	Euglenoids (*Euglena*)	*a, b*	–	β-carotene, xanthophylls, ± τ-carotene	3
Chrysophyta	6,000	Golden-brown, yellow-green algae; diatoms, (*Cyclotella*)	*a*, c_1/c_2, rarely *d*	–	α-, ß-, ε-carotene, fucoxanthin, xanthophylls	3
Phaeophyta	1,500	Brown algae (*Sargassum*)	*a, c*	–	β-carotene, fucoxanthin, xanthophylls	3
Rhodophyta	3,900	Red algae (*Corallina*)	*a,* rarely *d*	C-phycocyanin, allophycocyanin, phycoerythrin	Xanthophylls (β-carotene, zeaxanthine, ± α-carotene)	1
Pyrrhophyta	1,100	Dinoflagellates (*Gymnodinium*)	*a*, c_1, c_2	–	β-carotene, fucoxanthin, peridinin, dinoxanothin	3

[a] Refers specifically to the vegetative cells. Spores, akinetes, zygotes contain waxes, nonsaponifiable polymers, and phenolic substances.

[b] The following abbreviations are used: fresh water (fw), brackish water (bw), salt water (sw), terrestrial (t).

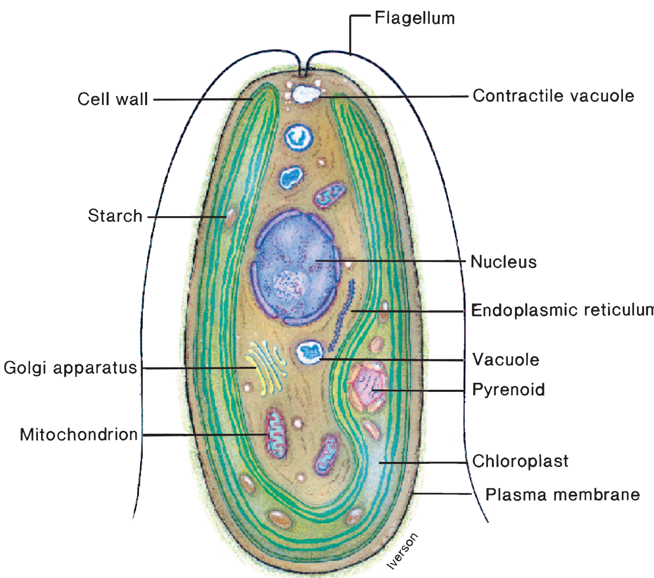


Figure 26.1 Algal Morphology. Schematic drawing of a typical eucaryotic algal cell showing some of its organelles and other structures.

Storage Products	Flagella	Cell Wall[a]	Habitat[b]
Sugars, starch, fructosan	1, 2–8; equal, apical or subapical	Cellulose, mannan, protein, $CaCO_3$	fw, bw, sw, t
Starch	2; subapical	Cellulose, $CaCO_3$	fw, bw
Paramylon, oils, sugars	1–3; slightly apical	Absent	fw, bw, sw, t
Chrysolaminarin, oils	1–2; equal or unequal, apical; or none	Cellulose, silica, $CaCO_3$, chitin, or absent	fw, bw, sw, t
Laminarin, mannitol, oils	2; unequal, lateral	Cellulose, alginic acid, fucoidan	bw, sw
Glycogenlike starch (floridean glycoside)	Absent	Cellulose, xylans, galactans, $CaCO_3$	fw, bw, sw
Starch, glucan, oils	2; 1 trailing, 1 girdling	Cellulose, or absent	fw, bw, sw

has a typical nuclear envelope with pores; within the nucleus are a nucleolus, chromatin, and karyolymph. The chloroplasts have membrane-bound sacs called thylakoids that carry out the light reactions of photosynthesis. These organelles are embedded in the stroma where the dark reactions of carbon dioxide fixation take place. A dense proteinaceous area, the **pyrenoid** that is associated with synthesis and storage of starch may be present in the chloroplasts.

Mitochondrial structure varies greatly in the algae. Some algae (euglenoids) have discoid cristae; some, lamellar cristae (green and red algae); and the remaining, (golden-brown and yellow-green, brown, and diatoms) have tubular cristae.

1. Define the word algae.
2. To what two kingdoms do the algae belong? How do the classical and molecular classification systems differ?
3. What are some general characteristics of an algal cell?

26.4 Algal Nutrition

Algae can be either autotrophic or heterotrophic. Most are photoautotrophic; they require only light and CO_2 as their principal source of energy and carbon. Chemoheterotrophic algae require external organic compounds as carbon and energy sources. Types of microbial nutrition (pp. 97–98); Photosynthesis (pp. 195–99, 207–8)

26.5 Structure of the Algal Thallus (Vegetative Form)

The vegetative body of algae is called the **thallus** [pl., thalli]. It varies from the relative simplicity of a single cell to the more striking complexity of multicellular forms, such as the giant kelps. Single-celled algae may be as small as bacteria, whereas kelp can attain a size over 75 m in length. Algae are unicellular (**figure 26.2*a,b,g***), colonial (figure 26.2*c*), filamentous (figure 26.2*d*), membranous and bladelike (figure 26.2*e*), or tubular (figure 26.2*f*).

26.6 Algal Reproduction

Some unicellular algae reproduce asexually. In this kind of reproduction, gametes do not fuse to form a zygote. There are three basic types of asexual reproduction: fragmentation, spores, and binary fission. In **fragmentation** the thallus breaks up and each fragmented part grows to form a new thallus. **Spores** can be formed in ordinary vegetative cells or in specialized structures termed sporangia [s., sporangium; Greek *spora,* seed, and *angeion,* vessel]. Flagellated motile spores are called **zoospores.** Nonmotile spores produced by sporangia are termed **aplanospores.** In some unicellular algae **binary fission** occurs (nuclear division followed by division of the cytoplasm).

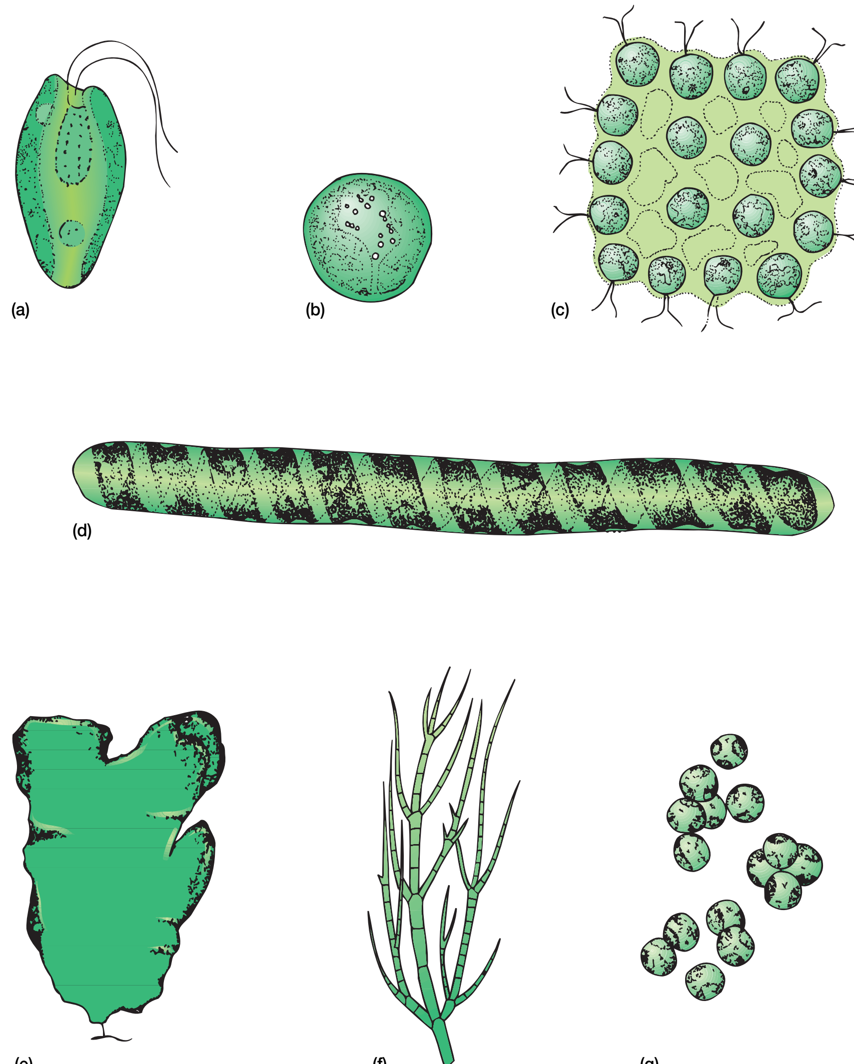

Figure 26.2 Diagrammatic Algal Bodies: (**a**) unicellular, motile, *Cryptomonas;* (**b**) unicellular, nonmotile, *Palmellopsis;* (**c**) colonial, *Gonium;* (**d**) filamentous, *Spirotaenia;* (**e**) bladelike kelp, *Monostroma;* (**f**) leafy tubular axis, branched tufts or plumes, *Stigeoclonium;* (**g**) unicellular, nonmotile, *Chrysocapsa.*

Other algae reproduce sexually. Eggs are formed within relatively unmodified vegetative cells called **oogonia** [s., oogonium] that function as female structures. Sperm are produced in special male reproductive structures called **antheridia** [s., antheridium]. In sexual reproduction these gametes fuse to produce a diploid **zygote.**

1. How can algae be classified based on their mode of nutrition?
2. What are the different types of algal thalli?
3. How do algae reproduce asexually?
4. How do algae reproduce sexually?

26.7 Characteristics of the Algal Divisions

Chlorophyta (Green Algae)

The *Chlorophyta* or green algae [Greek *chloros,* green] are an extremely varied division. They grow in fresh and salt water, in soil, on other organisms, and within other organisms. The *Chlorophyta* have chlorophylls a and b along with specific carotenoids, and they store carbohydrates as starch. Many have cell walls of cellulose. They exhibit a wide diversity of body forms, ranging from unicellular to colonial, filamentous, membranous or sheetlike, and tubular types (**figure 26.3**). Some species have a holdfast structure

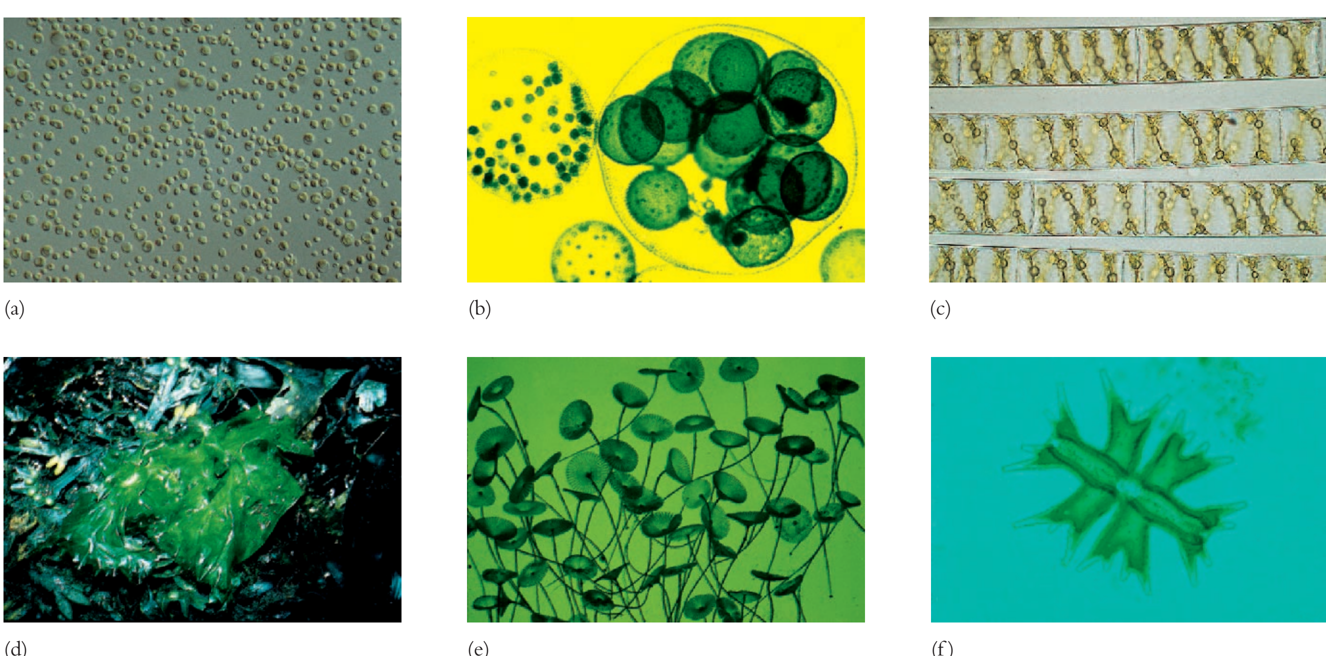

Figure 26.3 ***Chlorophyta* (Green Algae); Light Micrographs.** (**a**) *Chlorella,* a unicellular nonmotile green alga (×160). (**b**) *Volvox,* a typical green algal colony (×450). (**c**) *Spirogyra,* a filamentous green alga (×100). Four filaments are shown. Note the ribbonlike, spiral chloroplasts within each filament. (**d**) *Ulva,* commonly called sea lettuce, has a leafy appearance. (**e**) *Acetabularia,* the mermaid's wine goblet. (**f**) *Micrasterias,* a large desmid (×150).

that anchors them to the substratum. Both asexual and sexual reproduction occur in green algae. In molecular classification schemes, green algae are associated with the land plants and have mitochondria with lamellar cristae (**Phylogenetic Diagram 26**).

Chlamydomonas is a representative unicellular green alga (**figure 26.4**). Individuals have two flagella of equal length at the anterior end by which they move rapidly in water. Each cell has a single haploid nucleus, a large chloroplast, a conspicuous pyrenoid, and a **stigma (eyespot)** that aids the cell in phototactic responses. Two small contractile vacuoles at the base of the flagella function as osmoregulatory organelles that continuously remove water. *Chlamydomonas* reproduces asexually by producing zoospores through cell division. The alga also reproduces sexually when some products of cell division act as gametes and fuse to form a four-flagellated diploid zygote that ultimately loses its flagella and enters a resting phase. Meiosis occurs at the end of this resting phase and produces four haploid cells that give rise to adults.

From organisms like *Chlamydomonas,* several distinct lines of evolutionary specialization have evolved in the green algae. The first line contains nonmotile unicellular green algae, such as *Chlorella. Chlorella* (figure 26.3*a*) is widespread both in fresh and salt water and also in soil. It only reproduces asexually and lacks flagella, eyespots, and contractile vacuoles; the nucleus is very small.

Motile, colonial organisms such as *Volvox* represent a second major line of evolutionary specialization. A *Volvox* colony (figure 26.3*b; see also figure 2.8*b) is a hollow sphere made up of a single layer of 500 to 60,000 individual cells, each containing two flagella and resembling a *Chlamydomonas* cell. The flagella of all the cells beat in a coordinated way to rotate the colony in a clockwise direction as it moves through the water. Only a few cells are reproductive, and these are located at the posterior end of the colony. Some divide asexually and produce new colonies. Others produce gametes. After fertilization, the zygote divides to form a daughter colony. In both cases the daughter colonies stay within the parental colony until it ruptures.

A green alga, *Prototheca moriformis,* causes the disease **protothecosis** in humans and animals. *Prototheca* cells are fairly common in the soil, and it is from this site that most infections occur. Severe systemic infections, such as massive invasion of the bloodstream, have been reported in animals. More common in humans is the subcutaneous type of infection. It starts as a small lesion and spreads slowly through the lymph glands, covering large areas of the body.

1. What body forms do the green algae exhibit?
2. How do green algae reproduce?
3. Describe the structure of *Chlamydomonas, Chlorella,* and *Volvox.*
4. Why is the green alga, *Prototheca,* medically important?

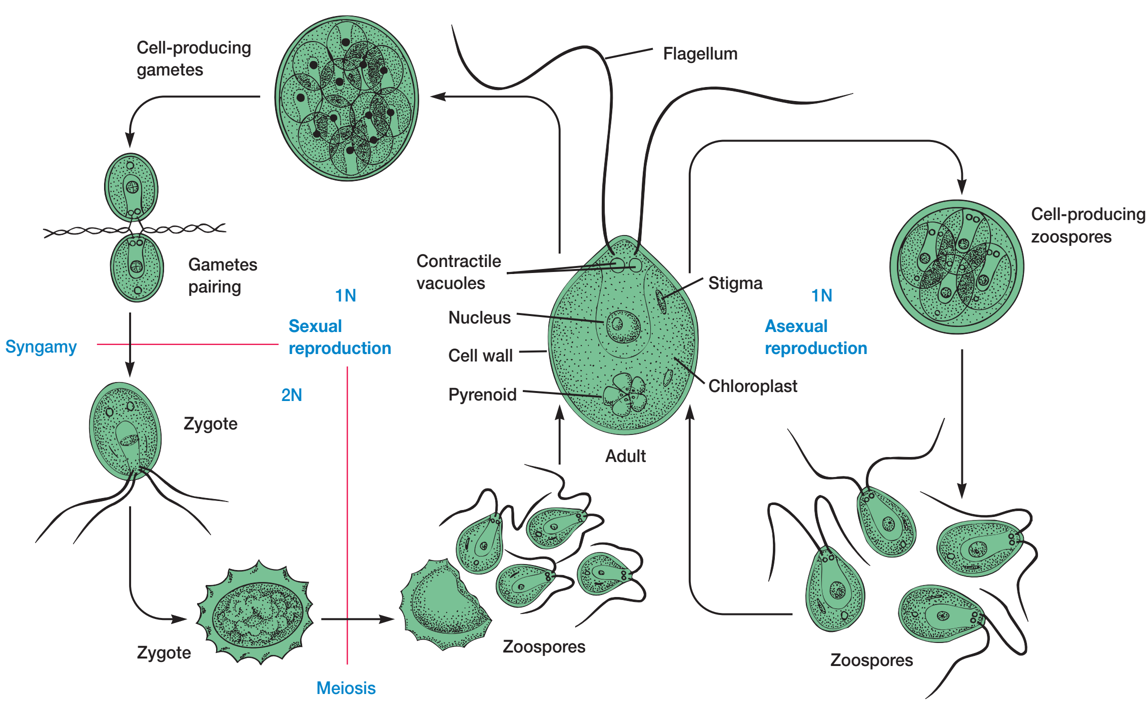

Figure 26.4 ***Chlamydomonas:* The Structure and Life Cycle of This Motile Green Alga.** During asexual reproduction, all structures are haploid; during sexual reproduction, only the zygote is diploid.

Charophyta (Stoneworts/Brittleworts)

The **stoneworts** are abundant in fresh to brackish waters and have a worldwide distribution. Often they appear as a dense covering on the bottom of shallow ponds. Some species precipitate calcium and magnesium carbonate from the water to form a limestone covering, thus giving the *Charophyta* their common names of stoneworts or brittleworts.

Euglenophyta (Euglenoids)

The **euglenoids** share with the *Chlorophyta* and *Charophyta* the presence of chlorophylls *a* and *b* in their chloroplasts. The primary storage product is paramylon (a polysaccharide composed of β-1,3 linked glucose molecules), which is unique to euglenoids. They occur in fresh, brackish, and marine waters and on moist soils; they often form water blooms in ponds and cattle water tanks. In molecular classification schemes, euglenoids are associated with the amoeboflagellates (flagellated protozoa) and kinetoplastids because all members have related rRNA sequences and mitochondria with discoid cristae at some stage in their life cycle (Phylogenetic Diagram 26).

The representative genus is *Euglena.* A typical *Euglena* cell (**figure 26.5**) is elongated and bounded by a plasma membrane. Inside the plasma membrane is a structure called the **pellicle,** which is composed of articulated proteinaceous strips lying side by side. The pellicle is elastic enough to enable turning and flexing of the cell, yet rigid enough to prevent excessive alterations in shape. The several chloroplasts contain chlorophylls a and b together with carotenoids. The large nucleus contains a prominent nucleolus. The stigma is located near an anterior reservoir. A large contractile vacuole near the reservoir continuously collects water from the cell and empties it into the reservoir, thus regulating the osmotic pressure within the organism. Two flagella arise from the base of the reservoir, although only one emerges from

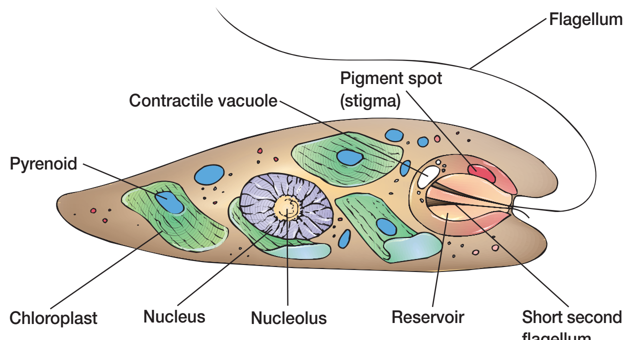

Figure 26.5 ***Euglena.* A Diagram Illustrating the Principal Structures Found in This Euglenoid.** Notice that a short second flagellum does not emerge from the anterior invagination. In some euglenoids both flagella are emergent.

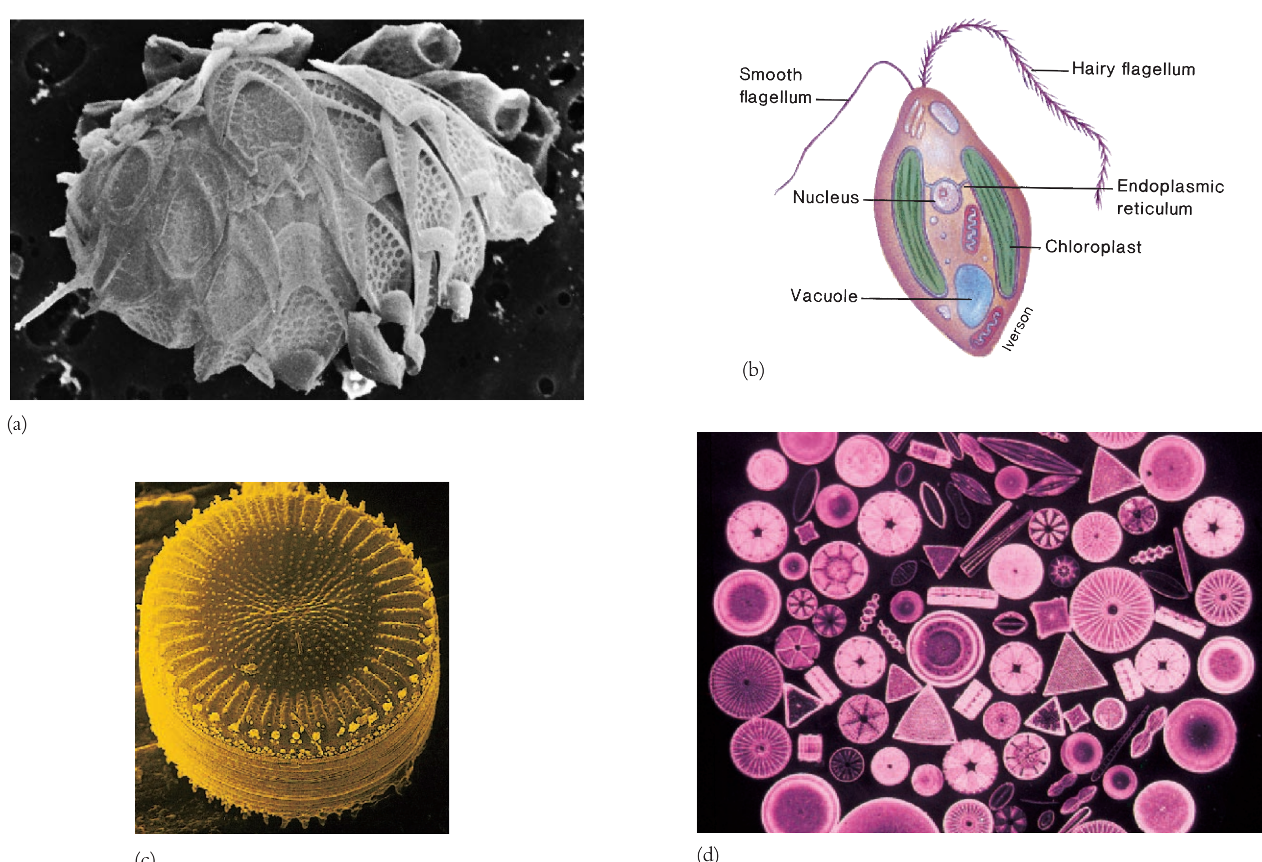

Figure 26.6 ***Chrysophyta*** **(Yellow-Green and Golden-Brown Algae; Diatoms).** (**a**) Scanning electron micrograph of *Mallomonas,* a chrysophyte, showing its silica scales. The scales are embedded in the pectin wall but synthesized within the Golgi apparatus and transported to the cell surface in vesicles (×9,000). (**b**) *Ochromonas,* a unicellular chrysophyte. the canal and actively beats to move the cell. Reproduction in euglenoids is by longitudinal mitotic cell division.

Chrysophyta (Golden-Brown and Yellow-Green Algae; Diatoms)

The division *Chrysophyta* is quite diversified with respect to pigment composition, cell wall, and type of flagellated cells. In molecular classification schemes, these algae are associated with the stramenopiles and have mitochondria with tubular cristae (Phylogenetic Diagram 26). The division is divided into three major classes: golden-brown algae [Greek *chrysos,* gold], yellow-green algae, and diatoms. The major photosynthetic pigments are usually chlorophylls *a* and c_1/c_2, and the carotenoid fucoxanthin. When fucoxanthin is the dominant pigment, the cells have a golden-brown color. The major carbohydrate reserve in the *Chrysophyta* is **chrysolaminarin** (a polysaccharide storage product composed principally of β-1,3 linked glucose residues).

Some *Chrysophyta* lack cell walls; others have intricately patterned coverings external to the plasma membrane, such as **scales (figure 26.6*a*),** walls, and plates. Diatoms have a distinctive two-piece wall of silica, called a **frustule.** Two anteriorly attached flagella of unequal length are common among *Chrysophyta* (figure 26.6*b*), but some species have no flagella, and others have either one flagellum or two that are of equal length.

Most *Chrysophyta* are unicellular or colonial. Reproduction usually is asexual but occasionally sexual. Although some marine forms are known, most of the yellow-green and golden-brown algae live in fresh water. Blooms of some species produce unpleasant odors and tastes in drinking water.

The **diatoms** (figure 26.6*c,d; see also figure 4.1*b) are photosynthetic, circular or oblong chrysophyte cells with frustules composed of two halves or thecae that overlap like a petri dish [therefore their name is from the Greek *diatomsos,* cut in two]. The larger half is the **epitheca,** and the smaller half is the **hypotheca.** Diatoms grow in freshwater, salt water, and moist soil and comprise a large

Box 26.1

Practical Importance of Diatoms

Diatoms have both direct and indirect economic significance for humans. Because diatoms make up most of the phytoplankton of the cooler parts of the ocean, they are the most important ultimate source of food for fish and other marine animals in these regions. It is not unusual for 1 liter of seawater to contain almost a million diatoms.

When diatoms die, their frustules sink to the bottom. Because the siliceous part of the frustule is not affected by the death of the cell, diatom frustules tend to accumulate at the bottom of aquatic environments. These form deposits of material called **diatomaceous earth.** This material is used as an active ingredient in many commercial preparations, including detergents, fine abrasive polishes, paint removers, decolorizing and deodorizing oils, and fertilizers. Diatomaceous earth also is used extensively as a filtering agent, as a component in insulating (firebrick) and soundproofing products, and as an additive to paint to increase the night visibility of signs and license plates.

The use of diatoms as indicators of water quality and of pollution tolerance is becoming increasingly important. Specific tolerances for given species to various environmental parameters (concentrations of salts, pH, nutrients, nitrogen, temperature) have been compiled.

Recently a diatomaceous earth product to control insects, called INSECTO, has been introduced. Insects have their soft body parts exposed but covered by a waxy film to prevent dehydration. When they contact the diatoms in INSECTO, the silica frustules break the waxy film on the insects, causing them to dehydrate and die. INSECTO is a physical control product to which insects cannot build up resistance. Yet this product can be fed to poultry, livestock, and pets with no ill effects.

part of the phytoplankton (**Box 26.1**). The chloroplasts of these chrysophytes contain chlorophylls *a* and *c* as well as carotenoids. Some diatoms are facultative heterotrophs and can absorb carbon-containing molecules through the holes in their walls. The vegetative cells of diatoms are diploid; exist as unicellular, colonial, or filamentous shapes; lack flagella; and have a single large nucleus and smaller plastids. Reproduction consists of the organism dividing asexually, with each half then constructing a new theca within the old one. Because of this mode of reproduction, diatoms get smaller with each reproductive cycle. However, when they diminish to about 30% of their original size, sexual reproduction usually occurs. The diploid vegetative cells undergo meiosis to form gametes, which then fuse to produce a zygote. The zygote develops into an auxospore, which increases in size again and forms a new wall. The mature auxospore eventually divides mitotically to produce vegetative cells with normal frustules.

Diatom frustules are composed of crystallized silica [$Si(OH)_4$] with very fine markings (figure 26.6*c,d*). They have distinctive, and often exceptionally beautiful, patterns that are different for each species. Frustule morphology is very useful in diatom identification.

1. Why are the *Charophyta* called stoneworts?
2. Briefly describe the major characteristics of the euglenoids, *Chrysophyta,* and diatoms.
3. How do euglenoids and diatoms reproduce?
4. How do the cells of diatoms differ from those of other organisms?

Phaeophyta (Brown Algae)

The *Phaeophyta* or brown algae [Greek *phaeo,* brown] consist of multicellular organisms that occur almost exclusively in the sea. Some species have the largest linear dimensions (length) known in the eucaryotic world (chapter opening figure). Since the brown algae have tubular cristae, they are associated with stramenopiles in molecular classification schemes (Phylogenetic Diagram 26). Most of the conspicuous seaweeds that are brown to olive green in color are assigned to this division. The simplest brown algae consist of small openly branched filaments; the larger, more advanced species have a complex arrangement. Some large **kelps** are conspicuously differentiated into flattened blades, stalks, and holdfast organs that anchor them to rocks (**figure 26.7**). Some, such as *Sargassum,* form huge floating masses that dominate the Sargasso Sea. The color of these algae reflects the presence of the brown pigment fucoxanthin, in addition to chlorophylls *a* and *c,* β-carotene, and violaxanthin. The main storage product is **laminarin,** which is quite similar in structure to chrysolaminarin.

Rhodophyta (Red Algae)

The division Rhodophyta, the red algae [Greek *rhodon,* rose], includes most of the seaweeds (**figure 26.8**). A few reds are unicellular but most are filamentous and multicellular. Some red algae are up to 1 m long. The stored food is the carbohydrate called floridean starch (composed of α-1,4 and α-1,6 linked glucose residues).

The red algae contain the red pigment phycoerythrin, one of the two types of phycobilins that they possess. The other accessory pigment is the blue pigment phycocyanin. The presence of these pigments explains how the red algae can live at depths of 100 m or more. The wavelengths of light (green, violet, and blue) that penetrate these depths are not absorbed by chlorophyll *a* but instead by these phycobilins. Not surprisingly the concentrations of these pigments often increases with depth as light intensity decreases. The phycobilins, after absorbing the light energy, pass it on to chlorophyll *a.* The algae appear decidedly red when phycoerythrin predominates over the other pigments. When phycoerythrin un-

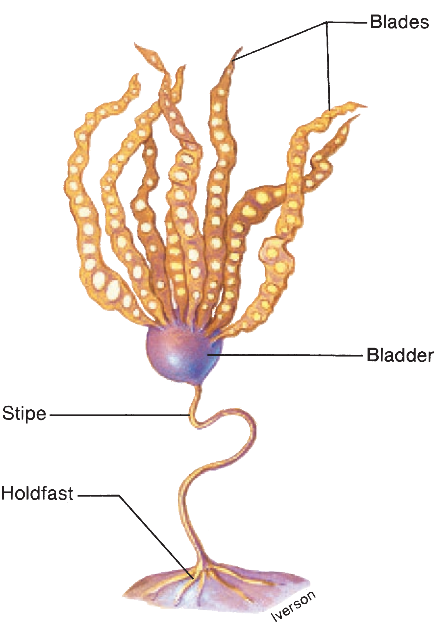

Figure 26.7 ***Phaeophyta* (Brown Algae).** Diagram of the parts of the brown alga, *Nereocystis.* Due to the holdfast organ, the heaviest tidal action and surf seldom dislodge brown algae from their substratum. The stipe is a stalk that varies in length; the bladder is a gas-filled float.

Figure 26.8 ***Rhodophyta* (Red Algae).** These algae (e.g., *Corallina gracilis*) are much smaller and more delicate than the brown algae. Most red algae have a filamentous, branched morphology as seen here.

dergoes photodestruction in bright light, other pigments predominate and the algae take on shades of blue, brown, and dark green.

The cell walls of most red algae include a rigid inner part composed of microfibrils and a mucilaginous matrix. The matrix is composed of sulfated polymers of galactose called agar, funori, porphysan, and carrageenan. These four polymers give the red algae their flexible, slippery texture. Agar is used extensively in the laboratory as a culture medium component (*see section 5.7*). Many red algae also deposit calcium carbonate in their cell walls and play an important role in building coral reefs.

Pyrrhophyta (Dinoflagellates)

The *Pyrrhophyta* or **dinoflagellates** are unicellular, photosynthetic alveolate algae (Phylogenetic Diagram 26). Most dinoflagellates are marine, but some live in fresh water. Along with the chrysophytes and diatoms, the dinoflagellates make up a large part of freshwater and marine plankton and are at the base of many food chains. Species of *Noctiluca, Pyrodinium, Gonyaulax,* and other genera can produce light and are responsible for much of the luminescence (phosphorescence) seen in ocean waters at night. Sometimes dinoflagellate populations reach such high levels that poisonous red tides result (**Box 26.2**).

The flagella, protective coats (plates), and biochemistry of the dinoflagellates are distinctive. Many dinoflagellates are armored or clad in stiff, patterned, cellulose plates or thecae, which may become encrusted with silica (**figure 26.9**). Most have two flagella. In armored dinoflagellates these flagella beat in two grooves that girdle the cell—one transverse (the cingulum), the other longitudinal (the sulcus). The longitudinal flagellum extends posteriorly as a rudder; the flattened, ribbonlike transverse flagellum propels the cell forward while causing it to spin. Due to this spinning, the dinoflagellates received their name from the Greek *dinein,* "to whirl."

Most dinoflagellates have chlorophylls *a* and *c,* in addition to carotenoids and xanthophylls. As a result they usually have a yellowish-green to brown color. Their mitochondria have tubular cristae.

Some dinoflagellates can ingest other cells; others are colorless and heterotrophic. A few even occur as symbionts in many groups of jellyfish, sea anemones, mollusks, and corals. When dinoflagellates form symbiotic relationships, they lose their cellulose plates and flagella, become spherical golden-brown globules in the host cells, and are then termed **zooxanthellae.**

1. What is a seaweed?
2. Describe a kelp.
3. Why do red algae appear red?
4. What is unique about the flagellar arrangement in the dinoflagellates?

Box 26.2

Toxic Algal Blooms

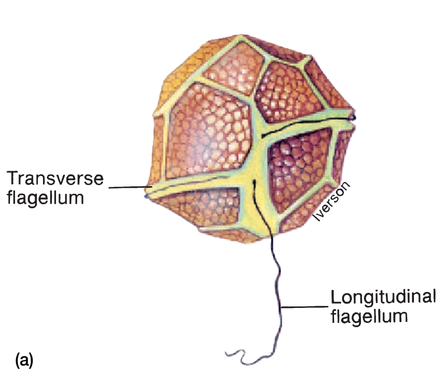
The Bible reports that the first plague Moses visited on the Egyptians was a blood-red tide that killed fish and fouled water. The Red Sea probably is named after these toxic algal blooms. Thousands of years later we still have problems with this plague.

The poisonous and destructive **red tides** that occur frequently in coastal areas often are associated with population explosions, or "blooms," of dinoflagellates. *Gymnodinium* and *Gonyaulax* species are the dinoflagellates most often involved. The pigments in the dinoflagellate cells are responsible for the red color of the water. Under these bloom conditions, the dinoflagellates produce a powerful neurotoxin called saxitoxin. The toxin paralyzes the striated respiratory muscles in many vertebrates by inhibiting sodium transport, which is essential to the function of their nerve cells. The toxin does not harm the shellfish that feed on the dinoflagellates. However, the shellfish do accumulate the toxin and are themselves highly poisonous to organisms, such as humans, who consume the shellfish, resulting in a condition known as **paralytic shellfish poisoning** or neurotoxic shellfish poisoning. Paralytic shellfish poisoning is characterized by numbness of the mouth, lips, face, and extremities. Duration of the illness ranges from a few hours to a few days and usually is not fatal.

Another type of poisoning in humans is called **ciguatera.** It results from eating marine fishes (e.g., grouper, snapper) that have consumed the dinoflagellate *Gambierdiscus toxicus.* The alga's toxin, called ciguatoxin, accumulates in the flesh of fish. This is one of the most powerful toxins known and remains in the flesh even after it has been cooked. Unfortunately it cannot be detected in the fishes and they are not visibly affected. In humans the toxin may cause gastrointestinal disturbances, profuse diarrhea, central nervous system involvement, and respiratory failure.

In 1988 a red tide that has long plagued the Gulf Coast of Florida spread northward to North Carolina. The dinoflagellates released a neurotoxin called brevetoxin, and this prompted state health authorities to shut down all shellfishing for three months. In 1987, in Prince Edward Island, Canada, several people died and hundreds became sick from eating mussels contaminated with domoic acid. The domoic acid was traced to a bloom of diatoms, golden-brown algae once thought to be innocent of all toxicity. The resulting disease, called **amnesic shellfish poisoning,** produces short-term memory loss in its victims. In 1991 pelicans eating anchovies off the California coast were found to be dying from domoic acid poisoning. Shellfish and crab fisheries from Washington to California were closed for several months, resulting in losses reaching hundreds of millions of dollars. In 1993 saxitoxin was found for the first time in crabs from Alaska. Unfortunately there are no treatments for the above types of poisonings. Supportive measures are the only therapy.

Overall, toxic algal blooms are on the rise. For example, in 1997 *Pfiesteria piscicida* (Latin for "fish killer") and other *Pfiesteria*-like dinoflagellates caused large fish kills along the coast of Maryland and Virginia. Similar fish kills have been occuring along the Atlantic coast at least since the 1980s. The flagellated form of the ambush-predator dinoflagellate swims toward the fish and releases toxins that kill the prey, which it can then feed on (*see p. 647*). No one is certain why these toxic blooms are becoming more frequent, but most phycologists believe that the blooms are caused by the continuous pumping of nutrients such as nitrogen and phosphorus into coastal waters. Sewage and agricultural runoff are probably the major sources. Another possibility is world trade: oceangoing ships are unintentionally trafficking in harmful algae, giving the algae a free ride to foreign ports and new habitats in which they can flourish. With people eating more seafood, this toxic menace in the world's oceans will become increasingly more common in the future.



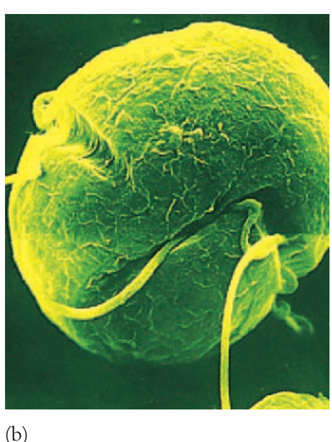


Figure 26.9 Dinoflagellates. (**a**) *Ceratium.* (**b**) Scanning electron micrograph of *Gymnodinium* (×4,000). Notice the plates of cellulose and the two flagella: one in the transverse groove and the other projecting outward.

Summary

1. Phycology (or algology) is the study of algae. Algae are eucaryotes that lack a well-developed vascular system and complex reproductive structures, but have chlorophyll and other pigments for carrying out oxygen-producing photosynthesis (or are closely related to photosynthetic species).
2. Algae are found in almost every environmental niche—in fresh, marine, and brackish water; in certain terrestrial environments; and on moist inanimate objects. They may be endosymbionts, parasites, or components of lichens, and make up a large part of the phytoplankton on the earth.
3. Classical algal classification is based primarily on cellular properties (**table 26.1**). Examples include cell wall structure and chemistry, nutrient storage forms, types of chlorophyll molecules and accessory pigments, flagella, morphology of the thallus, habitat, reproductive structures, and life history patterns (**table 26.2**). Molecular classification systems have shown the algae to be polyphyletic.
4. The vegetative structure of the algae varies from the relative simplicity of a single cell (**figure 26.1**) to the more striking complexity of organisms such as the giant kelps. Algae can be unicellular, colonial, filamentous, membranous, or tubular (**figure 26.2**).
5. Both sexual and asexual reproduction occur in the algae. Asexual reproduction includes fragmentation, the production of spores, and binary fission. In sexual reproduction gametes fuse to form a zygote.
6. Green algae (*Chlorophyta*) are a highly diverse group of organisms abundant in the sea, fresh water, and damp terrestrial habitats (**figure 26.3**).
7. Stoneworts/brittleworts (*Charophyta*) have more complex structures than the green algae. They contain whorls of short branches that arise regularly at their nodes. Their gametangia are complex and multicellular. Stoneworts are abundant in fresh to brackish water and are common as fossils.
8. Euglenoids (*Euglenophyta*) have chloroplasts that are biochemically similar to those of the green algae. They have a flexible proteinaceous pellicle inside the plasma membrane (**figure 26.5**).
9. The *Chrysophyta* contain golden-brown algae, yellow-green algae, and diatoms, and vary greatly in pigment composition, cell wall structure, and type of flagellated cells (**figure 26.6**).
10. Brown algae (*Phaeophyta*) are multicellular marine algae, some of which reach lengths of 75 m. The kelps—the largest of the brown algae—contribute greatly to the productivity of the sea as well as to many human needs (**figure 26.7**).
11. Red algae (*Rhodophyta*) have chlorophyll a and phycobilins and usually grow at great depths. Some produce agar (**figure 26.8**).
12. Dinoflagellates (*Pyrrhophyta*) are unicellular motile algae that play a role in the red tides that are poisonous to many forms of life (**figure 26.9**).

Questions for Thought and Review

1. How can algae be distinguished from the photosynthetic bacteria?
2. What characteristics are used in algal classification?
3. Although multicellularity must have originated many times in the different multicellular groups, how do present-day green algae provide an especially clear example of the probable origin of multicellularity?
4. What characteristics do euglenoids share with higher plants? With animals? Why are they considered protists?
5. Why do marine algae vary so much more in shape and size than those found in fresh water?
6. The phytoplankton of the open oceans (e.g., the Sargasso Sea) are predominantly algae, and these cells form the base of oceanic food chains. Which morphological characteristics of algae are adaptations to a floating (planktonic) habitat?
7. Freshwater algae are distributed worldwide. They rapidly colonize artificial lakes and water impoundments. How do algae accomplish such widespread dispersal?
8. What problem do diatoms have with continued asexual reproduction? How is this problem solved?
9. How are the red algae similar to the cyanobacteria?
10. What are some important characteristics of the green algae? The red algae? The brown algae? The dinoflagellates?
11. Describe the distinguishing characteristics of each major algal group discussed in this chapter.

Critical Thinking Questions

1. Why do algae have so many different types of pigments for photosynthesis? Do these pigments serve other purposes?
2. Why don't we know as much about the basic biology of algae as we do about the biology of fungi, viruses, and bacteria?

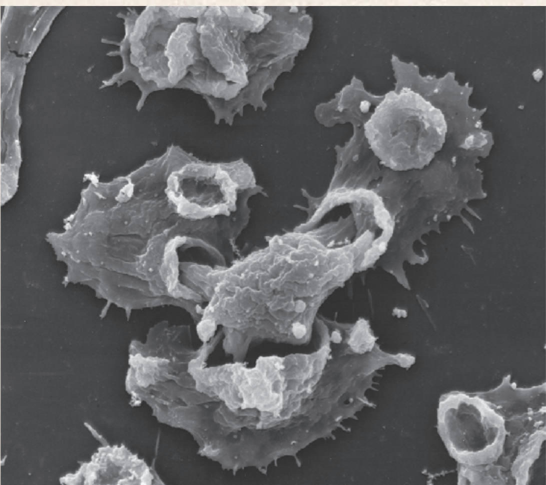
CHAPTER 27

The Protozoa



This is a scanning electron micrograph (×2,160) of the protozoan *Naegleria fowleri.* Three *N. fowleri* from an axenic culture, attacking and beginning to devour or engulf a fourth, presumably dead amoeba, with their amoebastomes (suckerlike structures that function in phagocytosis). This amoeba is the major cause of the disease in humans called primary amebic meningoencephalitis.

Concepts

1. Protozoa are protists exhibiting heterotrophic nutrition and various types of locomotion. They occupy a vast array of habitats and niches and have organelles similar to those found in other eucaryotic cells, and also specialized organelles.
2. Current protozoan taxonomy divides the protozoa into seven phyla: *Sarcomastigophora, Labyrinthomorpha, Apicomplexa, Microspora, Ascetospora, Myxozoa,* and *Ciliophora.* These phyla represent four major groups: flagellates, amoebae, ciliates, and sporozoa. In molecular classification schemes, the protozoa are polyphyletic eucaryotes.
3. Protozoa usually reproduce asexually by binary fission. Some have sexual cycles, involving meiosis and the fusion of gametes or gametic nuclei resulting in a diploid zygote. The zygote is often a thick-walled, resistant, and resting cell called a cyst. Some protozoa undergo conjugation in which nuclei are exchanged between cells.
4. All protozoa have one or more nuclei; some have a macro- and micronucleus.
5. Various protozoa feed by holophytic, holozoic, or saprozoic means; some are predatory or parasitic.

And a pleasant sight they are indeed. Their shapes range from teardrops to bells, barrels, cups, cornucopias, stars, snowflakes, and radiating suns, to the common amoebas, which have no real shape at all. Some live in baskets that look as if they were fashioned of exquisitely carved ivory filigree. Others use colored bits of silica to make themselves bright mosaic domes. Some even form graceful transparent containers shaped like vases or wine glasses of fine crystal in which they make their homes.

—*Helena Curtis*

Chapter 27 presents the major biological features of the protists known as protozoa. The most important groups are the flagellates, amoebae, sporozoa, and ciliates. The protists demonstrate the great adaptive potential of the basic single eucaryotic cell, as evidenced by their many nonrelated polyphyletic origins (**Phylogenetic Diagram 27**).

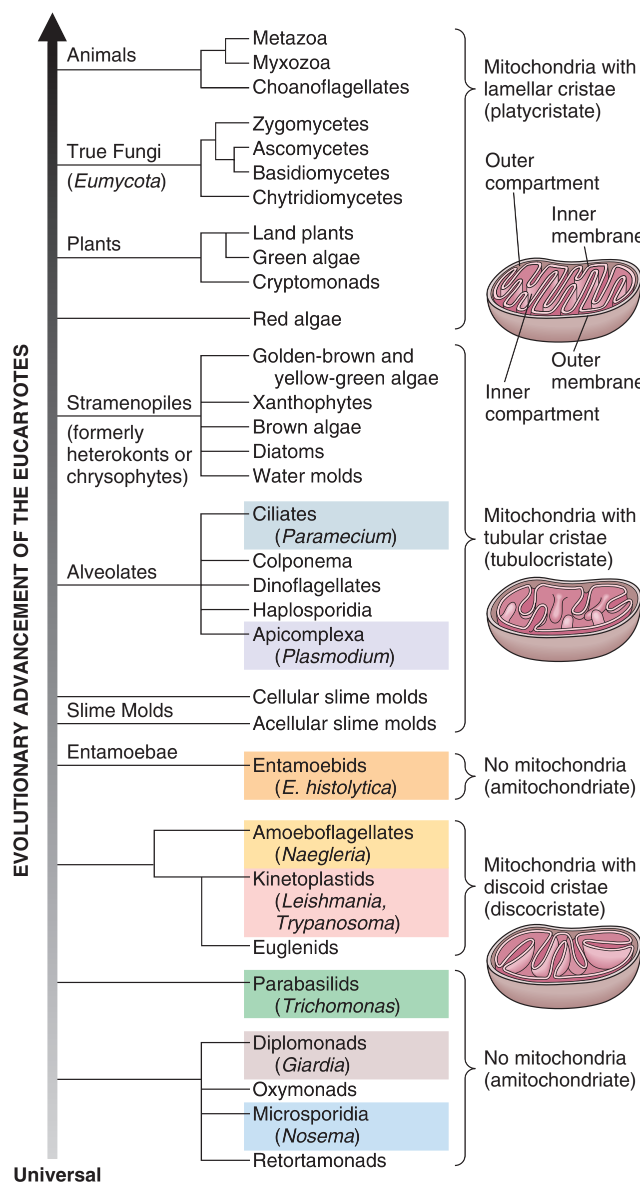
The microorganisms called **protozoa** [s., protozoan; Greek *protos,* first, and *zoon,* animal] are studied in the discipline called **protozoology.** A protozoan can be defined as a usually motile eucaryotic unicellular protist. Protozoa are directly related only on the basis of a single negative characteristic—they are not multicellular. All, however, demonstrate the basic body plan of a single protistan eucaryotic cell.

27.1 Distribution

Protozoa grow in a wide variety of moist habitats. Moisture is absolutely necessary for the existence of protozoa because they are susceptible to desiccation. Most protozoa are free living and inhabit freshwater or marine environments. Many terrestrial protozoa can be found in decaying organic matter, in soil, and even in beach sand; some are parasitic in plants or animals.

27.2 Importance

Protozoa play a significant role in the economy of nature. For example, they make up a large part of **plankton**—small, free-floating organisms that are an important link in the many aquatic food chains and food webs of aquatic environments. A **food chain** is a series of organisms, each feeding on the preceding one. A **food web** is a complex interlocking series of food chains. Protozoa are also useful in biochemical and molecular biological studies. Many biochemical pathways used by protozoa are present in all eucaryotic cells. Finally, some of the most important diseases of humans (*see section 40.2*) and animals (**table 27.1**) are caused by protozoa. Microorganisms and ecosystems (pp. 622–23)



Phylogenetic Diagram 27 Tentative Phylogeny of the Protozoan-Like Eucaryotes Based on 18S rRNA Sequence Comparisons. Recent molecular phylogeny of the nuclear SSU rRNA indicates that these eucaryotes are highly polyphyletic (protozoan groups are highlighted by different colors). Thus, like the algae, the protozoa do not represent a monophyletic group and the taxon "Protozoa" should not be used in classification schemes that seek to represent true molecular evolutionary histories. The word protozoa can still be used (as it is in this chapter) to denote a nonrelated polyphyletic group of eucaryotic organisms that share some morphological, reproductive, ecological, and biochemical characteristics.

Table 27.1 Pathogenic Protozoa That Cause Major Diseases of Domestic Animals

Protozoan Group[a]	Genus	Host	Preferred Site of Infection	Disease
Amoebae	*Entamoeba*	Mammals	Intestine	Amebiasis
	Iodamoeba	Swine	Intestine	Enteritis
Sporozoa	*Babesia*	Cattle	Blood cells	Babesiosis
	Theileria	Cattle, sheep, goats	Blood cells	Theileriasis
	Sarcocystis	Mammals, birds	Muscles	Sarcosporidiosis
	Toxoplasma	Cats	Intestine	Toxoplasmosis
	Isospora	Dogs	Intestine	Coccidiosis
	Eimeria	Cattle, cats, chickens, swine	Intestine	Coccidiosis
	Plasmodium	Many animals	Bloodstream, liver	Malaria
	Leucocytozoon	Birds	Spleen, lungs, blood	Leucocytozoonosis
	Cryptosporidium	Mammals	Intestine	Cryptosporidiosis
Ciliates	*Balantidium*	Swine	Large intestine	Balantidiasis
Flagellates	*Leishmania*	Dogs, cats, horses, sheep, cattle	Spleen, bone marrow, mucous membranes	Leishmaniasis
	Trypanosoma	Most animals	Blood	Trypanosomiasis
	Trichomonas	Horses, cattle	Genital tract	Trichomoniasis (abortion)
	Histomonas	Birds	Intestine	Blackhead disease
	Giardia	Mammals	Intestine	Giardiasis

[a]These groups are distinguished from one another largely by their mechanism of locomotion (see text).

27.3 Morphology

Because protozoa are eucaryotic cells, in many respects their morphology and physiology are the same as the cells of multicellular animals (*see figures 4.2 and 4.3*). However, because all of life's various functions must be performed within the individual protozoan, some morphological and physiological features are unique to protozoan cells. In some species the cytoplasm immediately under the plasma membrane is semisolid or gelatinous, giving some rigidity to the cell body. It is termed the **ectoplasm.** The bases of the flagella or cilia and their associated fibrillar structures are embedded in the ectoplasm. The plasma membrane and structures immediately beneath it are called the **pellicle.** Inside the ectoplasm is the area referred to as the **endoplasm,** which is more fluid and granular in composition and contains most of the organelles. Some protozoa have one nucleus, others have two or more identical nuclei. Still other protozoa have two distinct types of nuclei—a macronucleus and one or more micronuclei. The **macronucleus,** when present, is typically larger and associated with trophic activities and regeneration processes. **The micronucleus** is diploid and involved in both genetic recombination during reproduction and the regeneration of the macronucleus.

One or more vacuoles are usually present in the cytoplasm of protozoa. These are differentiated into contractile, secretory, and food vacuoles. **Contractile vacuoles** function as osmoregulatory organelles in those protozoa that live in a hypotonic environment, such as a freshwater lake. Osmotic balance is maintained by continuous water expulsion. Most marine protozoa and parasitic species are isotonic to their environment and lack such vacuoles. **Phagocytic vacuoles** are conspicuous in holozoic and parasitic species and are the sites of food digestion (*see figure 4.10*). **Secretory vacuoles** usually contain specific enzymes that perform various functions (such as excystation).

Most anaerobic protozoa (such as *Trichonympha,* which lives in the gut of termites; *see figure 28.26*) have no mitochondria, no cytochromes, and an incomplete tricarboxylic acid cycle. However, some do have small, membrane-delimited organelles termed **hydrogenosomes.** These structures contain a unique electron transfer pathway in which hydrogenase transfers electrons to protons (which act as the terminal electron acceptors), and molecular hydrogen is formed. Other protozoa have mitochondria with discoid cristae (trypanosomes), tubular mitochondrial cristae (ciliates, sporozoa), and lamellar cristae (foraminiferans).

1. Describe a typical protozoan.
2. What roles do protozoa play in the trophic structure of their communities and in the organisms with which they associate?
3. What is unique about the nuclei of some protozoa?
4. Where can protozoa be found?
5. What are the functions of contractile, phagocytic, and secretory vacuoles?

27.4 Nutrition

Most protozoa are chemoheterotrophic. Two types of heterotrophic nutrition are found in the protozoa: holozoic and saprozoic. In **holozoic nutrition,** solid nutrients such as bacteria are acquired by phagocytosis and the subsequent formation of phagocytic vacuoles. Some ciliates have a specialized structure for phagocytosis called the **cytostome** (cell mouth). In **saprozoic nutrition,** soluble nutrients such as amino acids and sugars cross the plasma membrane by pinocytosis, diffusion, or carrier-mediated transport (facilitated diffusion or active transport).

27.5 Encystment and Excystment

Many protozoa are capable of **encystation.** They develop into a resting stage called a **cyst,** which is a dormant form marked by the presence of a wall and by very low metabolic activity. Cyst formation is particularly common among aquatic, free-living protozoa and parasitic forms. Cysts serve three major functions: (1) they protect against adverse changes in the environment, such as nutrient deficiency, desiccation, adverse pH, and low partial pressure of O_2; (2) they are sites for nuclear reorganization and cell division (reproductive cysts); and (3) they serve as a means of transfer between hosts in parasitic species.

Although the exact stimulus for **excystation** (escape from the cysts) is unknown, excystation generally is triggered by a return to favorable environmental conditions. For example, cysts of parasitic species excyst after ingestion by the host and form the vegetative form called the **trophozoite.**

27.6 Locomotory Organelles

A few protozoa are nonmotile. Most, however, can move by one of three major types of locomotory organelles: pseudopodia, flagella, or cilia. **Pseudopodia** [s., pseudopodium; false feet] are cytoplasmic extensions found in the amoebae that are responsible for the movement and food capture. There are many types of pseudopodia. Flagellates and ciliates move by flagella and cilia. Electron microscopy has shown that protozoan flagella and cilia are structurally the same and identical in function to those of other eucaryotic cells (*see figures 4.22–4.25*).

27.7 Reproduction

Most protozoa reproduce asexually, and some also carry out sexual reproduction. The most common method of asexual reproduction is **binary fission.** During this process the nucleus first undergoes mitosis, then the cytoplasm divides by cytokinesis to form two identical individuals (**figure 27.1**).

Figure 27.1 Protozoan Reproduction. Binary fission in *Paramecium caudatum* (×100).

The most common method of sexual reproduction is **conjugation.** In this process there is an exchange of gametes between paired protozoa of complementary mating types (**conjugants;** *see figure 2.13*b). Conjugation is most prevalent among ciliate protozoa. A well-studied example is *Paramecium caudatum* (**figure 27.2**). At the beginning of conjugation, two ciliates unite, fusing their pellicles at the contact point. The macronucleus in each is degraded. The individual micronuclei divide twice by meiosis to form four haploid pronuclei, three of which disintegrate. The remaining pronucleus divides again mitotically to form two gametic nuclei, a stationary one and a migratory one. The migratory nuclei pass into the respective conjugates. Then the ciliates separate, the gametic nuclei fuse, and the resulting diploid zygote nucleus undergoes three rounds of mitosis. The eight resulting nuclei have different fates: one nucleus is retained as a micronucleus; three others are destroyed; and the four remaining nuclei develop into macronuclei. Each separated conjugant now undergoes cell division. Eventually progeny with one macronucleus and one micronucleus are formed.

1. What specific nutritional types exist among protozoa?
2. What functions do cysts serve for a typical protozoan? What causes excystation to occur?
3. What is a pseudopodium?
4. How do protozoa reproduce asexually?
5. How do protozoa reproduce sexually? Describe the process of ciliate conjugation.

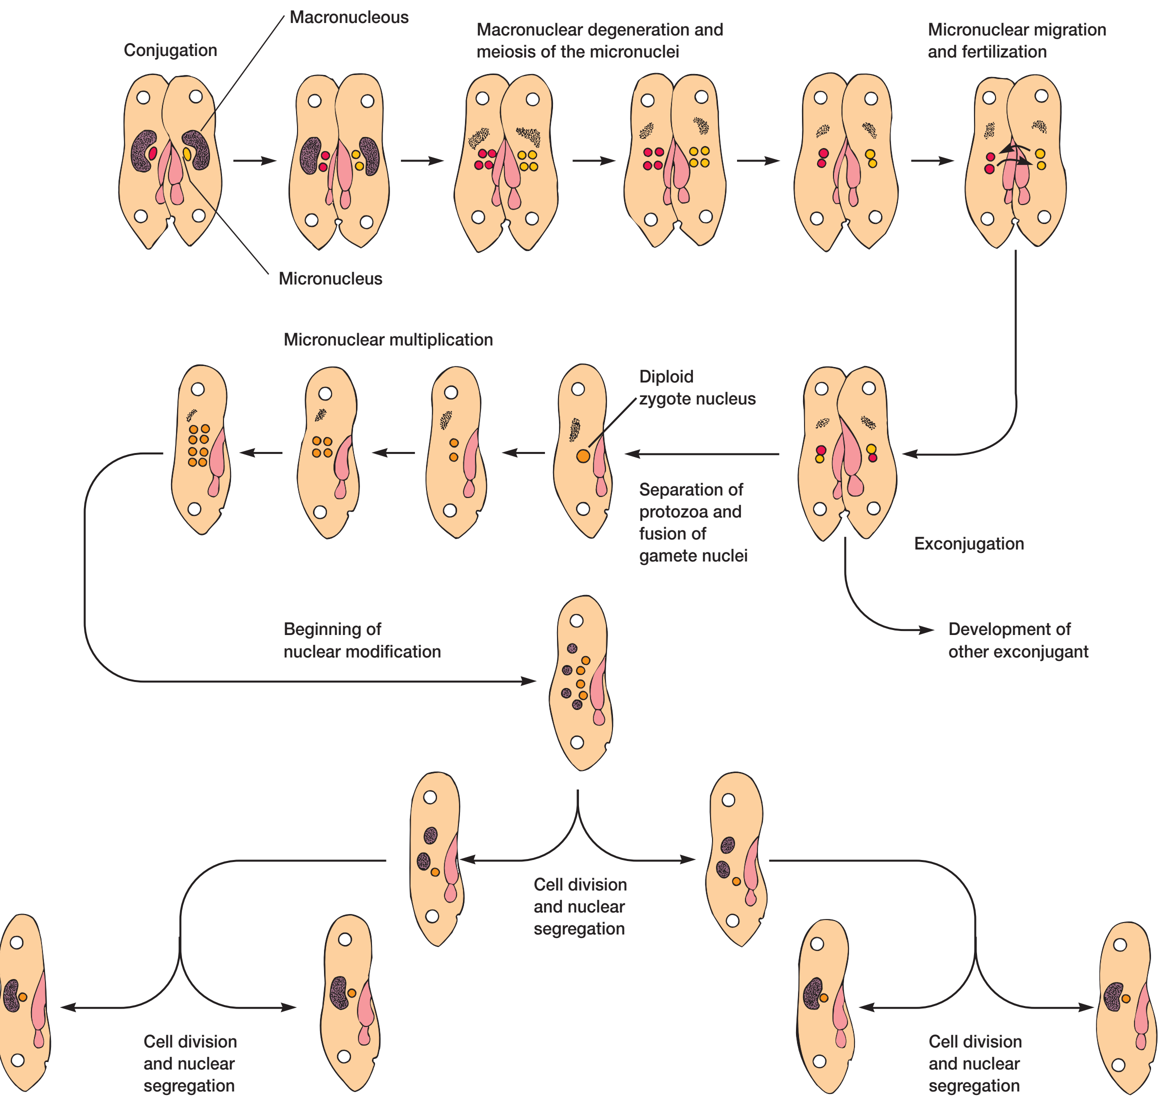


Figure 27.2 Conjugation in *Paramecium caudatum,* Schematic Drawing. Follow the arrows. After the conjugants separate, only one of the exconjugants is followed; however, a total of eight new protozoa result from the conjugation.

27.8 Classification

Many protozoan taxonomists regard the *Protozoa* as a subkingdom, which contains seven of the 14 phyla found within the kingdom *Protista* (**table 27.2**). The phylum *Sarcomastigophora* consists of flagellates and amoebae with a single type of nucleus. The phyla *Labyrinthomorpha, Apicomplexa, Microspora, Ascetospora,* and *Myxozoa* have either saprozoic or parasitic species. The phylum *Ciliophora* has ciliated protozoa with two types of nuclei. The classification of this subkingdom into phyla is based primarily on types of nuclei, mode of reproduction, and mechanism of locomotion.

More recent classifications are quite different. In 1993 T. Cavalier-Smith proposed that the protozoa be elevated to

Table 27.2 Abbreviated Classification of the Subkingdom *Protozoa*[a]

Taxonomic Group	Characteristics	Examples
Phylum: *Sarcomastigophora*	Locomotion by flagella, pseudopodia, or both; when present, sexual reproduction is essentially syngamy (union of gametes external to the parents); single type of nucleus	
Subphylum: *Mastigophora*	One or more flagella; division by longitudinal binary fission; sexual reproduction in some groups	
Class: *Zoomastigophorea*	Chromatophores absent; one to many flagella; amoeboid forms, with or without flagella; sexuality known in some groups; mainly parasitic	*Trypanosoma* *Giardia* *Trichomonas* *Leishmania* *Trichonympha*
Subphylum: *Sarcodina*	Locomotion primarily by pseudopodia; shells (tests) often present; flagella restricted to reproductive stages when present; asexual reproduction by fission; mostly free living	
Superclass: *Rhizopoda*	Locomotion by pseudopodia or by protoplasmic flow with discrete pseudopodia; some contain tests	*Amoeba* *Elphidium* *Coccodiscus*
Phylum: *Labyrinthomorpha*	Spindle-shaped cells capable of producing mucous tracks; trophic stage as ectoplasmic network; nonamoeboid cells; saprozoic and parasitic on algae and seagrass	*Labyrinthula*
Phylum: *Apicomplexa*	All members have a spore-forming stage in their life cycle; contain an apical complex; sexuality by syngamy; all species parasitic; cysts often present; cilia absent; often called the Sporozoa	*Plasmodium* *Toxoplasma* *Eimeria* *Cryptosporidium*
Phylum: *Microspora*	Unicellular spores with spiroplasm containing polar filaments; obligatory intracellular parasites	*Nosema*
Phylum: *Ascetospora*	Spore with one or more spiroplasms; no polar capsules or polar filaments; all parasitic in invertebrates	*Haplosporidium*
Phylum: *Myxozoa*	Spores of multicellular origin; one or more polar capsules; all parasitic, especially in fish	*Myxosoma*
Phylum: *Ciliophora*	Simple cilia or compound ciliary organelles in at least one stage in the life cycle; two types of nuclei; contractile vacuole present; binary fission transverse; sexuality involving conjugation; most species free living, but many commensal, some parasitic	*Didinium* *Stentor* *Vorticella* *Tetrahymena* *Paramecium* *Tokophrya* *Entodinium* *Nyctotherus* *Balantidium* *Ichthyophthirius*

[a]Based on the 1980 Committee on Systematics and Evolution of the Society of Protozoologists.

kingdom status with 18 phyla based on the structure of mitochondrial cristae and other characteristics (*see section 19.7*). The acceptance of this new classification by protozoologists, however, remains to be determined. In recent molecular classification schemes, the protozoa do not exist as a discrete taxon. Protozoan-like eucaryotes are found at all evolutionary levels (Phylogenetic Diagram 27).

27.9 Representative Types

This section describes some representatives of each group of protozoan protists to present an overview of protozoan diversity and to provide a basis for comparing different groups. For simplicity, the standard classification summarized in table 27.2 will be followed.

Phylum *Sarcomastigophora*

Protists that have a single type of nucleus and possess flagella (subphylum *Mastigophora*) or pseudopodia (subphylum *Sarcodina*) are placed in the phylum *Sarcomastigophora.* Both sexual and asexual reproduction are seen in this phylum.

The subphylum *Mastigophora* contains both phytoflagellates, chloroplast-bearing flagellates and close relatives, and **zooflagellates.** Zooflagellates do not have chlorophyll and are either holozoic, saprozoic, or symbiotic. Asexual reproduction occurs by longitudinal binary fission along the major body axis. Sexual reproduction is known for a few species, and encystment is common. Zooflagellates are characterized by the presence of one or more flagella. Most members are uninucleate. One major group, the kinetoplastids, has its mitochondrial DNA in a special region called the **kinetoplast** (**figure 27.3*a*;** *see also figures 2.13*c *and 4.13*).

Some zooflagellates are free living. The choanoflagellates are a distinctive example in that they have one flagellum, are solitary or colonial, and are on stalks. Other zooflagellates form symbiotic relationships. For example, *Trichonympha* species (*see figure 28.26*) are found in the intestine of termites and produce enzymes that the termite needs to digest the wood particles on which it feeds. The protozoan-termite relationship (p. 598)

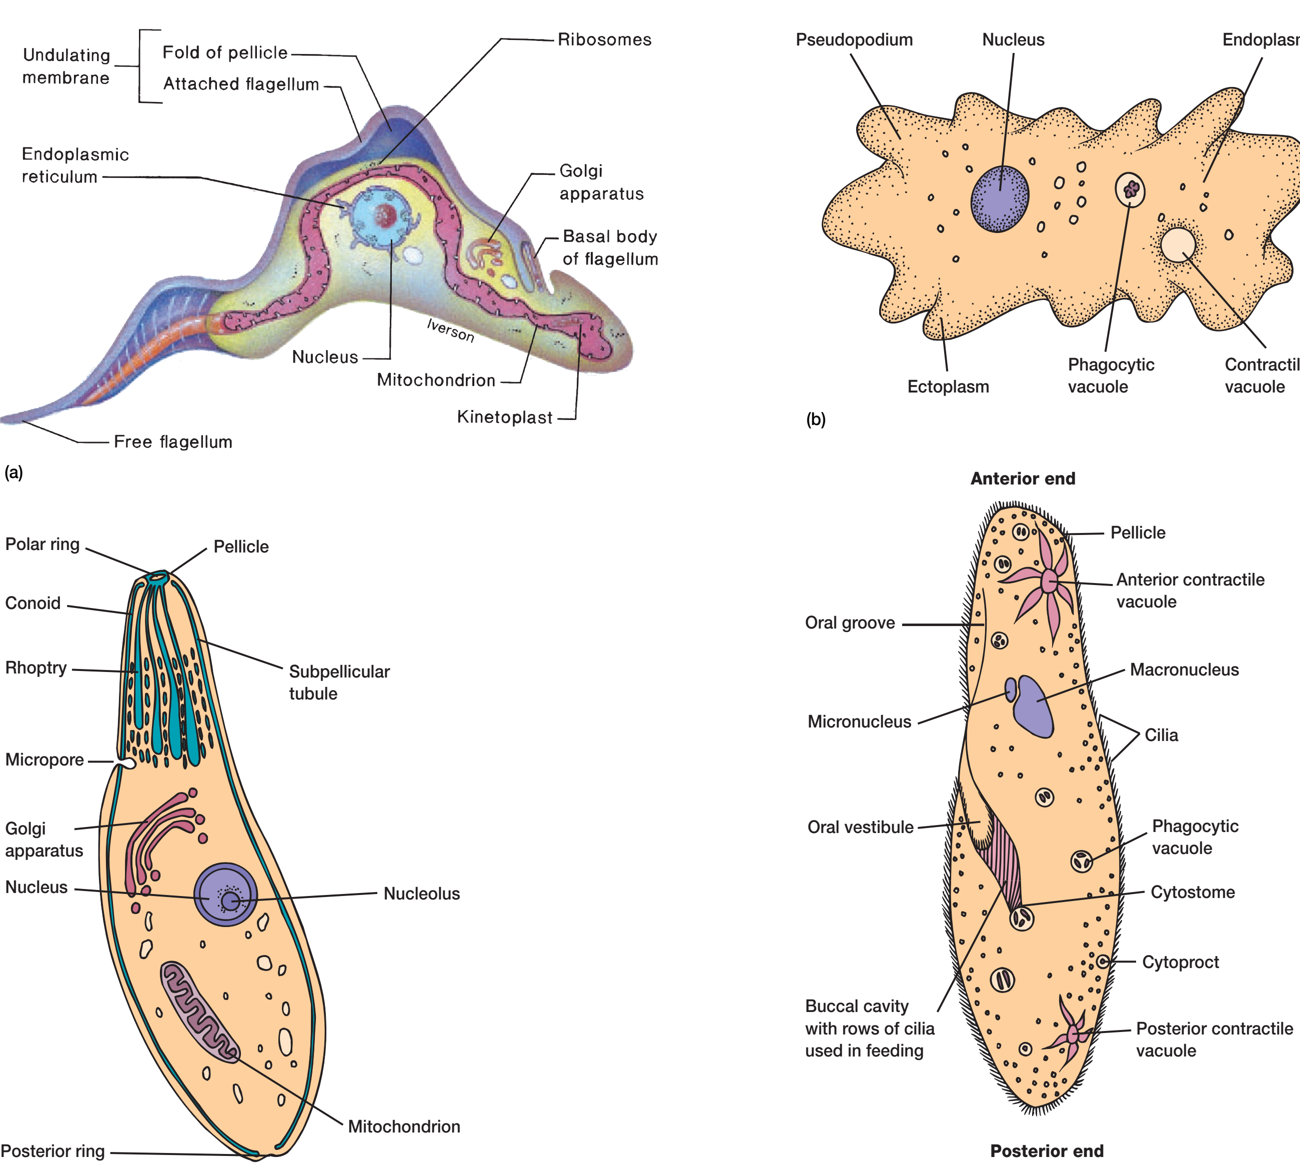

Figure 27.3 Drawings of Some Representative Protozoa. (**a**) Structure of the flagellate, *Trypanosoma brucei rhodesiense.* (**b**) The structure of the amoeboid protist, *Amoeba proteus.* (**c**) Structure of an apicomplexan sporozoite. (**d**) Structure of the ciliate *Paramecium caudatum.*

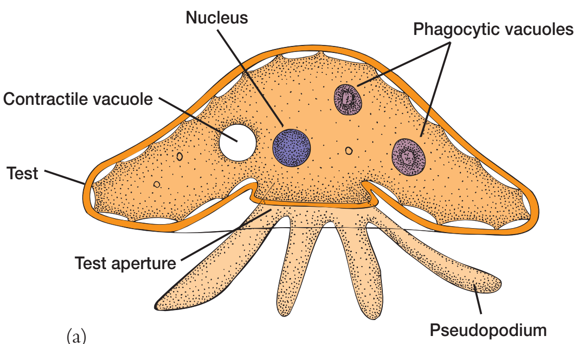
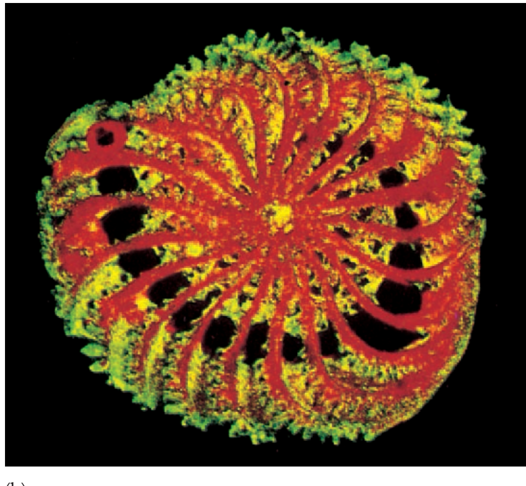
Many zooflagellates are important human parasites. *Giardia lamblia* (*see figure 40.18*) can be found in the human intestine where it may cause severe diarrhea. It is transmitted through water that has been contaminated with feces (*see section 40.2*). Trichomonads, such as *Trichomonas vaginalis,* live in the vagina and urethra of women and in the prostate, seminal vesicles, and urethra of men. They are transmitted primarily by sexual intercourse (*See table 39.4 on page 927 for a summary of all the sexually transmitted diseases covered in this textbook.*) Giardiasis (pp. 953–54). Trichomoniasis (p. 958)

The zooflagellates called **trypanosomes** are important blood pathogens of humans and animals in certain parts of the world. Because they live in the blood, they are also called hemoflagellates. These parasites (figure 27.3*a*) have a typical zooflagellate structure and appear to be the earliest diverging branch of protists with mitochondria and peroxisomes. A major human trypanosomal disease is African sleeping sickness caused by *Trypanosoma brucei rhodesiense* or *T. brucei gambiense* (*see section 40.2*).

The subphylum *Sarcodina* contains the amoeboid protists. They are found throughout the world in both fresh and salt water and



(a)



(b)

(c)

Figure 27.4 Some Free-living Sarcodines. (**a**) An illustration of *Arcella,* showing the test or shell that is made of chitinlike material secreted by the protist. (**b**) The test of the foraminiferan, *Elphidium cristum* (×100). (**c**) A group of siliceous radiolarian shells, light micrograph (×63).

are abundant in the soil. Several species are parasites of mammals. Simple amoebae [s., amoeba] move almost continually using their pseudopodia (**amoeboid movement**). Many have no definite shape, and their internal structures (figure 27.3*b*) occupy no particular position. The single nucleus, contractile and phagocytic vacuoles, and ecto- and endoplasm shift as the amoebae move. Amoebae engulf a variety of materials (small algae, bacteria, other protozoa) through phagocytosis. Some material moves into and out of the plasma membrane by pinocytosis. Reproduction in the amoebae is by simple asexual binary fission. Some amoebae can form cysts.

Many free-living forms are more complex than simple amoebae. *Arcella* manufactures a loose-fitting shell or **test** for protection (**figure 27.4*a***). These amoebae extend their pseudopodia from the test aperture to either feed or creep along. The foraminiferans and radiolarians primarily are marine amoebae, with a few occurring in fresh and brackish water. Most foraminiferans live on the seafloor, whereas radiolarians are usually found in the open sea (**Box 27.1**). Foraminiferan tests and radiolarian skeletons have many unique and beautiful shapes (figure 27.4*b,c*). They range in diameter from about 20 mm to several cm.

Finally, there are many symbiotic amoebae, most of which live in other animals. Two common genera are *Endamoeba* and *Entamoeba. Endamoeba blattae* is common in the intestine of cockroaches, and related species are present in termites. *Entamoeba histolytica* (*see figure 40.17*) is an important parasite of humans, in whom it often produces severe amoebic dysentery, which may be fatal. Free-living amoebae from two genera, *Naegleria* and *Acanthamoeba,* can cause disease in humans and other mammals (chapter opening figure; *see also section 40.2*).

1. What characteristics would be exhibited by a protozoan that belongs to the phylum *Sarcomastigophora?* What two subphyla does it contain?
2. How would you characterize a zooflagellate? An amoeba?
3. What two human diseases are caused by zooflagellates?
4. Where can two different symbiotic amoebae be found?

Phylum *Labyrinthomorpha*

The very small phylum *Labyrinthomorpha* consists of protists that have spindle-shaped or spherical nonamoeboid vegetative cells. In some genera, amoeboid cells move within a network of mucous

Box 27.1

The Importance of Foraminiferans

Of over 40,000 described species of foraminiferans, about 90% are fossil. During the Tertiary period (about 230 million years ago), the foraminiferans contributed massive shell accumulations to geologic formations. They were so abundant that they formed thick deposits, which became uplifted over time and exposed as great beds of limestone in Europe, Asia, and Africa. The White Cliffs of Dover, the famous landmark of southern England, are made up almost entirely of foraminiferan shells. The Egyptian pyramids of Gizeh, near Cairo, are built of foraminiferan limestone. Currently, foraminiferans are important aids to geologists in identifying and correlating rock layers as they search for oil-bearing strata. The calcareous shells of abundant planktonic foraminiferans are today settling and accumulating over much of the ocean floor as thick deposits called "globigerina ooze"—limestone of the distant future.

tracks using a typical gliding motion. Most members are marine and either saprozoic or parasitic on algae. Several years ago *Labyrinthula* killed most of the "eel grass" on the Atlantic coast, depriving ducks of their food and starving many of them.

Phylum *Apicomplexa*

The **apicomplexans,** often collectively called the sporozoans, have a spore-forming stage in their life cycle and lack special locomotory organelles (except in the male gametes, and the zygote or ookinete). They are either intra- or intercellular parasites of animals and are distinguished by a unique arrangement of fibrils, microtubules, vacuoles, and other organelles, collectively called the apical complex, which is located at one end of the cell.

The **apical complex** contains several components (figure 27.3*c*). One or two polar rings are at the apical end. The **conoid** consists of a cone of spirally arranged fibers lying next to the polar rings. Subpellicular microtubules radiate from the polar rings and probably serve as support elements. Two or more **rhoptries** extend to the plasma membrane and secrete their contents at the cell surface. These secretions aid in the penetration of the host cell. One or more micropores are thought to function in the intake of nutrients.

Apicomplexans have complex life cycles in which certain stages occur in one host (the mammal) and other stages in a different host (often a mosquito). The life cycle has both asexual and sexual phases and is characterized by an alternation of haploid and diploid generations. At some point an asexual reproduction process called schizogony occurs. **Schizogony** is a rapid series of mitotic events producing many small infective organisms through the formation of uninuclear buds. Sexual reproduction involves the fertilization of a large female macrogamate by a small, flagellated male gamete. The resulting zygote becomes a thick-walled cyst called an **oocyst.** Within the oocyst, meiotic divisions produce infective haploid spores.

The four most important sporozoan parasites are *Plasmodium* (the causative agent of malaria), *Cryptosporidium* (the causative agent of cryptosporidiosis), *Toxoplasma* (the causative agent of toxoplasmosis), and *Eimeria* (the causative agent of coccidiosis). Malaria (pp. 954–56)

Phylum *Microspora*

The small microsporans (3 to 6 μm) are obligatory intracellular parasites lacking mitochondria. The infective stage is transmitted from host to host as a resistant spore. Included in these protozoa are several species of some economic importance because they parasitize beneficial insects. *Nosema bombycis* parasitizes silkworms (**figure 27.5**) causing the disease **pebrine,** and *Nosema apis* causes serious dysentery (foul brood) in honeybees. There has been an increased interest in these parasites because of their possible role as biological control agents for certain insects. For example, *Nosema locustae* has been approved and registered by the United States Environmental Protection Agency for use in long-lasting control of rangeland grasshoppers. Recently seven microsporidian genera (*Nosema, Encephalitozoon, Pleistophora, Microsporidium, Vittaforma, Trachipleistophora,* and *Enterocytozoon*) have been implicated in human diseases in immunosuppressed and AIDS patients.

Phylum *Ascetospora*

Ascetospora is a relatively small phylum that consists exclusively of parasitic protists characterized by spores lacking polar caps or polar filaments. Ascetosporans such as *Haplosporidium* are parasitic primarily in the cells, tissues, and body cavities of mollusks.

Phylum *Myxozoa*

The myxozoans are all parasitic, most on freshwater and marine fish. They have a resistant spore with one to six coiled polar filaments. The most economically important myxozoan is *Myxosoma cerebralis,* which infects the nervous system and auditory organ of trout and salmon (salmonids). Infected fish lose their sense of balance and tumble erratically—thus the name whirling or tumbling disease. **Proliferative kidney disease,** caused by an unclassified myxozoan, has become one of the most important diseases of cultured salmon throughout the world.

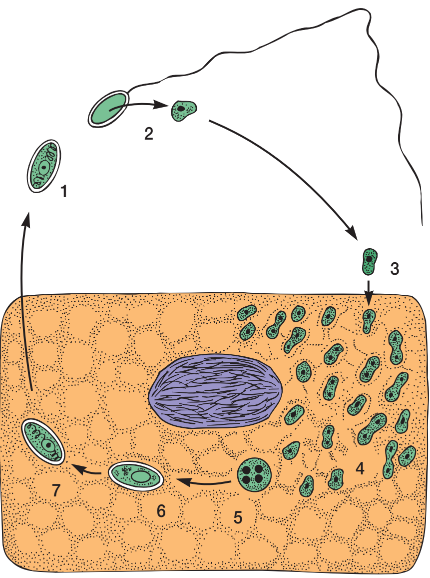


Figure 27.5 The Microsporean *Nosema bombycis,* Which is Fatal to Silkworms. (*1*) A typical spore with one coiled filament. (*2*) When ingested, it extrudes the filament. (*3*) The parasite enters an epithelial cell in the intestine of the silkworm and (*4*) divides many times to form small amoebae that eventually fill the cell and kill it. During this phase, some of the amoebae with four nuclei become spores (*5, 6, 7*). Silkworms are infected by eating leaves contaminated by the feces of infected worms.

1. Describe a typical apicomplexan (sporozoan) protist, including its apical complex.
2. Summarize the sporozoan life cycle. What is schizogony?
3. What are the four most important sporozoan parasites and the diseases they cause?
4. Give one economically important disease caused by a microsporan. What group of animals do myxosporans usually parasitize?

Phylum *Ciliophora*

The phylum *Ciliophora* is the largest of the seven protozoan phyla. There are about 8,000 species of these unicellular, heterotrophic protists that range from about 10 to 3,000 μm long. As their name implies, ciliates employ many cilia as locomotory organelles. The cilia are generally arranged either in longitudinal rows (figure 27.3*d; see also figure 4.24*) or in spirals around the body of the organism. They beat with an oblique stroke; therefore the protist revolves as it swims. Coordination of ciliary beating is so precise that the protist can go either forward or backward.

There is great variation in ciliate shape, and most do not look like the slipper-shaped *Paramecium* (*see figures 2.8*e *and 4.1*a). In some species (*Vorticella*) the protozoan attaches itself to the substrate by a long stalk. *Stentor* attaches to a substrate and stretches out in a trumpet shape to feed (*see figure 4.1*e). A few species have tentacles for the capture of prey. Some can discharge toxic thread-like darts called toxicysts, which are used in capturing prey.

A most striking feature of ciliates is their ability to capture many particles in a short time by the action of the cilia around the buccal cavity. Food first enters the cytostome and passes into phagocytic vacuoles that fuse with lysosomes after detachment from the cytostome. A vacuole's contents are digested when the vacuole is acidified and lysosomes release digestive enzymes into it. After the digested material has been absorbed into the cytoplasm, the vacuole fuses with a special region of the pellicle called the **cytoproct** and empties its waste material to the outside. Contractile vacuoles are used for osmoregulation and are present chiefly in freshwater species.

Most ciliates have two types of nuclei: a large macronucleus and a smaller micronucleus. The micronucleus is diploid and contains the normal somatic chromosomes. It divides by mitosis and transmits genetic information through meiosis and sexual reproduction. Macronuclei are derived from micronuclei by a complex series of steps. Within the macronucleus are many chromatin bodies, each containing many copies of only one or two genes. Macronuclei are thus polyploid and divide by elongating and then by constricting. They produce mRNA to direct protein synthesis, maintain routine cellular functions, and control normal cell metabolism.

Some ciliates reproduce asexually by transverse binary fission, forming two equal daughter protozoa. Many ciliates also reproduce by conjugation as previously described.

Although most ciliates are free living, symbiotic forms do exist. Some ciliated protozoa live as harmless commensals. For example, *Entodinium* is found in the rumen of cattle, and *Nyctotherus* occurs in the colon of frogs. Other ciliates are strict parasites. For example, *Balantidium coli* lives in the intestine of mammals, including humans, where it can produce dysentery. *Ichthyophthirius* lives in freshwater where it can attack many species of fish, producing a disease known as "ick."

1. Describe the morphology of a typical ciliated protozoan.
2. Describe the food-gathering structures found in the ciliated protozoa.
3. In ciliates, what is the function of the macronucleus? The micronucleus?
4. How do ciliates reproduce?
5. Where can the following ciliates be found: *Entodinium, Nyctotherus, Balantidium, Ichthyophthirius?*

Summary

1. Protozoa are protists that can be defined as usually motile eucaryotic unicellular microorganisms.
2. Protozoa are found wherever other eucaryotic organisms exist. They are important components of food chains and food webs. Many are parasitic in humans and animals (**table 27.1**), and some have become very useful in the study of molecular biology.
3. Because protozoa are eucaryotic cells, in many respects their morphology and physiology resemble those of multicellular animals. However, because all their functions must be performed within the individual protist, many morphological and physiological features are unique to protozoan cells.
4. Some protozoa can secrete a resistant covering and go into a resting stage (encystation) called a cyst. Cysts protect the organism against adverse environments, function as a site for nuclear reorganization, and serve as a means of transmission in parasitic species.
5. Protozoa move by one of three major types of locomotory organelles: pseudopodia, flagella, or cilia. Some have no means of locomotion.
6. Most protozoa reproduce asexually (**figure 27.1**), some use sexual reproduction (**figure 27.2**), and some employ both methods.
7. According to the classical classification scheme, there are seven protozoan phyla (**table 27.2**). The phylum *Sarcomastigophora* is characterized by protists that have a single type of nucleus, possess flagella (subphylum *Mastigophora*), pseudopodia (subphylum *Sarcodina*), or both types of locomotory organelles.
8. The subphylum *Sarcodina* consists of the amoeboid protists. They are found throughout the world in both fresh and salt water and in the soil. Some species are parasitic.
9. The phylum *Labyrinthomorpha* contains protists that have spindle-shaped or spherical nonamoeboid vegetative cells. Most members are marine and either saprozoic or parasitic on algae.
10. The phylum *Apicomplexa* consists of sporozoan protists that possess an apical complex, a unique arrangement of fibrils, microtubules, vacuoles, and other organelles at one end of the cell. Representative members include the *Plasmodium* parasites, which cause malaria; *Toxoplasma,* which causes toxoplasmosis; and *Eimeria,* the agent of coccidiosis.
11. The phylum *Microspora* consists of very small protists that are intracellular parasites of every major animal group. They are transmitted from one host to the next as a spore, the form from which the group obtains its name (**figure 27.5**).
12. The phylum *Ascetospora* contains protists that produce spores lacking polar capsules. These protists are primarily parasitic in mollusks.
13. The phylum *Myxozoa* consists entirely of parasitic species, usually found in fish. The spore is characterized by one to six polar filaments.
14. The phylum *Ciliophora* comprises a group of protists that have cilia and two types of nuclei. Conjugation in the *Ciliophora* is a form of sexual reproduction that involves exchange of micronuclear material.

Questions for Thought and Review

1. What is the economic impact or human relevance of the protozoa?
2. What criteria are now used in the classification of protozoa?
3. Seven protozoan phyla have been discussed. What are their distinguishing characteristics?
4. What are some typical organelles found in the protozoa?
5. What advantage does cyst formation give to protozoa?
6. How do protozoa move? Reproduce?
7. If the diversity within the seven protozoan phyla is considered, which one shows the greatest evolutionary advancement? Defend your answer.
8. The protozoa are said to be grouped together for a negative reason. What does this mean?
9. Describe how DNA is distributed to daughter cells when the ciliate *Paramecium* divides. Include a discussion of both conjugation and binary fission.
10. How does a protozoan cyst differ from a bacterial endospore?

Critical Thinking Questions

1. Why don't we know as much about the basic biology of protozoa as we know about the biology of fungi, viruses, and bacteria?
2. The text suggests that excystation requires the recognition of environmental signals. Following this line of thinking, suggest some antiprotozoan targets that could be exploited to prevent excystation in patients who have ingested cysts. Once the cysts emerge, are there other targets?
3. Suggest a reason or mechanism why, in some protozoa, the cytoplasmic material (ectoplasm) just under the plasma membrane is so rigid.

CHAPTER 28

Microorganism Interactions and Microbial Ecology

Microorganisms living in environments where most known organisms cannot survive are important for understanding microbial diversity. These strands of iron-oxidizing *Ferroplasma* were discovered growing at pH 0 in an abandoned mine near Redding, California. This hardy microorganism has only a plasma membrane to protect itself from the rigors of this harsh environment.

28.5 Methods in Microbial Ecology 626

Concepts

1. Most microorganisms in complex communities have not been grown or characterized. This has limited our understanding of microorganism interactions and their roles in nature and disease. Molecular techniques are providing a better understanding of these uncultured organisms.
2. The term symbiosis, or "together-life," can be used to describe many of the interactions between microorganisms, and also microbial interactions with higher organisms, including plants and animals. These interactions may be positive or negative.
3. Microbial ecology is the study of microbial relationships with other organisms and also with their nonliving environments. These relationships, based on interactive uses of resources, have effects extending to the global scale.
4. Positive interactions include mutualism, protocooperation, and commensalism. Negative interactions include parasitism, predation, amensalism, and competition. These interactions are important in natural processes and in the occurrence of disease. The interactions can vary depending on the environment and changes in the interacting organisms.
5. Microorganisms, as they interact, can form complex physical assemblages that are often described as biofilms. These occur on living and inert surfaces and have major impacts on microbial survival and the occurrence of disease.
6. Microorganisms also interact by the use of chemical signal molecules, which allow the microbial population to respond to increased population density. Such responses include quorum sensing, which controls a wide variety of microorganism properties.
7. Energy, electrons, and nutrients must be available in a suitable physical environment for microorganisms to function. Microbes interact with their environment to obtain energy (from light or chemical sources), electrons, and nutrients, which leads to a process called biogeochemical cycling. Microorganisms change the physical state and mobility of many nutrients as they use them in their growth processes.
8. Microorganisms are an important part of ecosystems, or self-regulating biological communities and their physical environments. Microorganisms play an important role in succession, or the predictable changes that occur in ecosystems when they are disturbed.
9. Extreme environments restrict the range of microbial types able to survive and function. This can be due to physical factors such as temperature, pH, pressure, or salinity. Many microorganisms found in "extreme" environments are especially adapted not only to survive, but to function metabolically under these particular conditions.
10. Methods used to study microbial interactions and microbial ecology provide information on environmental characteristics; microbial biomass, numbers, types and activity; and community structure. Microscopic, chemical, enzymatic, and molecular techniques are used in these studies.
11. It is now possible to determine the nucleic acid sequences of specific microorganisms or organelles isolated from natural environments and to study the phylogeny of uncultured microorganisms. This should lead to important new advances in the study of microbial ecology.

Everything is everywhere, the environment selects.

M. W. Beijerinck

In previous chapters microorganisms usually have been considered as isolated entities. The basic characteristics of microorganisms, including the structure and function of microbial cells, metabolism, growth and the control of growth, have been discussed. In addition, metabolism, genetics, and molecular aspects of microorganisms, including genomics, have been described. In this chapter, microbial interactions with both the physical environment and with other organisms will be considered.

28.1 Foundations of Microbial Ecology

Two major themes will be developed in this chapter: (1) the nature of microbial relationships with other living organisms, or the nature of **symbioses,** and (2) the interactions of these organisms with each other and with their nonliving physical environment, or the area of **microbial ecology** (**Box 28.1**). The term symbiosis is used in its original broadest sense, as an association of two or more different species of organisms, as suggested by H. A. deBary in 1879.

Microorganisms function as **populations** or assemblages of similar organisms, and as **communities,** or mixtures of different microbial populations. These microorganisms have evolved while interacting with the inorganic world and with higher organisms, and they largely play beneficial and vital roles; disease-causing organisms are only a minor component of the microbial world. Microorganisms, as they interact with other organisms and their environment, also contribute to the functioning of **ecosystems,** or self-regulating biological communities and their physical environment (p. 622). Knowledge of these interactions is important in understanding both microbial contributions to the natural world and microbial roles in disease processes.

A major problem in understanding microbial interactions is that most microscopically observable microorganisms cannot be grown. The differences between observable and culturable microorganisms, which limit this field even today, have been noted for at least 70 years. This problem was discussed in a 1932 textbook on soil microbiology written by Selman Waksman, the discoverer of streptomycin, and has not yet been solved (*see section 6.5*). The use of molecular techniques, however, is providing valuable information on these still uncultured microorganisms, and rapid progress is being made in this area. This remains as a central challenge in attempting to understand microbial interactions, microbial ecology, and biology itself.

28.2 Microbial Interactions

Microorganisms can be physically associated with other organisms in a variety of ways. One organism can be located on the surface of another, as an **ectosymbiont.** In this case, the ectosymbiont usually is a smaller organism located on the surface of a larger organism. Often, dissimilar organisms of similar size are in physical contact. The term **consortium** can be used to describe this physical relationship. Consortia in aquatic environments are frequently complex, involving multiple layers of similar-looking microorganisms that often have complementary physiological properties. In contrast, one organism can be located within another organism as an **endosymbiont.** There also are many cases in which microorganisms live on both the inside and the outside of another organism, a phenomenon called **ecto/endosymbiosis.** Interesting examples of ecto/endosymbioses include a *Thiothrix* species, a sulfur-using bacterium, which is attached to the surface of a mayfly larva and which itself contains a parasitic bacterium. Fungi associated with plant roots (mycorrhizal fungi) often contain endosymbiotic bacteria, as well as having bacteria living on their surfaces (*see pp. 679–82).*

Box 28.1

Microbial Ecology and Environmental Microbiology

The term "microbial ecology"is now used in a general way to describe the presence and contributions of microorganisms, through their activities, to the places where they are found. Students of microbiology should be aware that much of the information on microbial presence and contributions to soils, waters, and associations with plants, now described by this term, would have been considered as "environmental microbiology" in the past. Thomas D. Brock, the discoverer of *Thermus aquaticus,* which is known the world over as the source of *Taq* polymerase for the polymerase chain reaction (PCR), has given a definition of microbial ecology that may be useful: "Microbial ecology is the study of the behavior and activities of microorganisms in their natural environments." The important operator in this sentence is *their* environment instead of *the* environment. To emphasize this point, Brock has noted that "microbes are small; their environments also are small." In these small environments or "microenvironments," other kinds of microorganisms (and macroorganisms) often also are present, a critical point that was emphasized by Sergei Winogradsky in 1947.

Environmental microbiology, in comparison, relates primarily to all-over microbial processes that occur in a soil, water, or food, as examples. It is not concerned with the particular "microenvironment" where the microorganisms actually are functioning, but with the broader-scale effects of microbial presence and activities. One can study these microbially mediated processes and their possible global impacts at the scale of "environmental microbiology" without knowing about the specific microenvironment (and the organisms functioning there) where these processes actually take place. However, it is critical to be aware that microbes function in their localized environments and affect ecosystems at greater scales, including causing global-level effects. In the last decades the term "microbial ecology" largely has lost its original meaning, and recently the statement has been made that "microbial ecology has become a 'catch-all' term." As you read various textbooks and scientific papers, possible differences between "microbial ecology" and "environmental microbiology" should be kept in mind.

These physical associations can be intermittent and cyclic or permanent. Examples of intermittent and cyclic associations of microorganisms with plants and marine animals are shown in **table 28.1.** Important human diseases, including listeriosis, malaria, leptospirosis, legionellosis, and vaginosis also involve such intermittent and cyclic symbioses. These diseases will be discussed in chapters 39 and 40. Interesting permanent relationships also occur between bacteria and animals, as shown in **table 28.2.** Hosts include squid, leeches, aphids, nematodes, and mollusks. In each of these cases, an important characteristic of the host animal is conferred by the permanent bacterial symbiont.

Although it is possible to observe microorganisms in these varied physical associations with other organisms, the fact that there is some type of physical contact provides no information on the types of interactions that might be occurring. These interactions can be positive (mutualism, protocooperation, and

Table 28.1 Intermittent and Cyclical Symbioses of Microorganisms with Plants and Marine Animals

Symbiosis	Host	Cyclical Symbiont
Plant-bacterial	*Gunnera* (tropical angiosperm)	*Nostoc* (cyanobacterium)
	Azolla (rice paddy fern)	*Anabaena* (cyanobacterium)
	Phaseolus (bean)	*Rhizobium* (N_2 fixer)
	Ardisia (angiosperm)	*Protobacterium*
Marine animals	Coral coelenterates	*Symbiodinium* (dinomastigote)

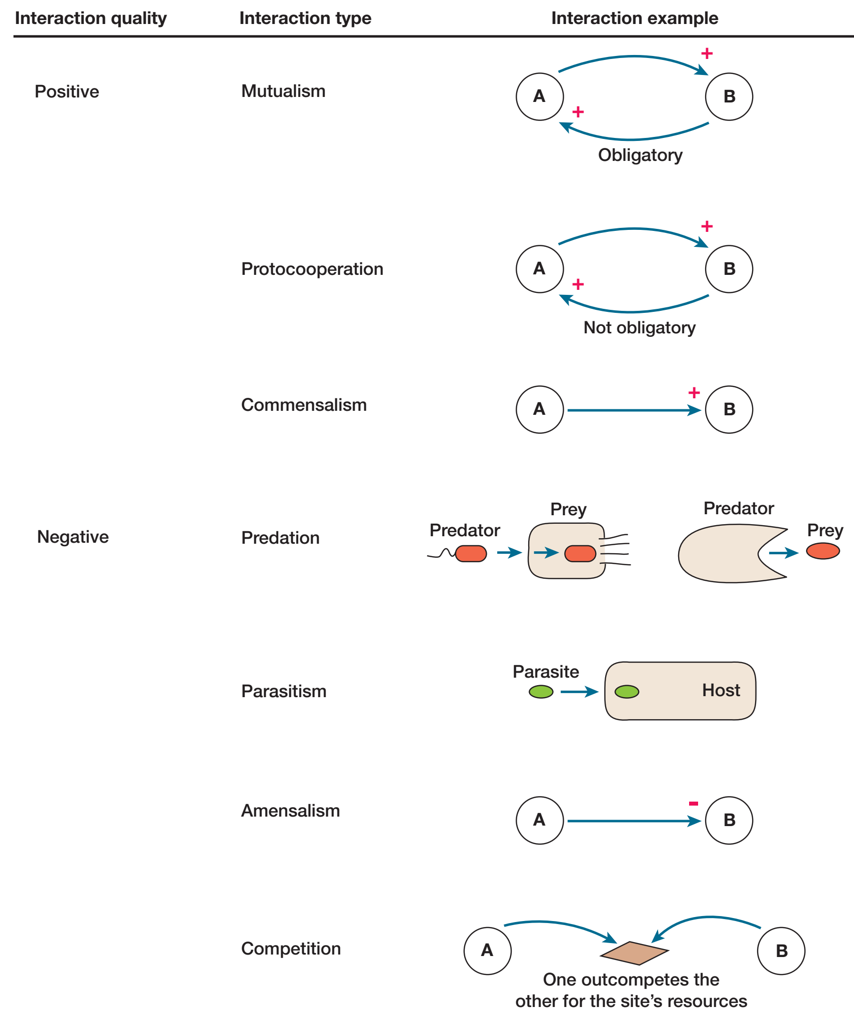

Figure 28.1 Microbial Interactions. Basic characteristics of positive (+) and negative (−) interactions that can occur between different organisms.

commensalism) or negative (predation, parasitism, amensalism, and competition) as shown in **figure 28.1.** These interactions will be discussed next.

1. Define the terms symbiosis and microbial ecology. How are they similar and different?
2. In what ways can different microorganisms be in physical contact?
3. Define the terms population, community, and ecosystem.
4. List several important diseases that involve cyclic and intermittent symbioses.

Mutualism

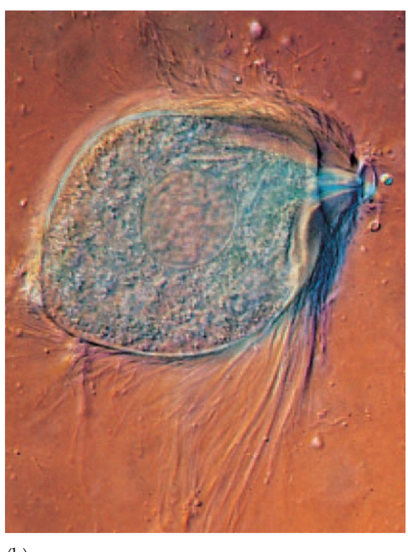
Mutualism [Latin *mutuus,* borrowed or reciprocal] defines the relationship in which some reciprocal benefit accrues to both partners. This is an obligatory relationship in which the **mutualist** and the host are metabolically dependent on each other. Several examples of mutualism are presented next.

The protozoan-termite relationship is a classic example of mutualism in which the flagellated protozoa live in the gut of termites and wood roaches. (**figure 28.2*a***). These flagellates exist on a diet of carbohydrates, acquired as cellulose ingested by their host (figure 28.2*b*). The protozoa engulf wood particles, digest the cellulose, and metabolize it to acetate and other products. Termites oxidize the acetate released by their flagellates. Because the host is almost always incapable of synthesizing cellulases (enzymes that catalyse the hydrolysis of cellulose), it is dependent on the mutualistic protozoa for its existence.

This mutualistic relationship can be readily tested in the laboratory if wood roaches are placed in a bell jar containing wood chips and a high concentration of O_2. Because O_2 is toxic to the flagellates, they die. The wood roaches are unaffected by the high O_2 concentration and continue to ingest wood, but they soon die of starvation due to a lack of cellulases.

Lichens are another excellent example of mutualism (**figure 28.3**). **Lichens** are the association between specific ascomycetes (the fungus) and certain genera of either green algae or cyanobacteria. In a lichen, the fungal partner is termed the **mycobiont** and the algal or cyanobacterial partner, the **phycobiont.**

(a)



(b)

Figure 28.2 Mutualism. Light micrographs of (**a**) a worker termite of the genus *Reticulitermes* eating wood (×10), and (**b**) *Trichonympha,* a multiflagellated protozoan from the termite's gut (×135). Notice the many flagella that occur over most of its length. The ability of *Trichonympha* to break down cellulose enables termites to use wood as a food source.

The remarkable aspect of this mutualistic association is that its morphology and metabolic relationships are so constant that lichens are assigned generic and species names. The characteristic morphology of a given lichen is a property of the mutualistic association and is not exhibited by either symbiont individually. Ascomycetes (pp. 560–61); cyanobacteria (pp. 471–76)

Because the phycobiont is a photoautotroph—dependent only on light, carbon dioxide, and certain mineral nutrients—the fungus can get its organic carbon directly from the alga or cyanobacterium. The fungus often obtains nutrients from its partner by haustoria (projections of fungal hyphae) that penetrate the phycobiont cell wall. It also uses the O_2 produced during phycobiont photophosphorylation in carrying out respiration. In turn the fungus protects the phycobiont from excess light intensities, provides water and minerals to it, and creates a firm substratum within which the phycobiont can grow protected from environmental stress.

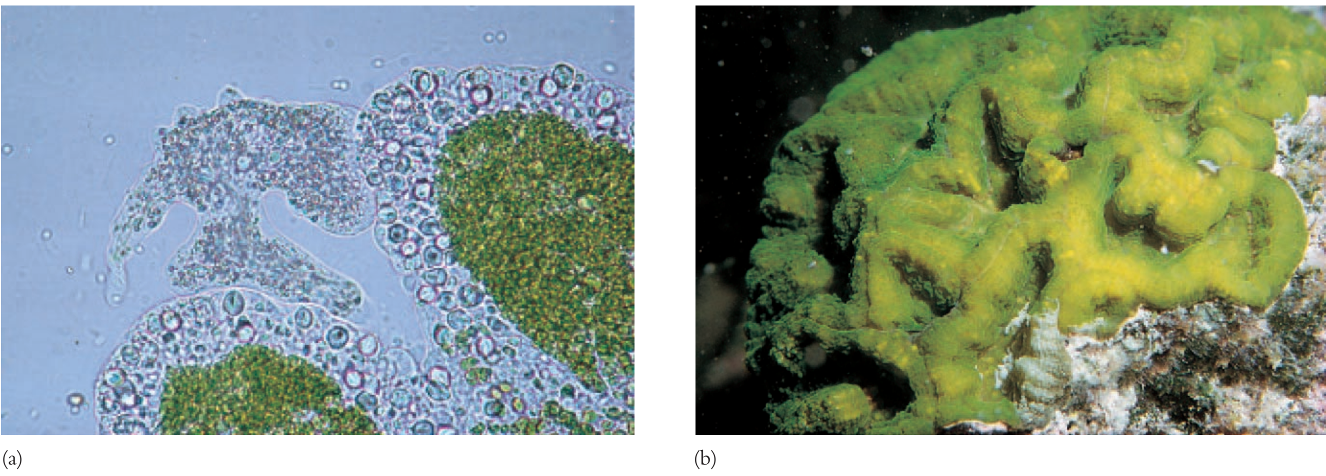
Many marine invertebrates (sponges, jellyfish, sea anemones, corals, ciliates) harbor endosymbiotic, spherical algal cells called **zooxanthellae** within their tissue (**figure 28.4*a***). Because the degree of host dependency on the mutualistic alga is somewhat variable, only one well-known example is presented.

The hermatypic (reef-building) corals (figure 28.4*b*) satisfy most of their energy requirements using their zooxanthellae. Pigments produced by the coral protect the algae from the harmful effects of ultraviolet radiation. Clearly the zooxanthellae also benefit the coral because the calcification rate is at least 10 times greater in the light than in the dark. Hermatypic corals lacking zooxanthellae have a very low rate of calcification. Based on their stable carbon isotopic composition, it has been determined that most of the organic carbon in the tissues of the hermatypic corals has come from the zooxanthellae. Because of this coral-algal mutualistic relationship—capturing, conserving, and cycling nutrients and energy—coral reefs are among the most productive and successful of known ecosystems.

Figure 28.3 Lichens. Crustose (encrusting) lichens growing on a granite post.

Sulfide-Based Mutualisms

Tube worm–bacterial relationships exist several thousand meters below the surface of the ocean, where the Earth's crustal plates are spreading apart (**figure 28.5**). Vent fluids are anoxic, contain high concentrations of hydrogen sulfide, and can reach a temperature of 350°C. The seawater surrounding these vents has sulfide



(a) (b)

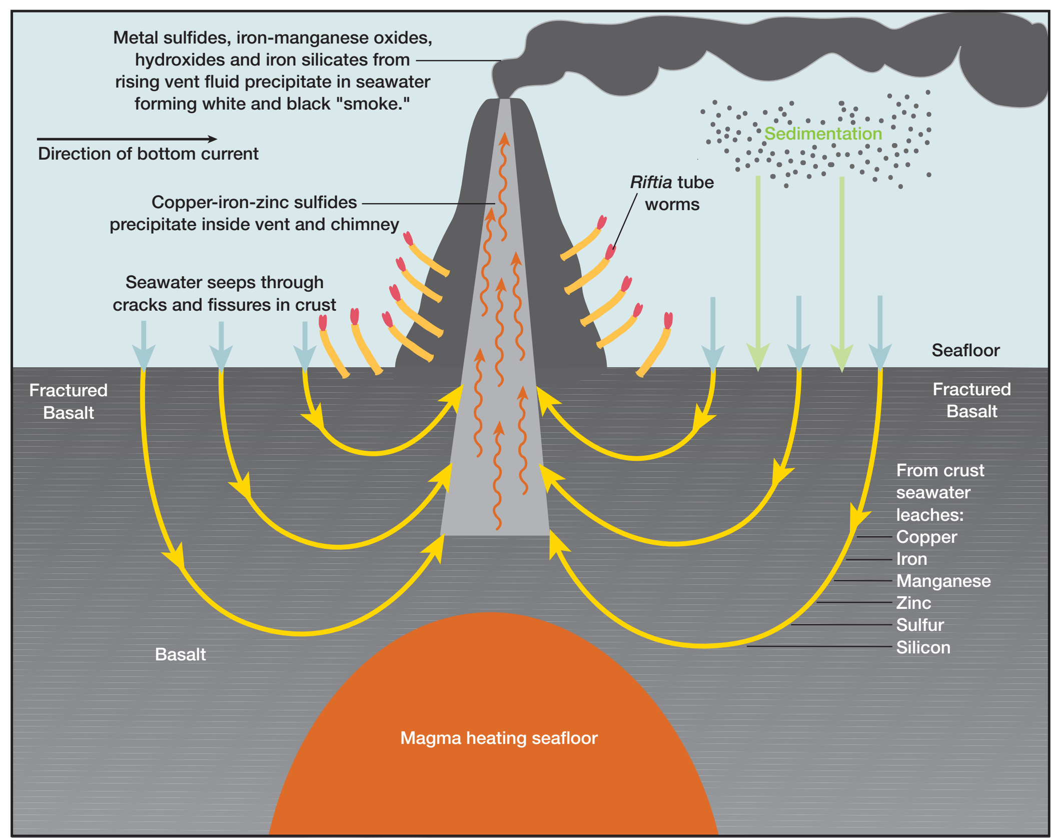

Figure 28.5 Basic Structure of a Hydrothermal Vent with its Mutualistic Microbe-Animal Associations. Reduced chemicals including sulfide are released as seawater penetrates the fractured basaltic ocean floor, is heated, and returns as vent fluid to the ocean, creating environments for growth of the tube worms and their procaryotic mutualists.

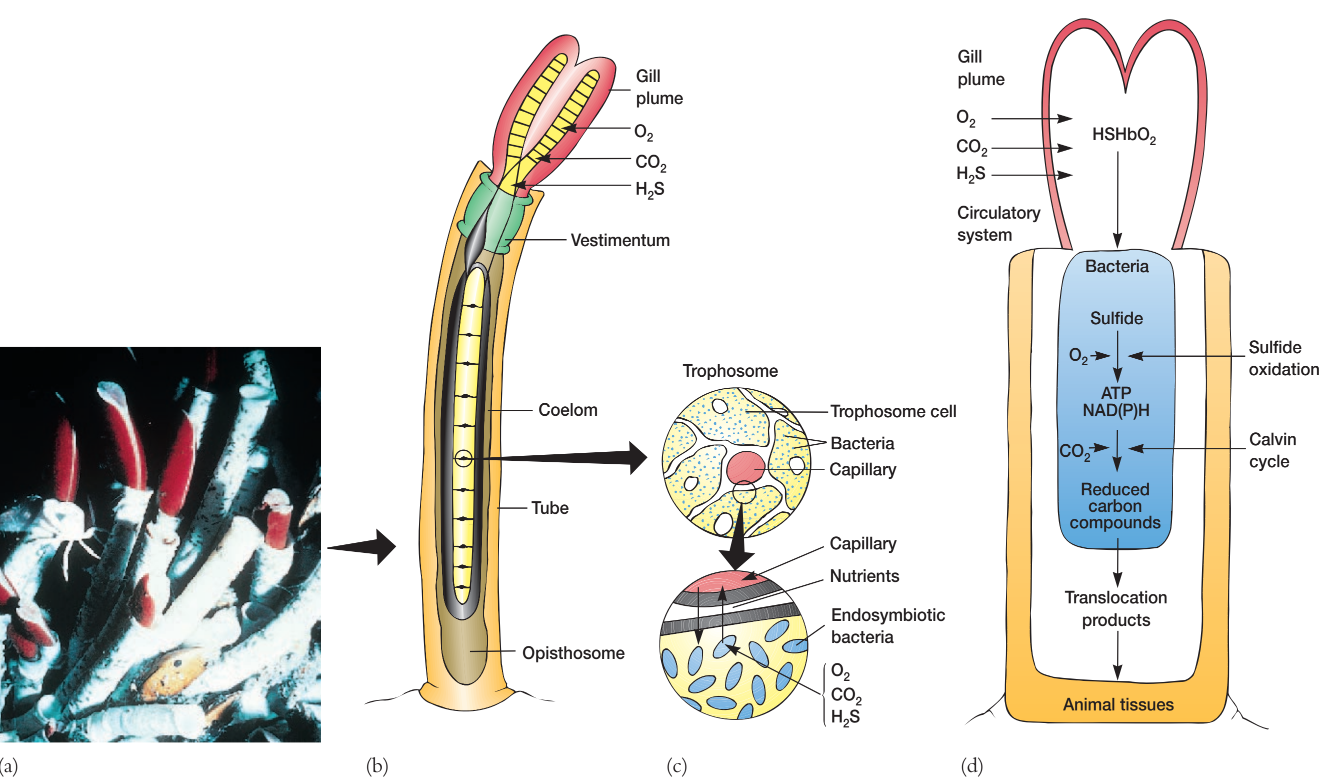

Figure 28.6 The Tube Worm—Bacterial Relationship. (**a**) A community of tube worms (*Riftia pachyptila*) at the Galápagos Rift hydrothermal vent site (depth 2,550 m). Each worm is more than a meter in length and has a 20 cm gill plume. (**b, c**) Schematic illustration of the anatomical and physiological organization of the tube worm. The animal is anchored inside its protective tube by the vestimentum. At its anterior end is a respiratory gill plume. Inside the trunk of the worm is a trophosome consisting primarily of endosymbiotic bacteria, associated cells, and blood vessels. At the posterior end of the animal is the opisthosome, which anchors the worm in its tube. (**d**) Oxygen, carbon dioxide, and hydrogen sulfide are absorbed through the gill plume and transported to the blood cells of the trophosome. Hydrogen sulfide is bound to the worm's hemoglobin ($HSHbO_2$) and carried to the endosymbiont bacteria. The bacteria oxidize the hydrogen sulfide and use some of the released energy to fix CO_2 in the Calvin cycle. Some fraction of the reduced carbon compounds synthesized by the endosymbiont is translocated to the animal's tissues.

concentrations around 250 μM and temperatures 10 to 20°C above the normal seawater temperature of 2.1°C.

The giant (>1 m in length), red, gutless tube worms (*Riftia* spp.) near these hydrothermal vents provide an example of a unique form of mutualism and animal nutrition in which chemolithotrophic bacterial endosymbionts are maintained within specialized cells of the tube worm host (**figure 28.6**). To date all attempts to culture these microorganisms have been unsuccessful.

The tube worm takes up hydrogen sulfide from the seawater and binds it to hemoglobin (the reason the worms are bright red). The hydrogen sulfide is then transported in this form to the bacteria, which use the sulfide-reducing power to fix carbon dioxide in the Calvin cycle (*see figure 10.4*). The CO_2 required for this cycle is transported to the bacteria in three ways: freely dissolved in the blood, bound to hemoglobin, and in the form of organic acids such as malate and succinate. These acids are decarboxylated to release CO_2 in the trophosome, the tissue containing bacterial symbionts. Using these mechanisms, the bacteria synthesize reduced organic material from inorganic substances. The organic material is then supplied to the tube worm through its circulatory system and serves as the main nutritional source for the tissue cells.

Methane-Based Mutualisms

Other unique food chains involve methane-fixing microorganisms as the first step in providing organic matter for consumers. Methanotrophs, bacteria capable of using methane, occur as intracellular symbionts of methane-vent mussels. In these mussels the thick fleshy gills are filled with bacteria. In addition, methanotrophic carnivorous sponges have been discovered in a mud volcano at a depth of 4,943 m in the Barbados Trench. Abundant methanotrophic symbionts were confirmed by the presence of enzymes related to methane oxidation in sponge tissues. These sponges are not satisfied to use bacteria to support themselves; they also trap swimming prey to give variety to their diet.

Microorganism-Insect Mutualisms

Mutualistic associations are common in the insects. This is related to the foods used by insects, which often include plant sap or animal fluids lacking in essential vitamins and amino acids. The required vitamins and amino acids are provided by bacterial symbionts in exchange for a secure physical habitat and ample nutrients. The aphid is an excellent example of this mutualistic relationship. This insect contains *Buchnera aphidicola* in its cytoplasm, and a mature insect contains literally millions of these bacteria in its body. The *Buchnera* provides its host with amino acids, particularly tryptophan, and if the insect is treated with antibiotics, it dies. *Wolbachia pipientis,* a rickettsia, is a cytoplasmic endosymbiont found in 15 to 20% of insect species and can control the reproduction of its host. This microbial association is thought to be a major factor in the evolution of sex and speciation in the parasitic wasps. *Wolbachia* also can cause cytoplasmic incompatibility in insects, parthenogenesis in butterflies, and the feminization of genetic males in isopods. What could be the advantage to the *Wolbachia*? By limiting sexual variability, the bacterium might benefit by creating a more stable asexual environment for its own longer-term maintenance. Our understanding of microbe-insect mutualisms, including the role of *Wolbachia* in insects, is constantly expanding with the increased use of molecular techniques.

1. What is a lichen? Discuss the benefits the phycobiont and mycobiont provide each other.
2. What is the critical characteristic of a mutualistic relationship?
3. How do tube worms obtain energy and organic compounds for their growth?
4. What is the source of the waters released in a deep hydrothermal vent, and how is it heated?
5. What are important roles of bacteria, such as *Buchnera* and *Wolbachia,* in insects?

The Rumen Ecosystem

Ruminants are a group of herbivorous animals that have a stomach divided into four compartments and chew a cud consisting of regurgitated, partially digested food. Examples include cattle, deer, elk, camels, buffalo, sheep, goats, and giraffes. This feeding method has evolved in animals that need to eat large amounts of food quickly, chewing being done later at a more comfortable or safer location. More importantly, by using microorganisms to degrade the thick cellulose walls of grass and other vegetation, ruminants digest vast amounts of otherwise unavailable forage. Because ruminants cannot synthesize cellulases, they have established a mutualistic relationship with anaerobic microorganisms that produce these enzymes. Cellulases hydrolyze the β $(1\rightarrow4)$ linkages between successive D-glucose residues of cellulose and release glucose, which is then fermented to organic acids such as acetate, butyrate, and propionate (*see figure 9.10*). These organic acids are the true energy source for the ruminant.

The upper portion of a ruminant's stomach expands to form a large pouch called the **rumen** (**figure 28.7**) and also a smaller

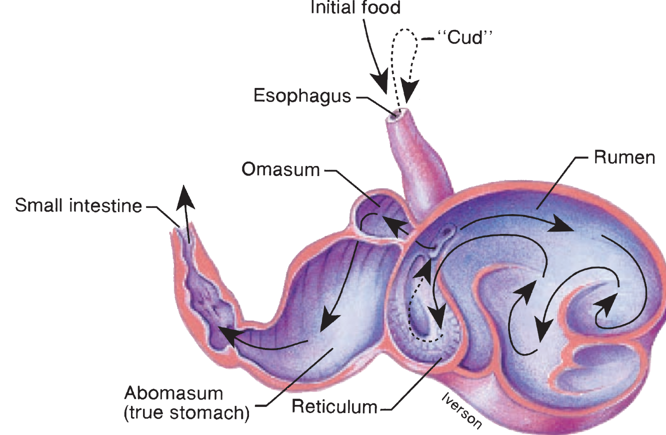

Figure 28.7 Ruminant Stomach. The stomach compartments of a cow. The microorganisms are active mainly in the rumen. Arrows indicate direction of food movement.

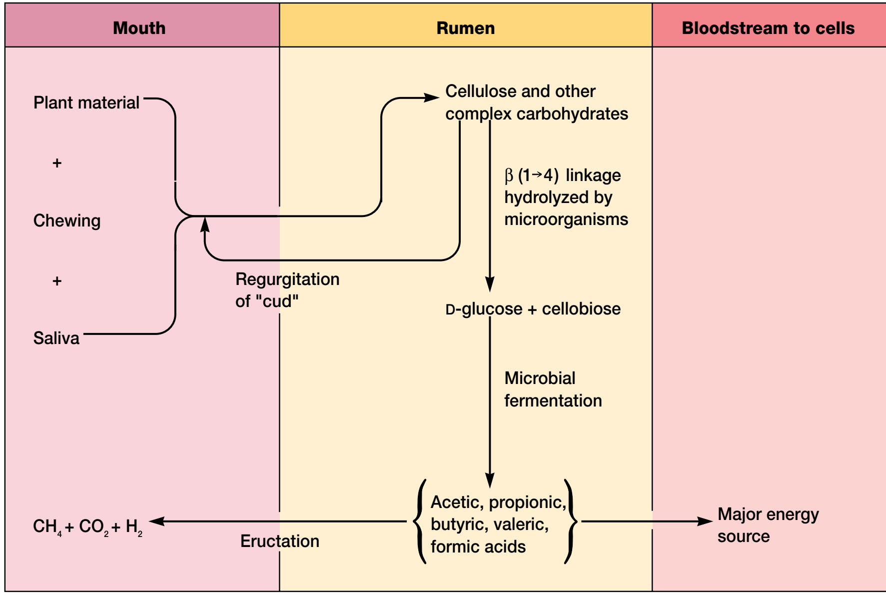
honeycomblike reticulum. The bottom portion of the stomach consists of an antechamber called the omasum, with the "true" stomach (abomasum) behind it.

The insoluble polysaccharides and cellulose eaten by the ruminant are mixed with saliva and enter the rumen. Within the rumen, food is churned in a constant rotary motion and eventually reduced to a pulpy mass, which is partially digested and fermented by microorganisms. Later the food moves into the reticulum. It is then regurgitated as a "cud," which is thoroughly chewed for the first time. The food is mixed with saliva, reswallowed, and reenters the rumen while another cud is passed up to the mouth. As this process continues, the partially digested plant material becomes more liquid in nature. The liquid then begins to flow out of the reticulum and into the lower parts of the stomach: first the omasum and then the abomasum. It is in the abomasum that the food encounters the host's normal digestive enzymes and the digestive process continues in the regular mammalian way.

The rumen contains a large and diverse microbial community (about 10^{12} organisms per milliliter), including procaryotes, anaerobic fungi such as *Neocallimastix,* and ciliates and other protozoans. Food entering the rumen is quickly attacked by the cellulolytic anaerobic procaryotes, fungi, and protozoa. Although the masses of procaryotes and protozoa are approximately equal, the processing of rumen contents is carried out mainly by the procaryotes. Microorganisms break down the plant material, as illustrated in **figure 28.8.** Because the reduction potential in the rumen is -30 mV, all indigenous microorganisms engage in anaerobic metabolism. The bacteria ferment carbohydrates to fatty acids, carbon dioxide, and hydrogen. The archaea (methanogens) produce methane (CH_4) from acetate, CO_2, and H_2.

Dietary carbohydrates degraded in the rumen include soluble sugars, starch, pectin, hemicellulose, and cellulose. The largest percentage of each carbohydrate is fermented to volatile fatty acids (acetic, propionic, butyric, formic, and valeric), CO_2, H_2, and methane. Fatty acids produced by the rumen organisms are absorbed into the bloodstream and are oxidized by the animal as its



(a)

Figure 28.8 Rumen Biochemistry. (**a**) An overview of the biochemical-physiological processes occurring in various parts of a cow's digestive system. (**b**) More specific biochemical pathways involved in rumen fermentation of the major plant carbohydrates. The top boxes represent substrates and the bottom boxes some of the end products.

main source of energy. The CO_2 and methane, produced at a rate of 200 to 400 liters per day in a cow, are released by eructation [Latin *eructare,* to belch], a continuous, scarcely audible reflex process similar to belching. ATP produced during fermentation is used to support the growth of rumen microorganisms. These microorganisms in turn produce most of the vitamins needed by the ruminant. In the remaining two stomachs, the microorganisms, having performed their symbiotic task, are digested to yield amino acids, sugars, and other nutrients for ruminant use.

Syntrophism

Syntrophism [Greek *syn,* together, and *trophe,* nourishment] is an association in which the growth of one organism either depends on or is improved by growth factors, nutrients, or substrates provided by another organism growing nearby. Sometimes both organisms benefit. This type of mutualism is also known as cross-feeding or the satellite phenomenon.

A very important syntrophism occurs in anaerobic methanogenic ecosystems such as sludge digesters (*see section 29.6*), anaerobic freshwater aquatic sediments, and flooded soils. In these environments, fatty acids can be degraded to produce H_2 and methane by the interaction of two different bacterial groups. Methane production by methanogens depends on **interspecies hydrogen transfer.** A fermentative bacterium generates hydrogen gas, and the methanogen uses it quickly as a substrate for methane gas production.

Various fermentative bacteria produce low molecular weight fatty acids that can be degraded by anaerobic bacteria such as *Syntrophobacter* to produce H_2 as follows:

$$\text{Propionic acid} \rightarrow \text{acetate} + CO_2 + H_2$$

Syntrophobacter uses protons ($H^+ + H^+ \rightarrow H_2$) as terminal electron acceptors in ATP synthesis. The bacterium gains sufficient energy for growth only when the H_2 it generates is consumed. The products H_2 and CO_2 are used by methanogenic archaea (e.g., *Methanospirillum*) as follows:

$$4H_2 + CO_2 \rightarrow CH_4 + 2H_2O$$

By synthesizing methane, *Methanospirillum* maintains a low H_2 concentration in the immediate environment of both bacteria. Continuous removal of H_2 promotes further fatty acid fermentation and H_2 production. If the hydrogen is not consumed, it will inhibit *Syntrophobacter.* Because increased H_2 production and consumption stimulate the growth rates of *Syntrophobacter* and *Methanospirillum,* both participants in the relationship benefit.

1. What structural features of the rumen make it suitable for a herbivorous type of diet? Why does a cow chew its cud?
2. What biochemical roles do the rumen microorganisms play in this type of symbiosis?
3. What is syntrophism? Is physical contact required for this relationship?
4. What is interspecies hydrogen transfer, and why can this be beneficial to both the producer and consumer of hydrogen?

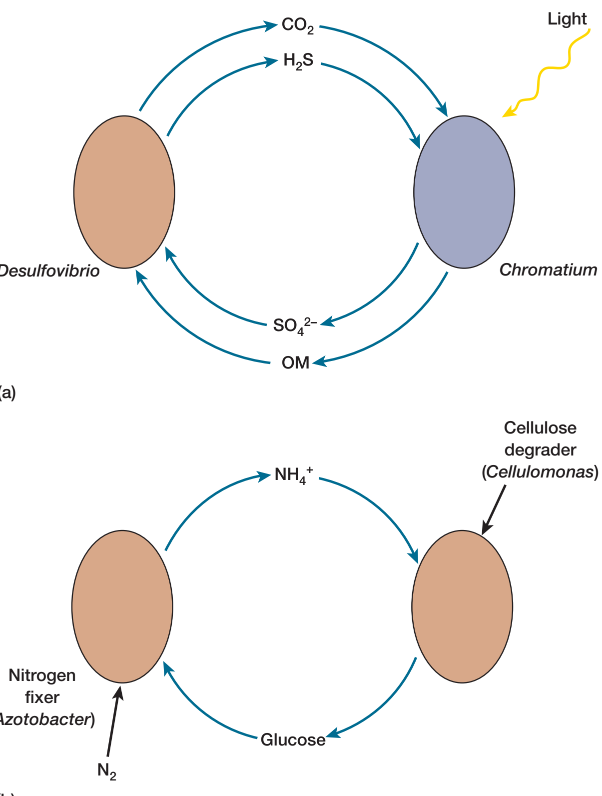

Figure 28.9 Examples of Protocooperative Symbiotic Processes. (**a**) The organic matter (OM) and sulfate required by *Desulfovibrio* are produced by the *Chromatium* in its photosynthesis-driven reduction of CO_2 to organic matter and oxidation of sulfide to sulfate. (**b**) *Azotobacter* uses glucose provided by a cellulose-degrading microorganism such as *Cellulomonas,* which uses the nitrogen fixed by *Azotobacter.*

Protocooperation

As noted in figure 28.1, **protocooperation** is a mutually beneficial relationship, similar to that which occurs in mutualism, but in protocooperation, this relationship is not obligatory. As noted in this figure, beneficial complementary resources are provided by each of the paired microorganisms. The organisms involved in this type of relationship can be separated, and if the resources provided by the complementary microorganism are supplied in the growth environment, each microorganism will function independently. Two examples of this type of relationship are the association of *Desulfovibrio* and *Chromatium* (**figure 28.9*a***), in which the carbon and sulfur cycles are linked, and the interaction of a nitrogen-fixing microorganism with a cellulolytic organism such as *Cellulomonas* (figure 28.9*b*). In the second example, the cellulose-degrading microorganism liberates glucose from the cellulose, which can be used by nitrogen-fixing microbes.

An excellent example of a protocooperative biodegradative association is shown in **figure 28.10.** In this case 3-chlorobenzoate degradation depends on the functioning of microorganisms with complementary capabilities. If any one of the three microorgan-

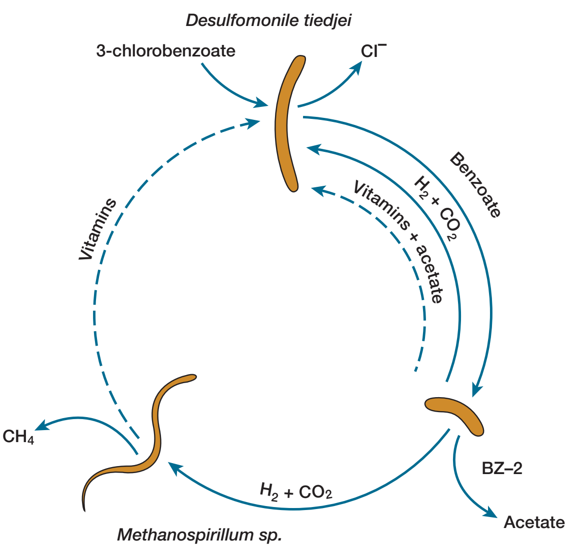

Figure 28.10 Associations in a Defined Three-Membered Protocooperative and Commensalistic Community That Can Degrade 3-Chlorobenzoate. If any member is missing, degradation will not take place. The solid arrows demonstrate nutrient flows, and the dashed lines represent hypothesized flows.

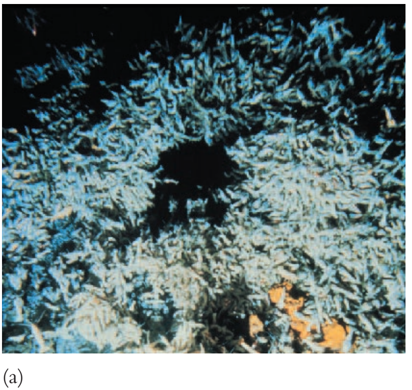
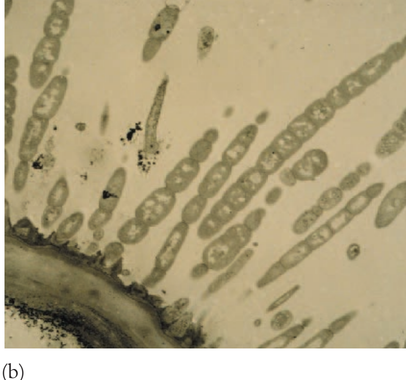
Figure 28.11 A Marine Worm-Bacterial Protocooperative Relationship. *Alvinella pompejana,* a 10 cm long worm, forms a protocooperative relationship with bacteria that grow as long threads on the worm's surface. These waters contain sulfur compounds that are used by the bacteria as electron acceptors in the presence of fumarate and pyruvate, and the worm uses the bacteria as a food source. The bacteria and *Alvinella* are found in tunnels near the black smoker–heated water fonts.



(a)

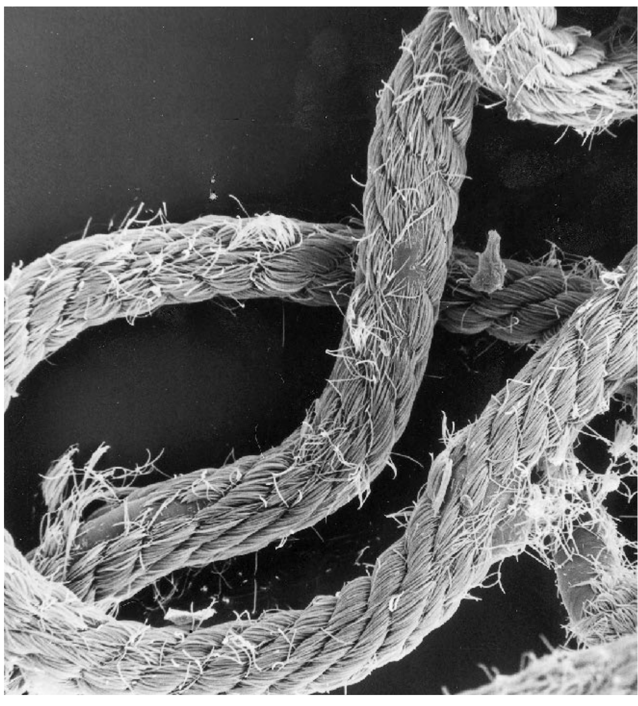


(b)

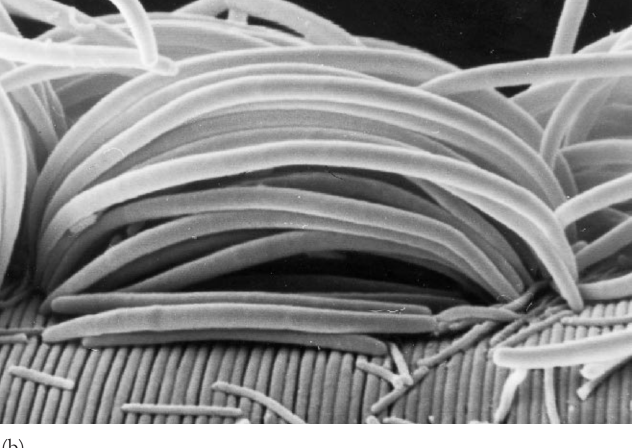
Figure 28.12 A Marine Crustacean-Bacterial Protocooperative Relationship. (**a**) A picture of the marine shrimp *Rimicaris exoculata* clustering around a hydrothermal vent area, showing the massive development of these crustaceans in the area where chemolithotrophic bacteria grow using sulfide as an electron and energy source. The bacteria, which grow on the vent openings and also on the surface of the crustaceans, fix carbon from CO_2 in their autotrophic metabolism, and serve as the nutrient for the shrimp. (**b**) An electron micrograph of a thin section across the leg of the marine crustacean *Rimicaris exoculata,* showing the chemolithotrophic bacteria that cover the surface of the shrimp. The filamentous nature of these bacteria, upon which this commensalistic relationship is based, is evident in this thin section.

isms is not present and active, the degradation of the substrate will not occur.

In other protocooperative relations, sulfide-dependent autotrophic filamentous microorganisms fix carbon dioxide and synthesize organic matter that serves as a carbon and energy source for a heterotrophic organism. One of the most interesting such relationship is the Pompeii worm (*Alvinella pompejana*), named for the deep-sea submersible from Woods Hole, Massachusetts. This unusual organism is 10 cm in length and lives in tunnels near waters that approach 80°C in a deep area of the Pacific Ocean (**figure 28.11**). It uses as a nutrient source bacteria that appear to oxidize organic matter and reduce sulfur compounds. A deep-sea crustacean has been discovered that uses sulfur-oxidizing autotrophic bacteria as its food source. This shrimp, *Rimicaris exoculata* (**figure 28.12**)



(a)



(b)

Figure 28.13 A Marine Nematode-Bacterial Protocooperative Relationship. Marine free-living nematodes, which grow at the oxidized-reduced zone where sulfide and oxygen are present, are covered by sulfide-oxidizing bacteria. The bacteria protect the nematode by decreasing sulfide concentrations near the worm, and the worm uses the bacteria as a food source. (**a**) The marine nematode *Eubostrichus parasitiferus* with bacteria arranged in a characteristic helix pattern. Bar scale = 100 μm. (**b**) The chemolithotrophic bacteria attached to the cuticle of the marine nematode *Eubostrichus parasitiferus.* Cells are fixed to the nematode surface at both ends. Bar = 10 μm. *See also figure 28.17.*

has filamentous sulfur-oxidizing bacteria growing on its surface. When these are dislodged the shrimp ingests them. This nominally "blind" shrimp can respond to the glow emitted by the black smoker, using a reflective organ on its back. The organ is sensitive to a light wavelength that is not detectable by humans.

Another interesting example of bacterial epigrowth is shown by nematodes, including *Eubostrichus parasitiferus,* that live at the interface between aerobic and anaerobic sulfide-containing marine sediments (**figure 28.13*a***). These animals are covered by sulfide-oxidizing bacteria that are present in intricate patterns (figure 28.13*b*). The bacteria not only decrease levels of toxic sulfide, which often surround the nematodes, but they also serve as a food supply.

In 1990, hydrothermal vents were discovered in a freshwater environment, at the bottom of Lake Baikal, the oldest (25 million years old) and deepest lake in the world. This lake is located in the far east of Russia (**figure 28.14*a***) and has the largest volume of any freshwater lake (not the largest area—which is Lake Superior). The bacterial growths, with long white strands, are in the center of the vent field where the highest temperatures are found (figure 28.14*b*). At the edge of the vent field, where the water temperature is lower, the bacterial mat ends, and sponges, gastropods, and other organisms, which use the sulfur-oxidizing bacteria as a food source, are present (figure 28.14*c*). Similar although less developed areas have been found in Yellowstone Lake, Wyoming.

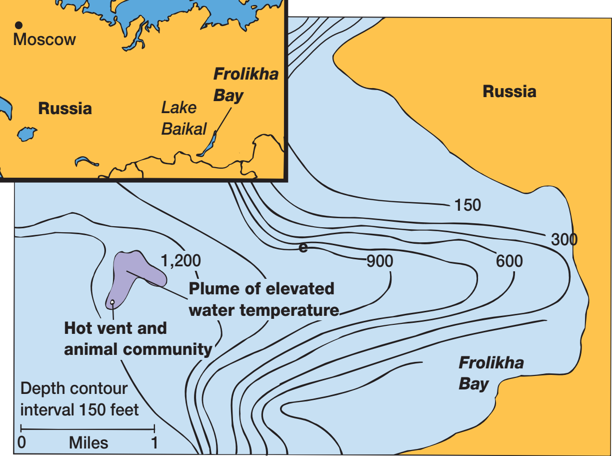
A hydrogen sulfide–based ecosystem has been discovered in southern Romania that is closer to the earth's surface. Caves in the area contain mats of microorganisms that fix carbon dioxide using hydrogen sulfide as the reductant. Forty-eight species of cave-adapted invertebrates are sustained by this chemoautotrophic base.

A form of protocooperation also occurs when a population of similar microorganisms monitors its own density, the process of quorum sensing, which was discussed in section 6.5. The microorganisms produce specific autoinducer compounds, and as the population increases and the concentration of these compounds reaches critical levels, specific genes are expressed. These responses are important for microorganisms that form associations with plants and animals, and particularly for human pathogens.

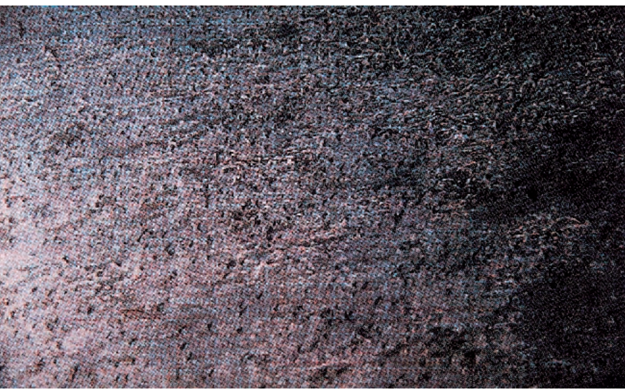
1. Why are *Alvinella, Rimicaris* and *Eubostrichus* good examples of protocooperative microorganism-animal interactions?
2. What important freshwater hydrothermal vent communities have been described?

Commensalism

Commensalism [Latin *com,* together, and *mensa,* table] is a relationship in which one symbiont, the **commensal,** benefits while the other (sometimes called the host) is neither harmed nor helped as shown in figure 28.1. This is a unidirectional process. Often both the host and the commensal "eat at the same table." The spatial proximity of the two partners permits the commensal to feed on substances captured or ingested by the host, and the commensal often obtains shelter by living either on or in the host. The commensal is not directly dependent on the host metabolically and causes it no particular harm. When the commensal is separated from its host experimentally, it can survive without being provided some factor or factors of host origin.



(a)



(b)

(c)

Figure 28.14 Hydrothermal Vent Ecosystems in Freshwater Environments. Lake Baikal (in Russia) has been found to have low temperature hydrothermal vents. (**a**) Location of Lake Baikal, site of the hydrothermal vent field. (**b**) Bacterial mat near the center of the vent field. (**c**) Bacterial filaments and sponges at the edge of the vent field. *(a) Source: Data from the National Geographic Society.*

Commensalistic relationships between microorganisms include situations in which the waste product of one microorganism is the substrate for another species. An example is nitrification, the oxidation of ammonium ion to nitrite by microorganisms such as *Nitrosomonas,* and the subsequent oxidation of the nitrite to nitrate by *Nitrobacter* and similar bacteria (*see pp. 193–94*). *Nitrobacter* benefits from its association with *Nitrosomonas* because it uses nitrite to obtain energy for growth.

Commensalistic associations also occur when one microbial group modifies the environment to make it more suited for another organism. For example, in the intestine the common, nonpathogenic strain of *Escherichia coli* lives in the human colon, but also grows quite well outside the host, and thus is a typical commensal. When oxygen is used up by the facultatively anaerobic *E. coli,* obligate anaerobes such as *Bacteroides* are able to grow in the colon. The anaerobes benefit from their association with the host and *E. coli,* but *E. coli* derives no obvious benefit from the anaerobes. In this case the commensal *E. coli* contributes to the welfare of other symbionts. Commensalism can involve other environmental modifications. The synthesis of acidic waste products during fermentation stimulate the proliferation of more acid-tolerant microorganisms, which are only a minor part of the microbial community at neutral pHs. A good example is the succession of microorganisms during milk spoilage. When biofilms are formed (section 28.4), the colonization of a newly exposed surface by one type of microorganism (an initial colonizer) makes it possible for other microorganisms to attach to the microbially modified surface.

Commensalism also is important in the colonization of the human body and the surfaces of other animals and plants. The microorganisms associated with an animal skin and body orifices can use volatile, soluble, and particulate organic compounds from the host as nutrients (*see section 31.2*). Under most conditions these microbes do not cause harm, other than possibly contributing to body odor. Sometimes when the host organism is stressed or the skin is punctured, these normally commensal microorganisms may become pathogenic. These interactions will be discussed in chapter 31.

1. How does commensalism differ from protocooperation?
2. Why is nitrification a good example of a commensalistic process?
3. Why are commensalistic microorganisms important for humans? Where are these found in relation to the human body?

Predation

Predation is a widespread phenomenon where the predator engulfs or attacks the prey, as shown in figure 28.1. The prey can be larger or smaller than the predator, and this normally results in the death of the prey.

An interesting array of predatory bacteria are active in nature. Several of the best examples are shown in **figure 28.15,** including *Bdellovibrio, Vampirococcus,* and *Daptobacter.* Each of these has a unique mode of attack against a susceptible bacterium. *Bdellovibrio* penetrates the cell wall and multiplies between the wall and the

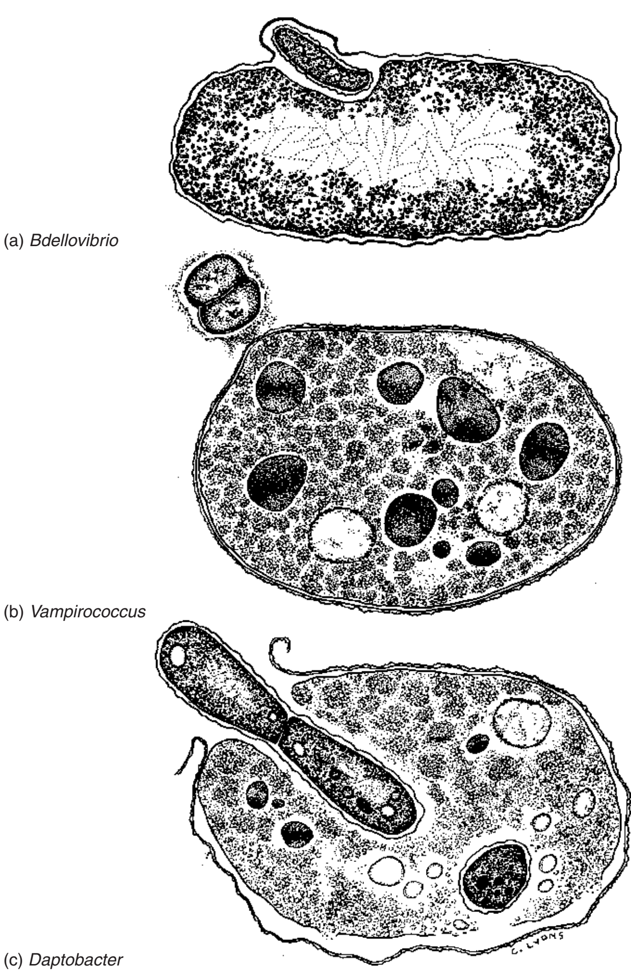


Figure 28.15 Examples of Predatory Bacteria Found in Nature. (**a**) *Bdellovibrio,* a periplasmic predator that penetrates the cell wall and grows outside the plasma membrane, (**b**) *Vampirococcus* with its unique epibiotic mode of attacking a prey bacterium, and (**c**) *Daptobacter* showing its cytoplasmic location as it attacks a susceptible bacterium.

plasma membrane, a periplasmic mode of attack, followed by lysis of the prey and release of progeny (*see figure 22.33*). This bacterium has an interesting life cycle, which is discussed in section 22.4.

Nonlytic forms also are observed. *Vampirococcus* attaches to the surface of the prey (an epibiotic relationship) and then secretes enzymes to release the cell contents. *Daptobacter* penetrates a susceptible host and uses the cytoplasmic contents as a nutrient source.

Ciliates are excellent examples of predators that engulf their prey, and based on work with fluorescently marked prey bacteria, a single ciliate can ingest 60 to 70 prey bacteria per hour! Predation on bacteria is important in the aquatic environment and in sewage treatment where the ciliates remove suspended bacteria that have not settled.

A surprising finding is that predation has many beneficial effects, especially when one considers interactive populations of predators and prey, as summarized in **table 28.3.** Simple ingestion and assimilation of a prey bacterium can lead to increased rates of nutrient cycling, critical for the functioning of the **microbial loop** (*see section 29.1* and *figure 29.4*). In this process, organic matter produced through photosynthetic and chemotrophic activity is mineralized before it reaches the higher consumers, allowing the minerals to be made available to the primary producers, in a "loop." This is important in freshwater, marine, and terrestrial environments. Ingestion and short-term retention of bacteria also is critical for functioning of ciliates in the rumen, where methanogenic bacteria contribute to the health of the ciliates by decreasing toxic hydrogen levels through using H_2 to produce methane, which then is passed from the rumen.

Predation also can provide a protective, high-nutrient environment for particular prey. Ciliates ingest *Legionella* and protect this important pathogen from chlorine, which often is used in an attempt to control *Legionella* in cooling towers and air-conditioning units. The ciliate serves as a reservoir host. *Legionella pneumophila* also has been found to have a greater potential to invade macrophages and epithelial cells after predation, indicating that ingestion not only provides protection but also may make the bacterium a better pathogen. A similar phenomenon of survival in protozoa been observed for *Mycobac-*

Table 28.3 The Many Faces of Predation

Predation Result	Example
Digestion	The microbial loop. Soluble organic matter from primary producers is normally used by bacteria, which become a particulate food source for higher consumers. Flagellates and ciliates prey on these bacteria and digest them, making the nutrients they contain available again in mineral form for use in primary production, creating the microbial loop. In this way a large portion of the carbon fixed by the photosynthetic microbes is mineralized and recycled (thus the term microbial loop) and does not reach the higher trophic levels of the ecosystem (*see figure 29.4*).
	Predation also can reduce the density-dependent stress factors in prey populations, allowing more rapid growth and turnover of the prey than would occur if the predator were not active.
Retention	Bacteria retained within the predator serve a useful purpose, as in the transformation of toxic hydrogen produced by ciliates in the rumen to harmless methane. Also, trapping of chloroplasts (kleptochloroplasty) by protozoa provides the predator with photosynthate.
Protection and increased fitness	The intracellular survival of *Legionella* ingested by ciliates protects it from stresses such as heating and chlorination. Ingestion also results in increased pathogenicity when the prey is again released to the external environment, and this may be required for infection of humans. The predator serves as a reservoir host.
	Nanoplankton may be ingested by zooplankton and grow in the zooplankton digestive system. They are then released to the environment in a fitter state. Dissemination to new locations also occurs.

terium avium, a pathogen of worldwide concern. These protective aspects of predation have major implications for survival and control of disease-causing microorganisms in the biofilms present in water supplies and air-conditioning systems. In marine systems the ingestion of nanoplankton by zooplankton provides a nutrient-rich environment that allows nanoplankton reproduction in the digestive tract and promotes dissemination in the environment. A similar process occurs after bacteria are ingested by polychaetes (segmented worms found mostly in marine environments).

Fungi often show interesting predatory skills. Some fungi can trap protozoa by the use of sticky hyphae or knobs, sticky networks of hyphae, or constricting or nonconstricting rings. A classic example is *Arthrobotrys,* which traps nematodes by use of constricting rings. After the nematode is trapped, hyphae grow into the immobilized prey and the cytoplasm is used as a nutrient. Other fungi have conidia that, after ingestion by an unsuspecting prey, grow and attack the susceptible host from inside the intestinal tract. In this situation the fungus penetrates the host cells in a complex interactive process.

Thus predation, which usually has a fatal and final outcome for an individual prey organism, has a wide range of beneficial effects on prey populations, and is critical in the functioning of natural environments.

Parasitism

Parasitism is one of the most complex microbial interactions; the line between parasitism and predation is difficult to define (figure 28.1; *see also section 34.1*). This is a relationship in which one of a pair benefits from the other, and the host is usually harmed. This can involve nutrient acquisition and/or physical maintenance in or on the host. In parasitism there is a degree of coexistence of the parasite in association with the host. Depending on the equilibrium between the two organisms, this may shift and what might have been a stable parasitic relationship may then become a pathogenic one which can be defined as predation.

Some bacterial viruses can establish a lysogenic relationship with their hosts, and the viruses, in their prophage state, can confer positive new attributes on the host bacteria, as occurs with toxin production by *Corynebacterium diphtheriae* (*see sections 17.5 and 34.3*). Parasitic fungi include *Rhizophydium sphaerocarpum* with the alga *Spyrogyra.* Also, *Rhizoctonia solani* is a parasite of *Mucor* and *Pythium,* which is important in **biocontrol processes,** the use of one microorganism to control another. Human diseases caused by viruses, bacteria, fungi, and protozoa are discussed in chapters 38 through 40.

1. Define predation and parasitism. How are these similar and different?
2. How can a predator confer positive benefits on its prey? Think of the responses of individual organisms versus populations as you consider this question.
3. What are examples of parasites that are important in microbiology?

Amensalism

Amensalism (from the Latin for *not* at the same table) describes the negative effect that one organism has on another organism as shown in figure 28.1. This is a unidirectional process based on the release of a specific compound by one organism which has a negative effect on another organism. A classic example of amensalism is the production of antibiotics that can inhibit or kill a susceptible microorganism (**figure 28.16*a***). The attine ant-fungal mutualistic relationship is promoted by antibiotic-producing bacteria that are maintained in the fungal garden system (figure 28.16*b*). In this case a streptomycete produces an antibiotic that controls *Escovopsis,* a persistent parasitic fungus that can destroy the ant's fungal garden. This unique amensalistic process appears to have evolved 50 million years ago in South America.

Other important amensalistic relationships involve microbial production of specific organic compounds that disrupt cell wall or plasma membrane integrity. These include the bacteriocins (*see p. 297, 712*). These substances are of increasing interest as food additives for controlling growth of undesired pathogens (*see section 41.3*). Antibacterial peptides can be released by the host and microorganisms in the intestine. These molecules, called cecropins in insects and defensins in mammals, recently have been recognized as effector molecules that play significant roles in innate immunity (*see p. 720*). In animals these molecules are released by phagocytes and intestinal cells, and are as powerful as tetracyclines. Finally, metabolic products, such as organic acids formed in fermentation, can produce amensalistic effects. These compounds inhibit growth by changing the environmental pH, for example, during natural milk spoilage (*see section 41.2*).

Competition

Competition arises when different microorganisms within a population or community try to acquire the same resource, whether this is a physical location or a particular limiting nutrient (figure 28.1). This principle of competition was studied by E. F. Gause, who in 1934 described this as the **competitive exclusion principle.** He found that if the two competing ciliates overlapped too much in terms of their resource use, one of the two protozoan populations was excluded. In chemostats (*see section 6.3*), we may see competition for a limiting nutrient among microorganisms with transport systems of differing affinity. This can lead to the exclusion of the slower-growing population under a particular set of conditions. If the dilution rate is changed, the previously slower-growing population may become dominant. Often two microbial populations that appear to be similar nevertheless coexist. In these cases there is a subtle difference in the characteristics of the microorganisms or their microenvironments that make this coexistence possible.

1. What is the origin of the term amensalism?
2. What are bacteriocins?
3. What is the competitive exclusion principle?

(**b**) A schematic diagram describing the use of antibiotic-producing streptomycetes by ants to control fungal parasites in their fungal garden.

Symbioses in Complex Systems

It should be emphasized that the symbiotic interactions discussed in this section do not occur independently. Each time a microorganism interacts with other organisms and their environments, a series of feedback responses occurs in the larger biotic community that will impact other parts of ecosystems. As an illustration, the interactions between the nematode *Eubostrichus parasitiferus* and its protocooperative sulfide-oxidizing bacterium (p. 606) involves a series of symbiotic interactions, as shown in **figure 28.17.** In this case, the protocooperative interaction between the nematodes and the sulfide-oxidizing epibiont is influenced by the population size of the associated bacterium, and whether it is host-associated or free-living. This equilibrium between host-associated and free-

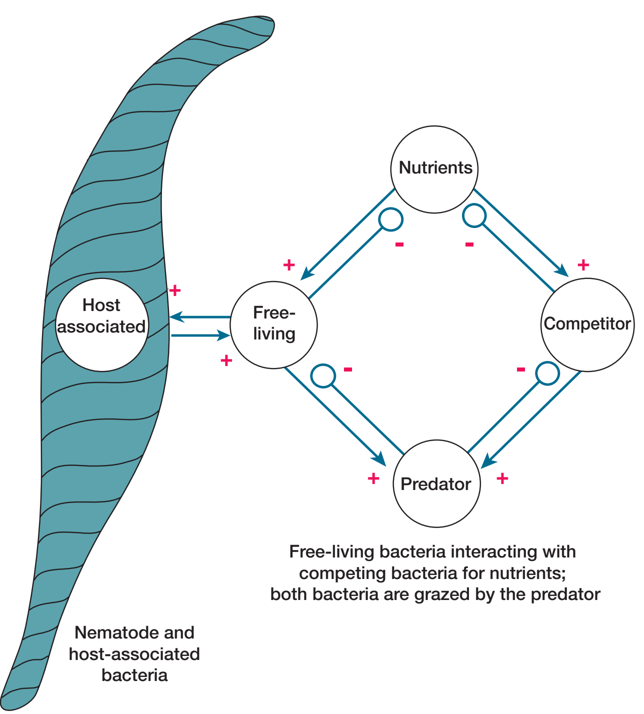

Figure 28.17 Complex Interactions in Microbial Ecology. Interactions between the marine nematode *Eubostrichus parasitiferus* and its host-associated and free-living protocooperative bacteria are influenced by levels of nutrients, as well as by other bacteria competing for these nutrients. Predators, in turn, use both the free-living protocooperative bacteria and the competing bacteria as food sources, leading to complex feedback responses in this dynamic ecosystem. Arrows show positive or enhancing interactions; lines with small circles indicate negative or damping interactions.

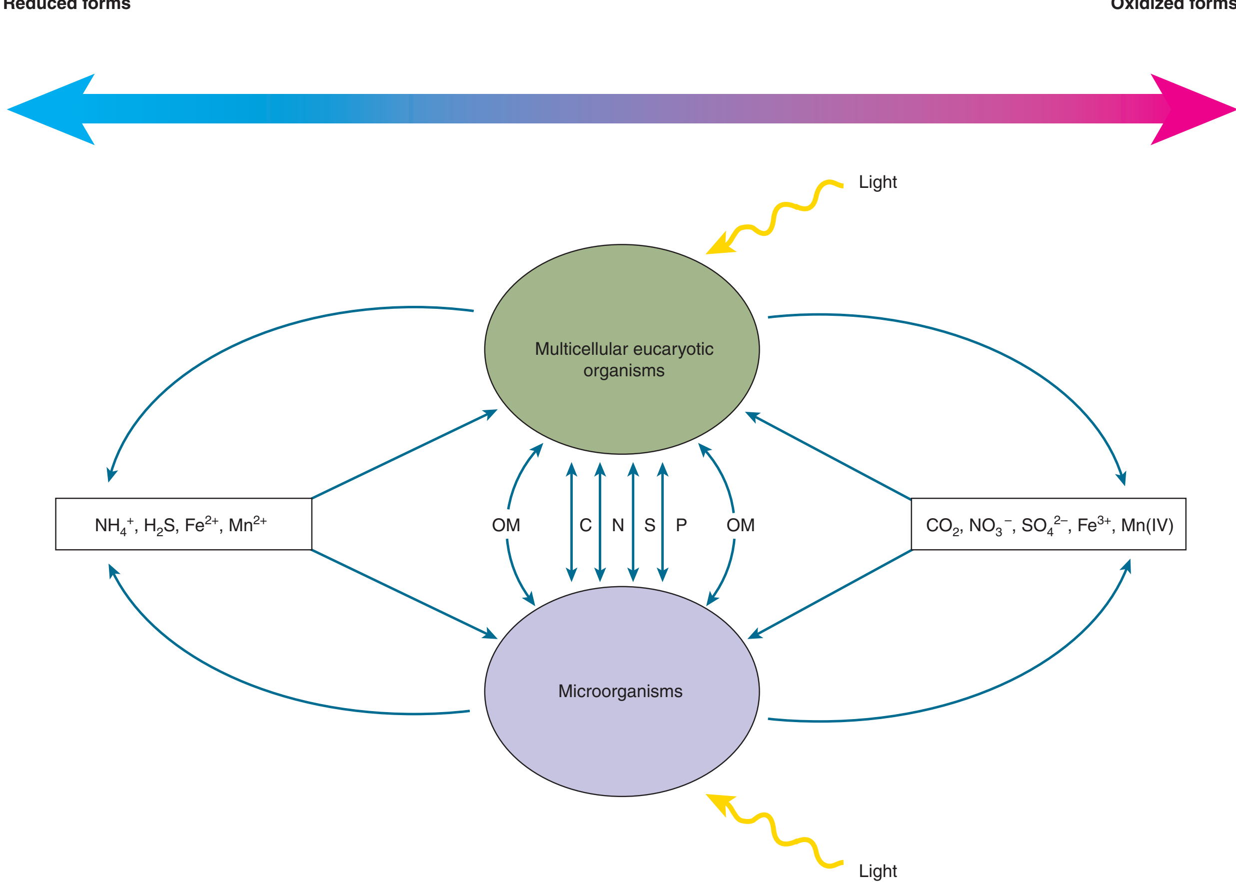

Figure 28.18 Macrobiogeochemistry: A Cosmic View of Mineral Cycling in Microorganisms, Higher Organisms, and the Abiotic Chemical World. All biogeochemical cycles are linked, with energy being obtained from light and pairs of reduced and oxidized compounds. Only major flows are shown. See individual cycles for details of energetic-linked relationships. The forms that move between the microorganisms and multicellular organisms can vary. The broad concept is that all cycles are linked. The biotic components include both living forms and those that have died/senesced and which are being processed. Flows from lithogenic sources are important for phosphorus. Methane transformations are only microbial (see discussion of the carbon cycle). Organic matter (OM).

living bacteria is controlled by a series of feedback processes that involve competition for sulfide with other bacteria, and predation on the epibiont and on the competing bacteria. Thus the equilibrium observed at any time is the result of a series of interactions, involving protocooperation, predation, and competition.

28.3 Nutrient Cycling Interactions

Microorganisms, in the course of their growth and metabolism, interact with each other in the cycling of nutrients, including carbon, sulfur, nitrogen, phosphorus, iron, and manganese. This nutrient cycling, called **biogeochemical cycling** when applied to the environment, involves both biological and chemical processes. Nutrients are transformed and cycled, often by oxidation-reduction reactions (*see section 8.5*) that can change the chemical and physical characteristics of the nutrients. All of the biogeochemical cycles are linked (**figure 28.18**), and the metabolism-related transformations of these nutrients have global-level impacts.

The major reduced and oxidized forms of the most important elements are noted in **table 28.4,** together with their valence states. Significant gaseous components occur in the carbon and nitrogen cycles and, to a lesser extent, in the sulfur cycles. Thus a soil, aquatic, or marine microorganism often can fix gaseous forms of carbon and nitrogen compounds. In the "sedimentary" cycles, such as that for iron, there is no gaseous component.

Carbon Cycle

Carbon can be present in reduced forms, such as methane (CH_4) and organic matter, and in more oxidized forms, such as carbon monoxide (CO) and carbon dioxide (CO_2). The major pools

Table 28.4 The Major Forms of Carbon, Nitrogen, Sulfur, and Iron Important in Biogeochemical Cycling

		Major Forms and Valences				
Cycle	**Significant Gaseous Component Present?**	**Reduced Forms**	**Intermediate Oxidation State Forms**			**Oxidized Forms**
C	Yes	CH_4 (–4)	CO (+2)			CO_2 (+4)
N	Yes	NH_4^+, organic N (–3)	N_2 (0)	N_2O (+1)	NO_2^- (+3)	NO_3^- (+5)
S	Yes	H_2S, SH groups in organic matter (–2)	S^0 (0)	$S_2O_3^{2-}$ (+2)	SO_3^{2-} (+4)	SO_4^{2-} (+6)
Fe	No	Fe^{2+} (+2)				Fe^{3+} (+3)

Note: The carbon, nitrogen, and sulfur cycles have significant gaseous components, and these are described as gaseous nutrient cycles. The iron cycle does not have a gaseous component, and this is described as a sedimentary nutrient cycle. Major reduced, intermediate oxidation state, and oxidized forms are noted, together with valences.

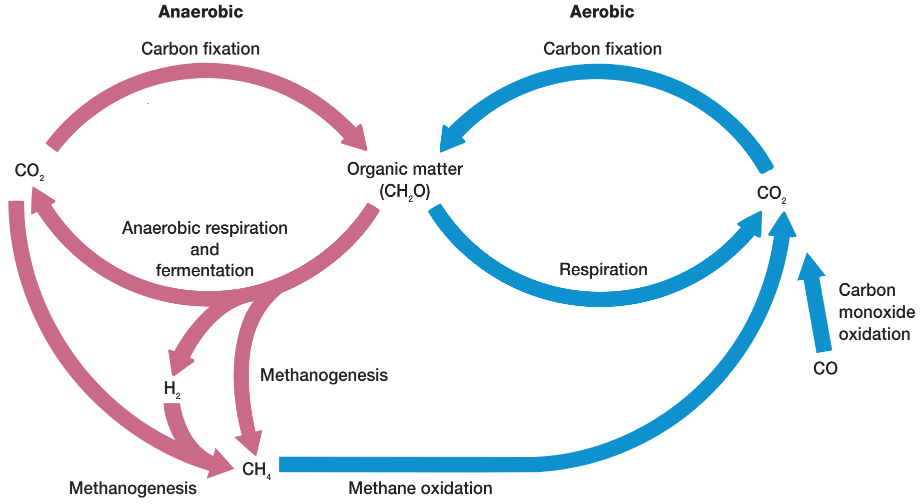

Figure 28.19 The Basic Carbon Cycle in the Environment. Carbon fixation can occur through the activities of photoautotrophic and chemoautotrophic microorganisms. Methane can be produced from inorganic substrates ($CO_2 + H_2$) or from organic matter. Carbon monoxide (CO)—produced by sources such as automobiles and industry—is returned to the carbon cycle by CO-oxidizing bacteria. Aerobic processes are noted with blue arrows, and anaerobic processes are shown with red arrows. Reverse methanogenesis will be discussed in chapter 29.

present in an integrated basic carbon cycle are shown in **figure 28.19.** Reductants (e.g., hydrogen, which is a strong reductant) and oxidants (e.g., O_2) influence the course of biological and chemical reactions involving carbon. Hydrogen can be produced during organic matter degradation especially under anaerobic conditions when fermentation occurs. If hydrogen and methane are generated, they can move upward from anaerobic to aerobic areas. This creates an opportunity for aerobic hydrogen and methane oxidizers to function.

Methane levels in the atmosphere have been increasing approximately 1% per year, from 0.7 to 1.6 to 1.7 ppm (volume) in the last 300 years. This methane is derived from a variety of sources. If an aerobic water column is above the anaerobic zone where the methanogens are located, the methane can be oxidized before it reaches the atmosphere. In many situations, such as in rice paddies without an overlying aerobic water zone, the methane will be released directly to the atmosphere, thus contributing to global atmospheric methane increases. Rice paddies, ruminants, coal mines, sewage treatment plants, landfills, and marshes are important sources of methane. Anaerobic microorganisms such as *Methanobrevibacter* in the guts of termites also can contribute to methane production.

Physiology of aerobic hydrogen and methane utilizers (pp. 193, 502–3)

Table 28.5 Complex Organic Substrate Characteristics That Influence Decomposition and Degradability

			Elements Present in Large Quantity					*Degradation*	
Substrate	**Basic Subunit**	**Linkages (if Critical)**	**C**	**H**	**O**	**N**	**P**	**With O_2**	**Without O_2**
Starch	Glucose	α(1→ 4) α(1→ 6)	+	+	+	–	–	+	+
Cellulose	Glucose	β(1→ 4)	+	+	+	–	–	+	+
Hemicellulose	C6 and C5 monsaccharides	β(1→ 4), β(1→ 3), β(1→ 6)	+	+	+	–	–	+	+
Lignin	Phenylpropane	C–C, C–O bonds	+	+	+	–	–	+	–
Chitin	*N*-acetylglucosamine	β(1→ 4)	+	+	+	+	–	+	+
Protein	Amino acids	Peptide bonds	+	+	+	+	–	+	+
Hydrocarbon	Aliphatic, cyclic, aromatic		+	+	–	–	–	+	+–
Lipids	Glycerol, fatty acids; some contain phosphate and nitrogen	Esters	+	+	+	+	+	+	+
Microbial biomass		Varied	+	+	+	+	+	+	+
Nucleic acids	Purine and pyrimidine bases, sugars, phosphate	Phosphodiester and *N*-glycosidic bonds	+	+	+	+	+	+	+

Carbon fixation occurs through the activities of cyanobacteria and green algae, photosynthetic bacteria (e.g., *Chromatium* and *Chlorobium*), and aerobic chemolithoautotrophs.

In the carbon cycle depicted in figure 28.19, no distinction is made between different types of organic matter that are formed and degraded. This is a marked oversimplification because organic matter varies widely in physical characteristics and in the biochemistry of its synthesis and degradation. Organic matter varies in terms of elemental composition, structure of basic repeating units, linkages between repeating units, and physical and chemical characteristics.

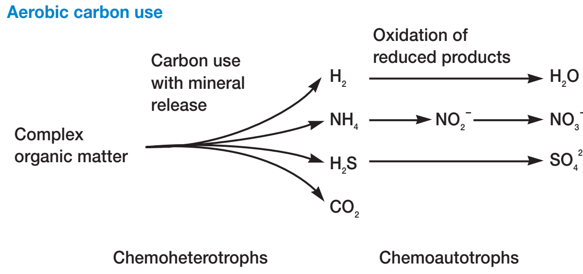
The formation of organic matter is discussed in chapters 10 through 12. The degradation of this organic matter, once formed, is influenced by a series of factors. These include (1) nutrients present in the environment; (2) abiotic conditions (pH, oxidation-reduction potential, O_2, osmotic conditions), and (3) the microbial community present.

The major complex organic substrates used by microorganisms are summarized in **table 28.5.** Of these, only previously grown microbial biomass contains all of the nutrients required for microbial growth. Chitin, protein, microbial biomass, and nucleic acids contain nitrogen in large amounts. If these substrates are used for growth, the excess nitrogen and other minerals that are not used in the formation of new microbial biomass will be released to the environment, in the process of **mineralization.** This is the process in which organic matter is decomposed to release simpler, inorganic compounds (e.g., CO_2, NH_4^+, CH_4, H_2).

The other complex substrates in table 28.5 contain only carbon, hydrogen, and oxygen. If microorganisms are to grow by using these substrates, they must acquire the remaining nutrients they need for biomass synthesis from the environment; in the process of **immobilization.**

The oxygen relationships for the use of these substrates also are of interest, because most of them can be degraded easily with or without oxygen present. The exceptions are hydrocarbons and lignin. Hydrocarbons are unique in that microbial degradation, especially of straight-chained and branched forms, involves the initial addition of molecular O_2. Recently, anaerobic degradation of hydrocarbons with sulfate or nitrate as oxidants has been observed. With sulfate present, organisms of the genus *Desulfovibrio* are active. This occurs only slowly and with microbial communities that have been exposed to these compounds for extended periods. Such degradation may have resulted in the sulfides that are present in "sour gases" associated with petroleum.

Lignin, an important structural component in mature plant materials, is a complex amorphous polymer based on a phenylpropane building block, linked by carbon-carbon and carbon-ether bonds. It makes up approximately 1/3 of the weight of wood. This is a special case in which biodegradability is dependent on O_2 availability. There often is no significant degradation because most filamentous fungi that degrade native lignin in situ can function only under aerobic conditions where oxidases can act by the release of active oxygen species. Lignin's lack of biodegradability under anaerobic conditions results in accumulation of lignified materials, including the formation of peat bogs and muck soils. This absence of lignin degradation under anaerobic conditions also is important in construction. Large masonry structures often are built on swampy sites by driving in wood pilings below the water table and placing the building footings on the pilings. As long as the foundations remain water-saturated and anaerobic, the structure is stable. If the water table drops, however, the pilings will begin to rot and the structure will be threatened. Similarly, the cleanup of harbors can lead to decomposition of costly docks built with wooden pilings due to increased aerobic degradation of wood by filamentous fungi. Rumen function provides a final example of the relationship between



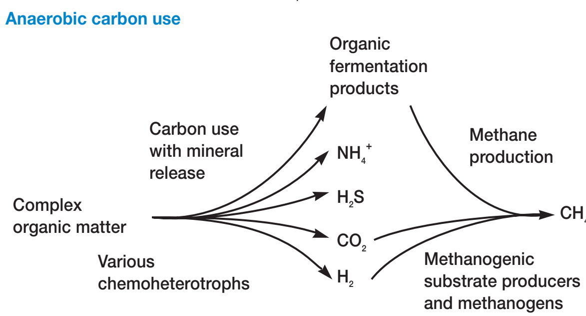


Figure 28.20 The Influence of Oxygen on Organic Matter Decomposition. Microorganisms form different products when breaking down complex organic matter aerobically than they do under anaerobic conditions. Under aerobic conditions oxidized products accumulate, while reduced products accumulate anaerobically. These reactions also illustrate commensalistic transformations of a substrate, where the waste products of one group of microorganisms can be used by a second type of microorganism.

lignin degradation and oxygen. The rumen (pp. 602–4), being almost free of oxygen, does not allow significant degradation of lignin present in animal feeds. The use of sugars and carbohydrates in the rumen leaves an inactive residue that can improve soils more effectively than the original feeds.

Patterns of microbial degradation are important in many habitats. They contribute to the accumulation of petroleum products, the formation of bogs, and the preservation of valuable historical objects.

The presence or absence of oxygen also affects the final products that accumulate when organic substrates have been processed by microorganisms and mineralized either under aerobic or anaerobic conditions. Under aerobic conditions, oxidized products such as nitrate, sulfate, and carbon dioxide (**figure 28.20**) will result from microbial degradation of complex organic matter. In comparison, under anaerobic conditions reduced end products tend to accumulate, including ammonium ion, sulfide, and methane.

These oxidized and reduced forms, if they remain in the aerobic or anaerobic environments where they were formed, will usually only serve as nutrients. If mixing occurs, oxidized species might be moved to a more reduced zone or reduced species might be moved to a more oxidized zone. Under such circumstances, additional energetic possibilities (linking of oxidants and reductants) will be created, leading to succession and further nutrient cycling as these mixed oxidants and reductants are exploited by the microbial community.

1. What is biogeochemical cycling?
2. Which organic polymers discussed in this section do and do not contain nitrogen?
3. What is unique about lignin and its degradation?
4. Define mineralization and immobilization and give examples.
5. What C, N, and S forms will accumulate after anaerobic degradation of organic matter?

Sulfur Cycle

Microorganisms contribute greatly to the sulfur cycle, a simplified version of which is shown in **figure 28.21.** Photosynthetic microorganisms transform sulfur by using sulfide as an electron source, allowing *Thiobacillus* and similar chemolithoautotrophic genera to function (*see pp. 193–94 and 496–98*). In contrast, when sulfate diffuses into reduced habitats, it provides an opportunity for different groups of microorganisms to carry out **sulfate reduction.** For example, when a usable organic reductant is present, *Desulfovibrio* uses sulfate as an oxidant (*see pp. 190 and 507–10*). This use of sulfate as an external electron acceptor to form sulfide, which accumulates in the environment, is an example of a **dissimilatory reduction** process and anaerobic respiration. In comparison, the reduction of sulfate for use in amino acid and protein biosynthesis is described as an **assimilatory reduction** process (*see section 10.4*). Other microorganisms have been found to carry out dissimilatory elemental sulfur reduction. These include *Desulfuromonas* (*see pp. 507–10*), thermophilic archaea (*see chapter 20*), and also cyanobacteria in hypersaline sediments. Sulfite is another critical intermediate that can be reduced to sulfide by a wide variety of microorganisms, including *Alteromonas* and *Clostridium,* as well as *Desulfovibrio* and *Desulfotomaculum. Desulfovibrio* is usually considered as an obligate anaerobe. Recent research, however, has shown that this interesting organism also respires using oxygen, when it is present at a dissolved oxygen level of 0.04%.

In addition to the very important photolithotrophic sulfur oxidizers such as *Chromatium* and *Chlorobium,* which function under strict anaerobic conditions in deep water columns, a large and varied group of bacteria carry out **aerobic anoxygenic photosynthesis.** These aerobic anoxygenic phototrophs use bacteriochlorophyll *a* and carotenoid pigments and are found in marine and freshwater environments; they are often components of microbial mat communities. Important genera include *Erythromonas, Roseococcus, Porphyrobacter,* and *Roseobacter.*

"Minor" compounds in the sulfur cycle play major roles in biology. An excellent example is dimethylsulfoniopropionate (DMSP), which is used by bacterioplankton (floating bacteria) as a sulfur source for protein synthesis, and which is transformed to dimethylsulfide (DMS), a volatile sulfur form that can affect atmospheric processes.

When pH and oxidation-reduction conditions are favorable, several key transformations in the sulfur cycle also occur as the

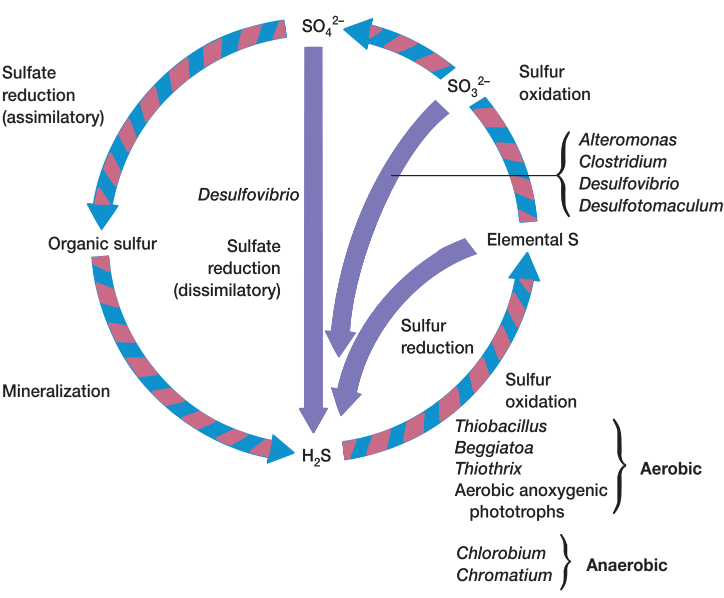

Figure 28.21 The Basic Sulfur Cycle. Photosynthetic and chemosynthetic microorganisms contribute to the environmental sulfur cycle. Sulfate and sulfite reductions carried out by *Desulfovibrio* and related microorganisms, noted with purple arrows, are dissimilatory processes. Sulfate reduction also can occur in assimilatory reactions, resulting in organic sulfur forms. Elemental sulfur reduction to sulfide is carried out by *Desulfuromonas,* thermophilic archaea, or cyanobacteria in hypersaline sediments. Sulfur oxidation can be carried out by a wide range of aerobic chemotrophs and by aerobic and anaerobic phototrophs.

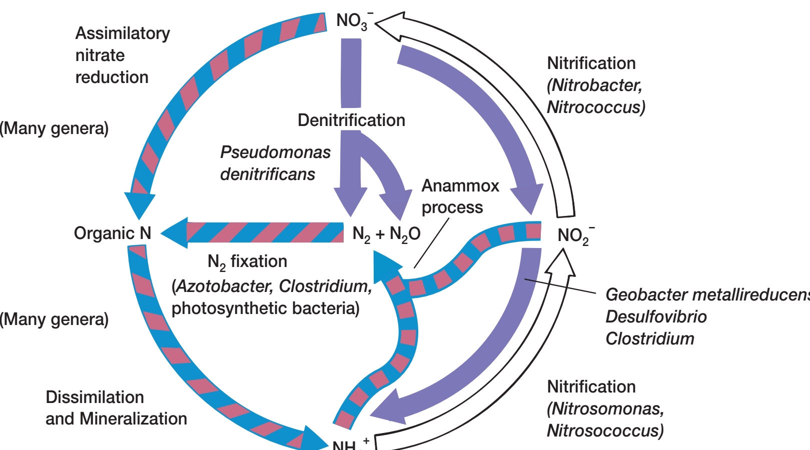

Figure 28.22 The Basic Nitrogen Cycle. Flows that occur predominantly under aerobic conditions are noted with open arrows. Anaerobic processes are noted with solid bold arrows. Processes occurring under both aerobic and anaerobic conditions are marked with cross-barred arrows. The anammox reaction of NO_2^- and NH_4^+ to yield N_2 is shown. Important genera contributing to the nitrogen cycle are given as examples.

result of chemical reactions in the absence of microorganisms. An important example of such an abiotic process is the oxidation of sulfide to elemental sulfur. This takes place rapidly at a neutral pH, with a half-life of approximately 10 minutes for sulfide at room temperature.

Nitrogen Cycle

Several important aspects of the basic nitrogen cycle will be discussed: the processes of nitrification, denitrification, and nitrogen fixation (**figure 28.22**). It should be emphasized that this is a "basic" nitrogen cycle. Although not mentioned in the figure, the heterotrophs can carry out nitrification, and some of these heterotrophs combine nitrification with anaerobic denitrification, thus oxidizing ammonium ion to N_2O and N_2 with depressed oxygen levels. The occurrence of anoxic ammonium ion oxidation (anammox is the term used for the commercial process) means that nitrification is not only an aerobic process. Thus as we learn more about the biogeochemical cycles, including that of nitrogen, the simple cycles of earlier textbooks are no longer accurate representations of biogeochemical processes.

Nitrification is the aerobic process of ammonium ion (NH_4^+) oxidation to nitrite (NO_2^-) and subsequent nitrite oxidation to nitrate (NO_3^-). Bacteria of the genera *Nitrosomonas* and *Nitrosococcus,* for example, play important roles in the first step, and *Nitrobacter* and related chemolithoautotrophic bacteria carry out the second step. Recently *Nitrosomonas eutropha* has been found to oxidize ammonium ion anaerobically to nitrite and nitric oxide (NO) using nitrogen dioxide (NO_2) as an oxidant in a denitrification-related reaction. In addition, **heterotrophic nitrification** by

bacteria and fungi contributes significantly to these processes in more acidic environments. Nitrification and nitrifiers (p. 193)

The process of **denitrification** requires a different set of environmental conditions. This dissimilatory process, in which nitrate is used as an oxidant in anaerobic respiration, usually involves heterotrophs such as *Pseudomonas denitrificans.* The major products of denitrification include nitrogen gas (N_2) and nitrous oxide (N_2O), although nitrite (NO_2^-) also can accumulate. Nitrite is of environmental concern because it can contribute to the formation of carcinogenic nitrosamines. Finally, nitrate can be transformed to ammonia in dissimilatory reduction by a variety of bacteria, including *Geobacter metallireducens, Desulfovibrio* spp., and *Clostridium.* Denitrification and anaerobic respiration (pp. 190–91)

Nitrogen assimilation occurs when inorganic nitrogen is used as a nutrient and incorporated into new microbial biomass. Ammonium ion, because it is already reduced, can be directly incorporated without major energy costs. However, when nitrate is assimilated, it must be reduced with a significant energy expenditure. In this process nitrite may accumulate as a transient intermediate. The biochemistry of nitrogen assimilation (pp. 210–14)

Nitrogen fixation can be carried out by aerobic or anaerobic procaryotes and does not occur in eucaryotes. Under aerobic conditions a wide range of free-living microbial genera (*Azotobacter, Azospirillum*) contribute to this process. Under anaerobic conditions the most important free-living nitrogen fixers are members of the genus *Clostridium.* Nitrogen fixation by cyanobacteria such as *Anabaena* and *Oscillatoria* can lead to the enrichment of aquatic environments with nitrogen. These nutrient-enrichment processes are discussed in chapter 29. In addition, nitrogen fixation can occur through the activities of bacteria that develop symbiotic associations with plants. These associations include *Rhizobium* and *Bradyrhizobium* with legumes, *Frankia* in association with many woody shrubs, and *Anabaena,* with *Azolla,* a water fern important in rice cultivation. The establishment of the *Rhizobium*-legume association (pp. 675–78)

The nitrogen-fixation process involves a sequence of reduction steps that require major energy expenditures. Ammonia, the product of nitrogen reduction, is immediately incorporated into organic matter as an amine. Reductive processes are extremely sensitive to O_2 and must occur under anaerobic conditions even in aerobic microorganisms. Protection of the nitrogen-fixing enzyme is achieved by means of a variety of mechanisms, including physical barriers, as occurs with heterocysts in some cyanobacteria (*see section 21.3*), O_2 scavenging molecules, and high rates of metabolic activity. The biochemistry of nitrogen fixation (pp. 212–14)

As shown in figure 28.22, microorganisms have been isolated that can couple the anaerobic oxidation of NH_4^+ with the reduction of NO_2^-, to produce gaseous nitrogen, in what has been termed the **anammox process** (*an*oxic *amm*onia *ox*idation). This may provide a means by which nitrogen can be removed from sewage plant effluents to decrease nitrogen flow to sensitive freshwater and marine ecosystems. It has been suggested that chemolithotrophic members of the planctomycetes (*see section 21.4*) play a role in this process.

1. What are the major oxidized and reduced forms of sulfur and nitrogen?
2. Diagram a simple sulfur cycle.
3. Why is dimethylsulfide (DMS), considered to be a "minor" part of the sulfur cycle, of such environmental importance?
4. What is aerobic anoxygenic photosynthesis?
5. What are nitrification, denitrification, nitrogen fixation, and the anammox process?

Iron Cycle

The iron cycle (figure 28.23) includes several different genera that carry out iron oxidations, transforming ferrous ion (Fe^{2+}) to ferric ion (Fe^{3+}). *Thiobacillus ferrooxidans* carries out this process under acidic conditions, *Gallionella* is active under neutral pH conditions, and *Sulfolobus* functions under acidic, thermophilic conditions. Much of the earlier literature suggested that additional genera could oxidize iron, including *Sphaerotilus* and *Leptothrix.* These two genera are still termed "iron bacteria" by many nonmicrobiologists. Confusion about the role of these genera resulted from the occurrence of the chemical oxidation of ferrous ion to ferric ion (forming insoluble iron precipitates) at neutral pH values, where microorganisms also grow on organic substrates. These microorganisms are now classified as chemoheterotrophs.

Recently microbes have been found that oxidize Fe^{2+} using nitrate as an electron acceptor. This process occurs in aquatic sediments with depressed levels of oxygen and may be another route by which large zones of oxidized iron have accumulated in environments with lower oxygen levels.

Iron reduction occurs under anaerobic conditions resulting in the accumulation of ferrous ion. Although many microorganisms can reduce small amounts of iron during their metabolism, most iron reduction is carried out by specialized iron-respiring microorganisms such as *Geobacter metallireducens, Geobacter sulfurreducens, Ferribacterium limneticum,* and *Shewanella putrefaciens,* which can obtain energy for growth on organic matter using ferric iron as an oxidant.

In addition to these relatively simple reductions to ferrous ion, some magnetotactic bacteria such as *Aquaspirillum magnetotacticum* (*see section 3.3*) transform extracellular iron to the mixed valence iron oxide mineral magnetite (Fe_3O_4) and construct intracellular magnetic compasses. Furthermore, dissimilatory iron-reducing bacteria accumulate magnetite as an extracellular product.

Magnetite has been detected in sediments, where it is present in particles similar to those found in bacteria, indicating a longer-term contribution of bacteria to iron cycling processes. Genes for magnetite synthesis have been cloned into other organisms, creating new magnetically sensitive microorganisms. Magnetotactic bacteria are now described as **magneto-aerotactic bacteria,** due to their using magnetic fields to migrate to the position in a bog or swamp where the oxygen level is best suited for their functioning. In the last decade new microorganisms have been discovered that use ferrous ion as an electron donor in anoxygenic photosynthesis. Thus, with production of ferric ion in lighted

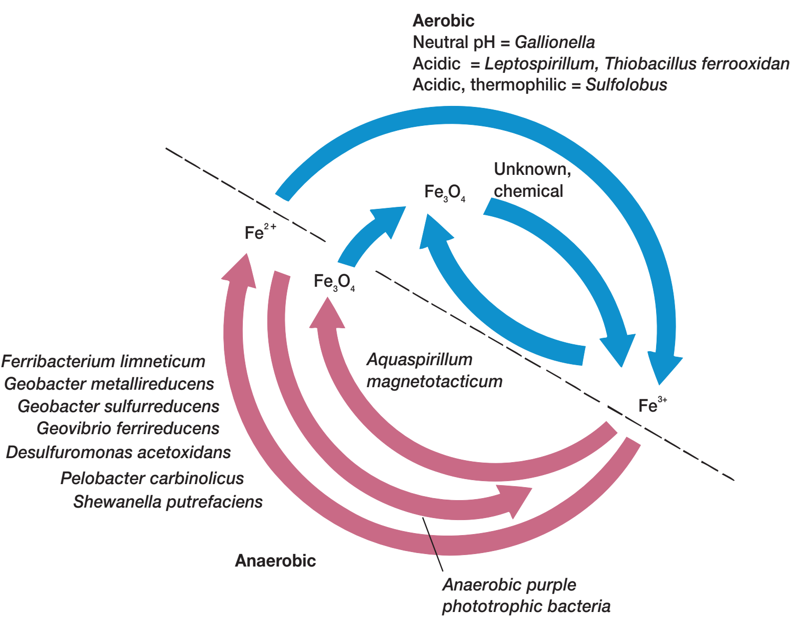

Figure 28.23 The Basic Iron Cycle. A simplified iron cycle with examples of microorganisms contributing to these oxidation and reduction processes. In addition to ferrous ion (Fe^{2+}) oxidation and ferric ion (Fe^{3+}) reduction, magnetite (Fe_3O_4), a mixed valence iron compound formed by magnetotactic bacteria is important in the iron cycle. Different microbial groups carry out the oxidation of ferrous ion depending on environmental conditions.

anaerobic zones by iron-oxidizing bacteria, the stage is set for subsequent chemotrophic-based iron reduction, such as by *Geobacter* and *Shewanella,* creating a strictly anaerobic oxidation/reduction cycle for iron.

Manganese Cycle

The importance of microorganisms in manganese cycling is becoming much better appreciated. The manganese cycle (**figure 28.24**) involves the transformation of manganous ion (Mn^{2+}) to MnO_2 (equivalent to manganic ion [Mn^{4+}]), which occurs in hydrothermal vents, bogs, and as an important part of rock varnishes. *Leptothrix, Arthrobacter, Pedomicrobium,* and the incompletely characterized "*Metallogenium*" are important in Mn^{2+} oxidation. *Shewanella, Geobacter,* and other chemoorganotrophs can carry out the complementary manganese reduction process.

Other Cycles and Cycle Links

Microorganisms can use a wide variety of additional metals as electron acceptors. Metals such as europium, tellurium, selenium, and rhodium can be reduced. Important microorganisms that reduce these metals include the photoorganotrophs *Rhodobacter, Rhodospirillum* and *Rhodopseudomonas.* For selenium, *Pseudomonas stutzeri, Thauera selenatis,* and *Wolinella succinogenes* are active. Such reductions can decrease the toxicity of a metal.

The microbial transformation of phosphorus involves primarily the transformation of phosphorus (+5 valence) from simple orthophosphate to various more complex forms, including polyphosphates found in metachromatic granules (*see p. 52*). A unique (and possibly microbial) product is phosphine (PH_3) with a −3 valence, which is liberated from swamps, soils, and marine regions and which ignites when exposed to air. This can then ignite methane

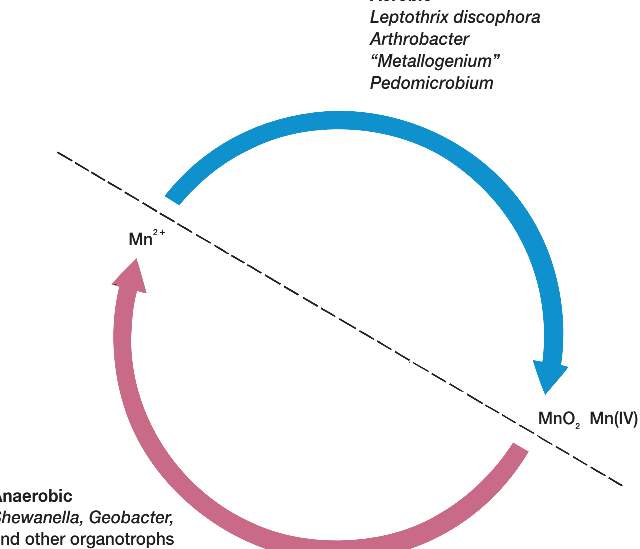

Figure 28.24 The Basic Manganese Cycle. Microorganisms make important contributions to the manganese cycle. Manganous ion (2+) is oxidized to manganic oxide (valence equivalent to 4+). Manganous oxide reduction is noted with a maroon arrow. Examples of organisms carrying out these processes are given.

produced in the same environment! The production of methane by anaerobic microorganisms will be discussed in the next chapter.

Having described the sulfur, iron, and manganese cycles as functioning independently, it is important to again emphasize that many microorganisms metabolically link these cycles by using

Table 28.6 Examples of Microorganism-Metal Interactions and Relations to Effects on Microorganisms and Homeothermic Animals

Metal Group	Metal		Interactions and Transformations: Microorganisms	Homeothermic Animals
Noble metals	Ag Au Pt	Silver Gold Platinum	Microorganisms can reduce ionic forms to the elemental state. Low levels of ionized metals released to the environment have antimicrobial activity.	Many of these metals can be reduced to elemental forms and do not tend to cross the blood-brain barrier. Silver reduction can lead to inert deposits in the skin.
Metals that form stable carbon metal bonds	As Hg Se	Arsenic Mercury Selenium	Microorganisms can transform inorganic and organic forms to methylated forms, some of which tend to bioaccumulate in higher trophic levels.	Methylated forms of some metals can cross the blood-brain barrier, resulting in neurological effects or death.
Other metals	Cu Zn Co	Copper Zinc Cobalt	In the ionized form, at higher concentrations, these metals can directly inhibit microorganisms. They are often required at lower concentrations as trace elements.	At higher levels, clearance from higher organisms occurs by reaction with plasma proteins and other mechanisms. Many of these metals serve as trace elements at lower concentrations.

commonly shared oxidants and reductants. For example, some sulfate-reducing microorganisms can reduce Fe^{3+} using H_2 or organic matter as a reductant and also can oxidize elemental sulfur to sulfate when Mn(IV) is present as an electron acceptor. The Mn(IV)-dependent production of sulfate under anaerobic conditions, carried out by *Desulfobulbus propionicus,* provides a way to link sulfur and manganese cycling anaerobically.

Recently, a unique energetic couple has been described by B. Schinck and M. Friedrich. They isolated a lithoautotrophic bacterium from anaerobic sediments that can link the oxidation of phosphite (PO_3^{3-}) to phosphate (PO_4^{3-}) with the reduction of sulfate to hydrogen sulfide. Schinck and Friedrich have suggested that this energetic cycle could have operated on the early Earth.

1. What major forms of iron, manganese, and phosphorus are important in biogeochemical cycling?
2. Why is *Aquaspirillum* considered to be a magneto-aerotactic bacterium?
3. What are some important microbial genera that contribute to manganese cycling?
4. What is phosphine? Under which conditions will it be produced?
5. Describe some links between oxidants and reductants that have been discovered recently.

Microorganisms and Metal Toxicity

In addition to metals such as iron and manganese, which are largely nontoxic to microorganisms and animals, there are a series of metals that have varied toxic effects on microorganisms and homeothermic animals. Microorganisms play important roles in modifying the toxicity of these metals (**table 28.6**).

The "metals" can be considered in broad categories. The "noble metals" tend not to cross the vertebrate blood-brain barrier but can have distinct effects on microorganisms. Microorganisms also can reduce ionic forms of noble metals to their elemental forms.

The second group includes metals or metalloids that microorganisms can methylate to form more mobile products called organometals. Some organometals can cross the blood-brain barrier and affect the central nervous system of vertebrates. Organometals contain carbon-metal bonds. These bonds are their unique identifying characteristics.

The mercury cycle is of particular interest and illustrates many characteristics of those metals that can be methylated. Mercury compounds were widely used in industrial processes over the centuries. One has only to think of Lewis Carroll's allusion to this problem when he wrote of the Mad Hatter in *Alice in Wonderland.* At that time mercury was used in the shaping of felt hats. Microorganisms methylated some of the mercury, thus rendering it more toxic to the hatmakers.

A devastating situation developed in southwestern Japan when large-scale mercury poisoning occurred in the Minamata Bay region because of industrial mercury released into the marine environment. Inorganic mercury that accumulated in bottom muds of the bay was methylated by anaerobic bacteria of the genus *Desulfovibrio* (**figure 28.25**). Such methylated mercury forms are volatile and lipid soluble, and the mercury concentrations increased in the food chain (by the process of **biomagnification**). The mercury was ultimately ingested by the human population, the "top consumers," through their primary food source—fish—leading to severe neurological disorders.

A similar situation has occurred in many of the freshwater lakes in the north-central United States and in Canada, where mercury compounds were used to control microbial growth in pulp mills. Even decades later the fish in lakes downstream from these pulp mills cannot yet be used for food, and fishing is only for recreation.

The third group of metals occurs in ionic forms directly toxic to microorganisms. The metals in this group also can affect more complex organisms. However, plasma proteins react with the ionic forms of these metals and aid in their excretion unless excessive long-term contact and ingestion occur. Relatively high doses of these metals are required to cause lethal effects. At lower concentrations many of these metals serve as required trace elements.

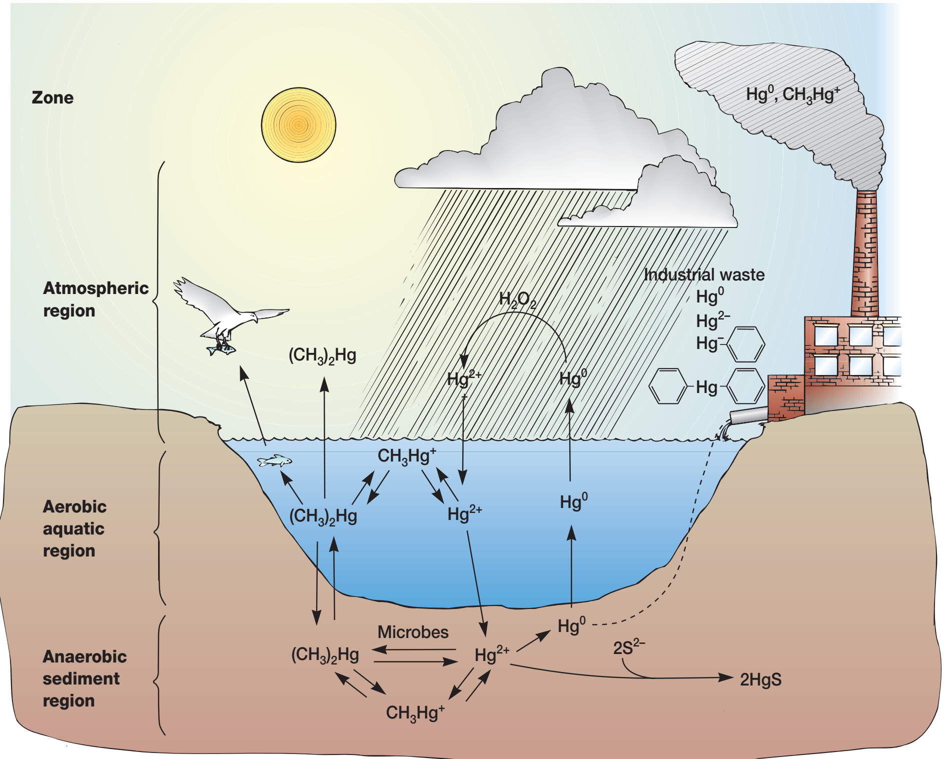

Figure 28.25 The Mercury Cycle. Interactions between the atmosphere, aerobic water, and anaerobic sediment are critical. Microorganisms in anaerobic sediments, primarily *Desulfovibrio,* can transform mercury to methylated forms that can be transported to water and the atmosphere. These methylated forms also undergo biomagnification. The production of volatile elemental mercury (Hg^0) releases this metal to waters and the atmosphere. Sulfide, if present in the anaerobic sediment, can react with ionic mercury to produce less soluble HgS.

The differing sensitivity of more complex organisms and microorganisms to metals forms the basis of many antiseptic procedures developed over the last 150 years (*see section 7.5*). The noble metals, although microorganisms tend to develop resistance to them, continue to be used in preference to antibiotics in some medical applications. Examples include the treatment of burns with silver-containing antimicrobial compounds and the use of silver-plated catheters.

1. What are examples of the three groups of metals in terms of their toxicity to microorganisms and homeothermic animals?
2. How can microbial activity render some metals more or less toxic to warm-blooded animals?
3. Why do metals such as mercury have such major effects on higher organisms?

28.4 The Physical Environment

Microorganisms, as they interact with each other and with other organisms in biogeochemical cycling, also are influenced by their immediate physical environment, whether this might be soil, water, the deep marine environment, or a plant or animal host. It is important to consider the specific environments where microorganisms interact with each other, other organisms, and the physical environment.

The Microenvironment and Niche

The specific physical location of a microorganism is its **microenvironment.** In this physical microenvironment, the flux of required oxidants, reductants, and nutrients to the actual location of the microorganism can be limited. At the same time, waste products may not be able to diffuse away from the microorganism at rates sufficient to avoid growth inhibition by high waste product concentrations. These fluxes and gradients create a unique **niche,** which includes the microorganism, its physical habitat, the time of resource use, and the resources available for microbial growth and function (**figure 28.26**).

This physically structured environment also can limit the predatory activities of protozoa. If the microenvironment has pores with diameters of 3 to 6 μm, it will protect bacteria in the pores from predation, while allowing diffusion of nutrients and waste products. If the pores are larger, perhaps greater than 6 μm in diameter, protozoa may be able to feed on the bacteria. It is important to emphasize that microorganisms can create their own microenvironments and niches.

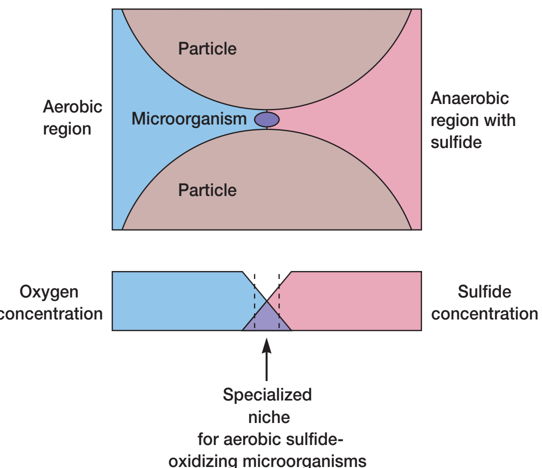

Figure 28.26 The Creation of a Niche from a Microenvironment. As shown in this illustration, two nearby particles create a physical microenvironment for possible use by microorganisms. Chemical gradients, as with oxygen from the aerobic region, and sulfide from the anaerobic region, create a unique niche. This niche thus is the physical environment and the resources available for use by specialized aerobic sulfide-oxidizing bacteria.

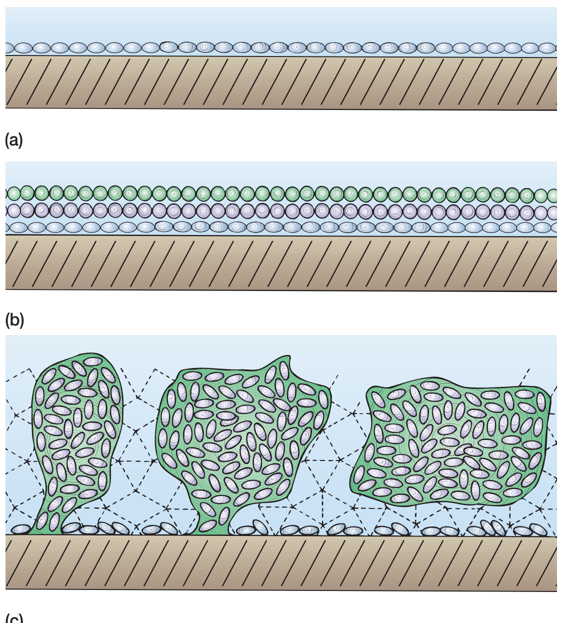

Figure 28.27 The Growth of Biofilms. Biofilms, or microbial growths on surfaces such as in freshwater and marine environments, can develop and become extremely complex, depending on the energy sources that are available. (**a**) Initial colonization by a single type of bacterium. (**b**) Development of a more complex biofilm with layered microorganisms of different types. (**c**) A mature biofilm with cell aggregates, interstitial pores, and conduits.

For example, microorganisms in the interior of a colony have markedly different microenvironments and niches than those of the same microbial populations located on the surface or edge of the colony. Microorganisms also can associate with clays and form "clay hutches" for protection (*see section 42.4*).

1. What are the similarities and differences between a microenvironment and a niche?
2. Why might pores in soils, waters, and animals be important for survival of bacteria if protozoa are present?
3. Why might conditions vary for a bacterium on the edge of a colony in comparison with the center of the colony?

Biofilms and Microbial Mats

As noted in the previous section, microorganisms tend to create their own microenvironments and niches, even without having a structured physical environment available, by creating **biofilms.** These are organized microbial systems consisting of layers of microbial cells associated with surfaces. Such biofilms are an important factor in almost all areas of microbiology, as shown in **figure 28.27*a*.** Simple biofilms develop when microorganisms attach and form a monolayer of cells.

Depending on the particular microbial growth environment (light, nutrients present and diffusion rates), these biofilms can become more complex with layers of organisms of different types (figure 28.27*b*). A typical example would involve photosynthetic organisms on the surface, facultative chemoorganotrophs in the middle, and possibly sulfate-reducing microorganisms on the bottom.

More complex biofilms can develop to form a four-dimensional structure (X, Y, Z, and time) with cell aggregates, interstitial pores, and conduit channels (figure 28.27*c*). This developmental process involves the growth of attached microorganisms, resulting in accumulation of additional cells on the surface, together with the continuous trapping and immobilization of free-floating microorganisms that move over the expanding biofilm. This structure allows nutrients to reach the biomass, and the channels are shaped by protozoa that graze on bacteria.

These more complex biofilms, in which microorganisms create unique environments, can be observed by the use of confocal scanning laser microscopy (CSLM) as discussed in chapter 2. The diversity of nonliving and living surfaces that can be exploited by biofilm-forming microorganisms is illustrated in **figure 28.28.** These include surfaces in catheters and dialysis units, which have intimate contact with human body fluids. Control of such microorganisms and their establishment in these sensitive medical devices is an important part of modern hospital care.

Microorganisms that form biofilms on living organisms such as plants or animals have additional advantages. In these cases the surfaces themselves often release nutrients, in the form of sloughed cells, soluble materials, and gases. These biofilms also can play major roles in disease (*see Box 39.3*) because they can protect pathogens from disinfectants, create a focus for later occurrence of

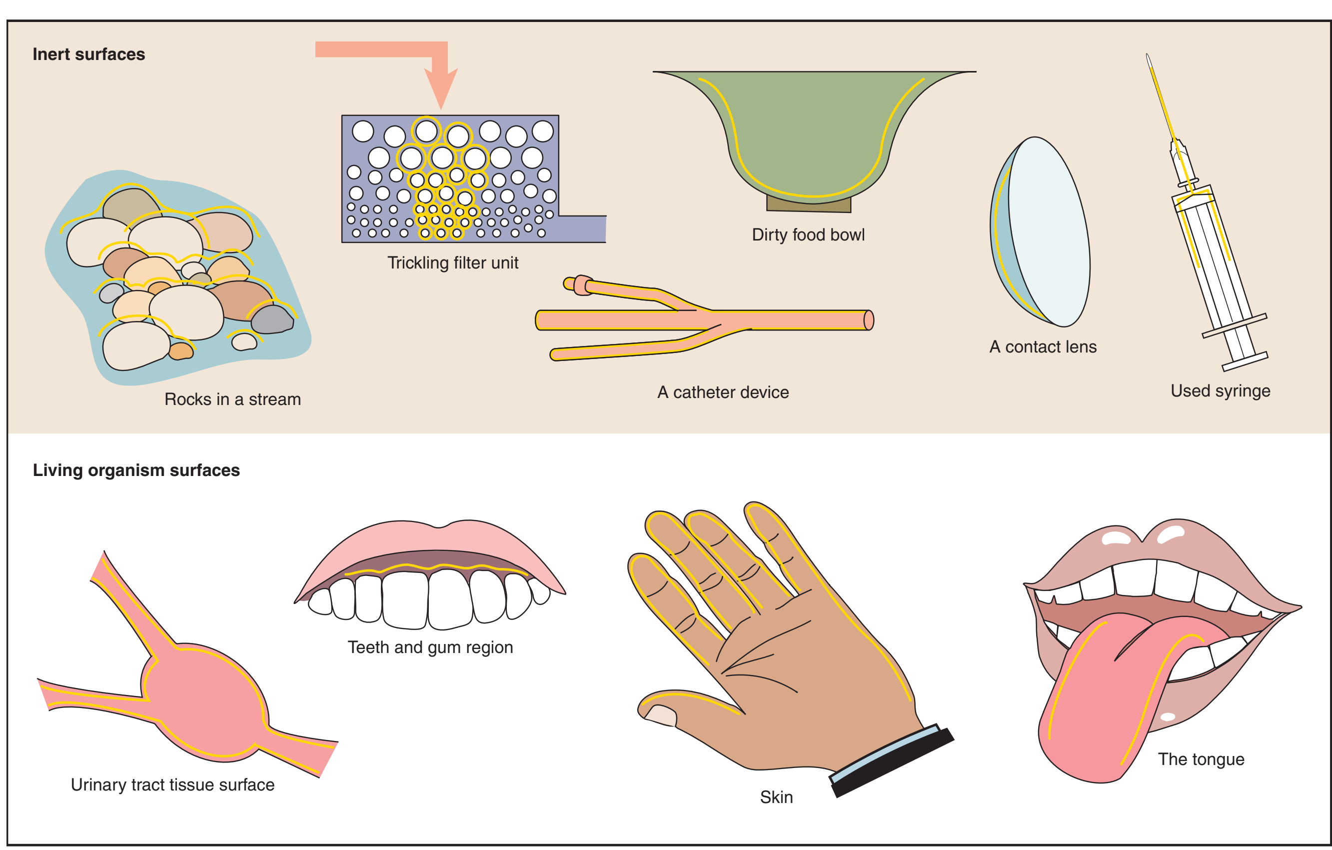

Figure 28.28 Biofilm Formation on Inert and Living Organism Surfaces. Biofilms, noted in yellow, are a part of microbial functioning in the environment, in biotechnology, and in human health.

disease, or release microorganisms and microbial products that may affect the immunological system of a susceptible host. Biofilms are critical in ocular diseases because *Chlamydia, Staphylococcus,* and other pathogens survive in ocular devices such as contact lenses and in cleaning solutions (**figure 28.29**).

Depending on environmental conditions, biofilms can become so large that they are visible and have macroscopic dimensions. Bands of microorganisms of different colors are evident as shown in **figure 28.30.** These thick biofilms, called **microbial mats,** are found in many freshwater and marine environments. These mats are complex layered microbial communities that can form at the surface of rocks or sediments in hypersaline and freshwater lakes, lagoons, hot springs, and beach areas. They consist of microbial filaments, including cyanobacteria. A major characteristic of mats is the extreme gradients that are present. Light only penetrates approximately 1 mm into these communities, and below this photosynthetic zone, anaerobic conditions occur and sulfate-reducing bacteria play a major role. The sulfide that these organisms produce diffuses to the anaerobic lighted region, allowing sulfur-dependent photosynthetic microorganisms to grow. Some believe that microbial mats could have allowed the

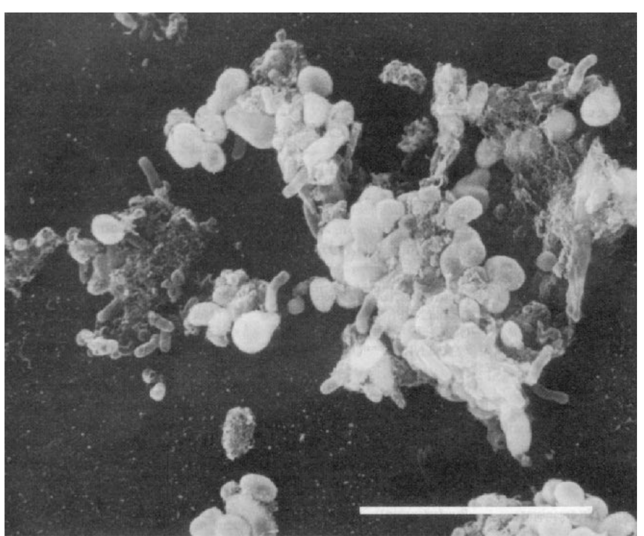

Figure 28.29 Contact Lenses Can Have Extensive Biofilms. Clumps of cocci and sparse rods on a contact lens. Bar = 10 μm.

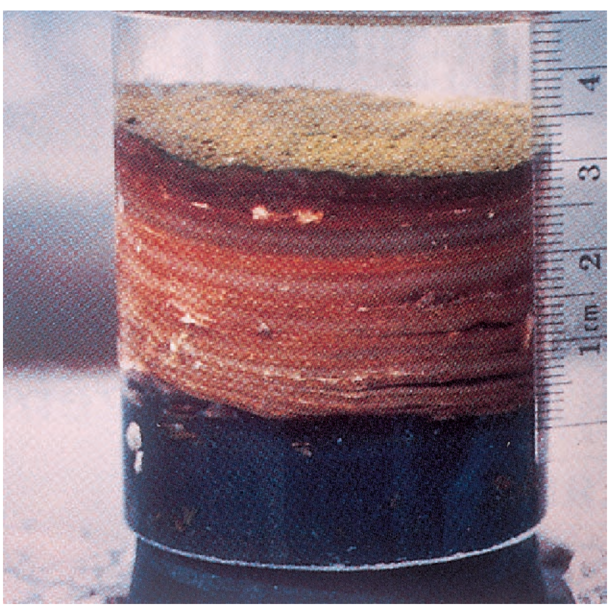

Figure 28.30 Microbial Mats. Microorganisms, through their metabolic activities, can create environmental gradients resulting in layered ecosystems. A vertical section of a hot spring (55°C) microbial mat, showing the various layers of microorganisms.

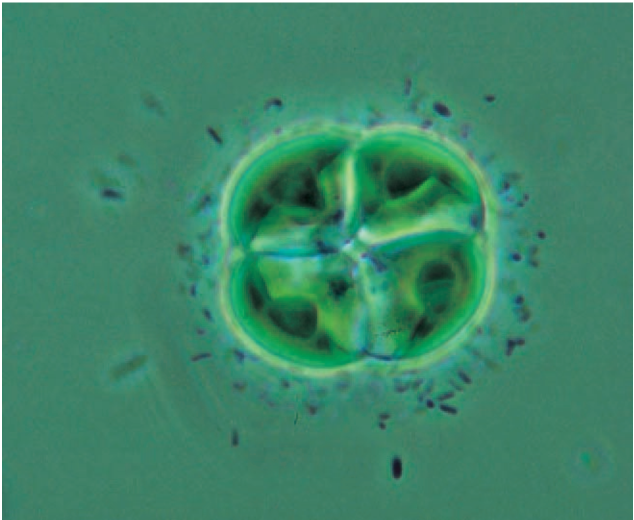

Figure 28.31 A Simple Ecosystem. An alga, which releases photosynthetically generated oxygen and organic matter to its environment, is surrounded by chemoheterotrophs that are using these products of primary production. These two types of microorganisms, producing and consuming oxygen and organic matter, form a self-regulating ecosystem (×1,000).

formation of terrestrial ecosystems prior to the development of vascular plants, and fossil microbial mats, called stromatolites, have been dated at over 3.5 billion years old (*see p. 423*). Molecular techniques and stable isotope measurements (see table 28.8) are being used to better understand these unique microbial communities.

1. What are biofilms? What types of surfaces on living organisms can provide a site for biofilm formation?
2. Why are biofilms important in human health?
3. What are microbial mats and where are they found?

Microorganisms and Ecosystems

Microorganisms, as they interact with each other and other organisms, and influence nutrient cycling in their specific microenvironments and niches, also contribute to the functioning of ecosystems. Ecosystems have been defined as "communities of organisms and their physical and chemical environments that function as self-regulating units." These self-regulating biological units respond to environmental changes by modifying their structure and function.

Microorganisms in ecosystems can have two complementary roles: (1) the synthesis of new organic matter from CO_2 and other inorganic compounds during **primary production** and (2) decomposition of this accumulated organic matter. A simple self-regulating ecosystem in which primary production of organic matter occurs is shown in **figure 28.31.** This consists of an alga and a "halo" of surrounding bacteria that are using the organic matter formed by algal photosynthesis as a carbon, electron, and energy source, and returning the organic matter to its original mineral constituents. Self-regulation in this ecological unit is shown by its response to light. Decreased light fluxes lead to a decrease in photosynthesis and organic matter release. Under these conditions, the heterotrophic bacterial community will be limited and its activity and biomass may be decreased.

The general relationships between the **primary producers** that synthesize organic matter, the heterotrophic **decomposers,** and the consumers are illustrated in **figure 28.32.** Microorganisms of different types contribute to each of these complementary relationships.

In terrestrial environments the primary producers are usually vascular plants. In freshwater and marine environments, the cyanobacteria and algae (*see section 21.3 and chapter 26*) play a similar role. The major energy source driving primary production is light in both habitats although in hydrothermal and hydrocarbon seep areas, chemotrophic ecosystems occur. The higher **consumers,** including humans, are chemoheterotrophs. These consumers depend on the "life support systems" provided by organisms that accumulate and decompose organic matter.

Microorganisms thus carry out many important functions as they interact in ecosystems, including:

1. Contributing to the formation of organic matter through photosynthetic and chemosynthetic processes.

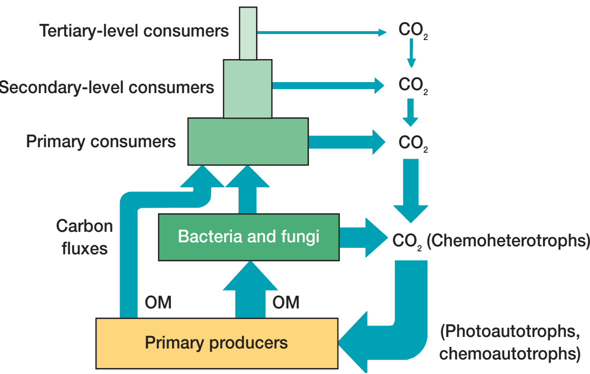

Figure 28.32 The Vital Role of Microorganisms in Ecosystems. Microorganisms play vital roles in ecosystems as primary producers, decomposers, and primary consumers. Carbon is fixed by the primary producers, including microorganisms, which use light or chemically bound energy. Chemoheterotrophic bacteria and fungi serve as the main decomposers of organic matter, making minerals again available for use by the primary producers. Ciliates and flagellates, important microbial primary consumers, feed on the bacteria and fungi, recycling nutrients as part of the microbial loop. Organic matter (OM).

2. Decomposing organic matter, often with the release of inorganic compounds (e.g., CO_2, NH_4^+, CH_4, H_2) in mineralization processes.
3. Serving as a nutrient-rich food source for other chemoheterotrophic microorganisms, including protozoa and animals.
4. Modifying substrates and nutrients used in symbiotic growth processes and interactions, thus contributing to biogeochemical cycling.
5. Changing the amounts of materials in soluble and gaseous forms. This occurs either directly by metabolic processes or indirectly by modifying the environment.
6. Producing inhibitory compounds that decrease microbial activity or limit the survival and functioning of plants and animals.
7. Contributing to the functioning of plants and animals through positive and negative symbiotic interactions.

1. Define the following terms: ecosystem, primary production, decomposer, mineralization.
2. List important functions of higher consumers in natural environments.
3. What are the important functions of microorganisms in ecosystems?

Microorganism Movement between Ecosystems

Microorganisms constantly are moving and being moved between ecosystems. This often happens naturally in many ways: (1) soil is transported around the Earth by windstorms and falls on land areas and waters far from its origins; (2) rivers transport eroded materials, sewage plant effluents, and urban wastes to the ocean; and (3) insects and animals release urine, feces, and other wastes to environments as they migrate around the Earth. When plants and animals die after moving to a new environment, they decompose and their specially adapted and coevolved microorganisms (and their nucleic acids) are released (*see section 29.2*). The fecal-oral route of disease transmission, often involving foods and waters, and the acquisition of diseases in hospitals (nosocomial infections) are important examples of pathogen movement between ecosystems. Each time a person coughs or sneezes, microorganisms also are being transported to new ecosystems.

Humans also both deliberately and unintentionally move microorganisms between different ecosystems. This occurs when microbes are added to environments to speed up microbially mediated degradation processes (*see bioremediation, section 42.4*) or when a plant-associated inoculum such as *Rhizobium,* is added to a soil to increase the formation of nitrogen-fixing nodules on legumes (*see pp. 675–78*). One of the most important accidental modes of microbial movement is the use of modern transport vehicles such as automobiles, trains, ships, and airplanes. These often rapidly move microorganisms long distances.

The fate of microorganisms placed in environments where they normally do not live, or of microorganisms returned to their original environments, is important both theoretically and practically. Pathogens that are normally associated with an animal host are greatly affected by such movement because these microorganisms largely have lost their ability to compete effectively with microorganisms indigenous to other environments. Upon moving to a new environment, the population of viable and culturable pathogens gradually decreases. However, more sensitive viability assessment procedures, particularly molecular techniques, indicate that **nonculturable microorganisms,** as observed with *Vibrio* (*see section 6.5*), may play critical roles in disease occurrence.

Many studies have been directed toward learning why microorganisms which have coevolved with animals gradually die after being released to soils and waters. Among the possibilities are predation by protozoa, *Bdellovibrio* (*see pp. 510–12*) and other organisms, lack of space, lack of nutrients, and the presence of toxic substances. After many years of study, it appears that the major reason "foreign" microorganisms die out is that they can no longer compete effectively with indigenous microorganisms for the low amounts of nutrients present in the environment.

Even microorganisms recovered from a particular environment, after growth in the laboratory on rich media, may lose their ability to survive when placed back in their original environment. The cause may be physical or physiological. From a physical standpoint the microorganisms may find themselves outside their protected physical niche, where they can be consumed by protozoa and other predators as noted previously. On the other hand, after growth in rich laboratory media, they may have lost the ability to compete physiologically with the native populations. It is of interest that these foreign microorganisms survive longer outside of their original hosts

Table 28.7 Characteristics of Extreme Environments in which Microorganisms Grow

Stress	Environmental Conditions	Microorganisms Observed
High temperature	110–113°C, deep marine trenches	*Pyrolobus fumarii*
		Methanopyrus kandleri
		Pyrodictium abyssi
	67–102°C, marine basins	*Pyrococcus abyssi*
	85°C, hot springs	*Thermus*
		Sulfolobus
	75°C, sulfur hot springs	*Thermothrix thiopara*
Low temperature	–12°C, antarctic ice	*Psychromonas ingrahamii*
Osmotic stress	13–15% NaCl	*Chlamydomonas*
	25% NaCl	*Halobacterium*
		Halococcus
Acidic pH	pH 3.0 or lower	*Saccharomyces*
		Thiobacillus
	pH 0.5	*Picrophilus oshimae*
	pH 0.0	*Ferroplasma acidarmanus*
Basic pH	pH 10.0 or above	*Bacillus*
Low water availability	a_w = 0.6–0.65	*Torulopsis*
		Candida
Temperature and low pH	85°C, pH 1.0	*Cyanidium*
		Sulfolobus acidocaldarum
Pressure	500–1,035 atm	*Colwellia hadaliensis*
Radiation	1.5 million rads	*Deinococcus radiodurans*

at lower temperatures (e.g., in polar regions, ice, or frozen foods). Under these conditions, the survival time of these foreign bacteria is greatly extended.

1. How can microorganisms move between different ecosystems?
2. Why might microorganisms isolated from soil or water, after being grown in the laboratory, lose the ability to survive in the environment from which they were taken?
3. What is the effect of temperature on the die-out rate of microorganisms that have been moved to a new, foreign environment?

Stress and Ecosystems

Microorganisms function in ecosystems that develop under a wide range of environmental conditions. These have varied pHs, temperatures, pressures, salinity, water availability, and ionizing radiation as summarized in **table 28.7.** Such stress factors have major effects on microbial populations and communities, and can create an **extreme environment,** as shown in **figure 28.33.** In these cases high salt concentrations, extreme temperature, and acidic conditions have affected the microbial communities. The microorganisms that survive in such environments are described as **extremophiles,** and such extreme environments are usually considered to have decreased microbial diversity, as judged by the microorganisms that can be cultured. With the increased use of molecular detection techniques, however, it appears that there is surprising diversity among the microorganisms that cannot be cultured from these extreme environments. Further work to establish relationships between the microorganisms that can be observed and detected by these molecular techniques and culturable microorganisms will be required in the future. The influence of environmental factors on growth (pp. 121–31)

Many microbial genera have specific requirements for survival and functioning in such so-called extreme environments. For example, a high sodium ion concentration is required to maintain membrane integrity in many halophilic bacteria, including members of the genus *Halobacterium.* Halobacteria require a sodium ion concentration of at least 1.5 M, and about 3 to 4 M for optimum growth. Halophilic archaea (pp. 123; 461–63)

The bacteria found in deep-sea environments have different pressure requirements, depending on the depth from which they are recovered. These bacteria can be described as **baro-** or **piezotolerant bacteria** (growth from approximately 1 to 500 atm), **moderately barophilic bacteria** (growth optimum 5,000 meters, and still able to grow at 1 atm), and **extreme barophilic bacteria,** which require approximately 400 atm or higher for growth (*see chapter 29*).

Intriguing changes in basic physiological processes occur in microorganisms functioning under extreme acidic or alkaline conditions. These acidophilic and alkalophilic microorganisms have markedly different problems in maintaining a more neutral internal pH and chemiosmotic processes (*see chapter 9*). Obligately acidophilic microorganisms can grow at a pH of 3.0 or lower, and major pH differences can exist between the interior and exterior of the cell. These acidophiles include members of the genera *Thiobacillus, Sulfolobus,* and *Thermoplasma.* The higher relative internal pH is maintained by a net outward translocation of protons. This may occur as the result of unique membrane lipids, hydrogen ion removal during reduction of oxygen to water, or the pH-dependent characteristics of membrane-bound enzymes.

Recently, an archaeal iron-oxidizing acidophile, *Ferroplasma acidarmanus,* capable of growth at pH 0, has been isolated from a sulfide ore body in California. This unique procaryote, capable of massive surface growth in flowing waters in the subsurface (**figure 28.34**), possesses a single peripheral cytoplasmic membrane and no cell wall.

The extreme alkalophilic microorganisms grow at pH values of 10.0 and higher and must maintain a net inward translocation of protons. These obligate alkalophiles cannot grow below a pH of 8.5 and are often members of the genus *Bacillus; Micrococcus* and *Exiguobacterium* representatives have also been reported. Some photosynthetic cyanobacteria also have similar characteristics. Increased internal proton concentrations may be maintained by means of coordinated hydrogen and sodium ion fluxes.

Box 28.2

The Potential of Microorganisms from High-Temperature Environments for Use in Modern Biotechnology

There is great interest in the characteristics of procaryotes isolated from the outflow mixing regions above deep hydrothermal vents that release water at 250 to 350°C. This is because these procaryotes can grow at temperatures as high as 113°C. The problems in growing these microorganisms, often archaea, are formidable. For example, to grow some of them, it will be necessary to use special culturing chambers and other specialized equipment to maintain water in the liquid state at these high temperatures.

Such microorganisms, termed hyperthermophiles, with optimum growth temperatures of 80°C or above (*see p. 126*), confront unique challenges in nutrient acquisition, metabolism, nucleic acid replication, and growth. Many of these are anaerobes that depend on elemental sulfur as an oxidant and reduce it to sulfide. Enzyme stability is critical. Some DNA polymerases are inherently stable at 140°C, whereas many other enzymes are stabilized in vivo with unique thermoprotectants. When these enzymes are separated from their protectant, they lose their unique thermostability.

These enzymes may have important applications in methane production, metal leaching and recovery, and for use in immobilized enzyme systems. In addition, the possibility of selective stereochemical modification of compounds normally not in solution at lower temperatures may provide new routes for directed chemical syntheses. This is an exciting and expanding area of the modern biological sciences to which microbiologists can make significant contributions.

Observations of microbial growth at temperatures approaching 113°C in thermal vent areas, or of **hyperthermophiles,** (**Box 28.2;** *see also Box 6.1*) indicate that this area will continue to be a fertile field for investigation. For some successful microorganisms, an extreme environment may not be "extreme" but required and even, perhaps, ideal. Thermophilic microorganisms (pp. 126; 463)

1. What are the main factors that lead to the creation of extreme environments?
2. Why are molecular techniques possibly changing our view of these environments?
3. What is unique about *Ferroplasma acidarmanus?*

28.5 Methods in Microbial Ecology

A wide variety of techniques can be used to evaluate the presence, types, and activities of microorganisms as populations, communities, and parts of ecosystems (**table 28.8**). Measurements made by these techniques can span a range of time scales and physical dimensions. In marine, freshwater, sewage, and plant root environments, as examples, responses can be measured in seconds and minutes. For deep marine and soil organic matter changes, a time scale of years, decades, or even centuries may be required. The physical scale used in a study may range from a single bacterium and its microenvironment to a lake, ocean, or an entire plant-soil system.

As noted at the beginning of this chapter, a fundamental problem in studying microorganisms in nature is the inability to culture and characterize most organisms that can be observed. This long-standing problem is now being approached by the use of molecular techniques, by which nonculturable microorganisms can be characterized and compared with known genomic sequences (*see chapter 19*).

Microbial community diversity can be assessed by several approaches, including molecular phylogeny based on analyses of small subunit (SSU) ribosomal RNA (*see pp. 433–35*). Small amounts of DNA also can be recovered from environmental samples or individual cells and "amplified" by use of the polymerase chain reaction (PCR). The polymerase chain reaction (pp. 326–27)

As noted in table 28.8, some of these techniques are limited in terms of the types of samples that can be analyzed. This may be due to low microbial populations (marine and some freshwater samples) or high concentrations of interfering organic matter or particulates in samples. In contrast, the newer molecular procedures, such as direct DNA extraction, DNA amplification fingerprinting (DAF), 16S and 18S RNA-based phylogenetic analysis, PCR, and DNA probe and hybridization techniques, are applicable to a wider variety of samples.

Recently gel array microchips containing mixtures of probes, called "genosensors," or **microarrays,** have been developed (*see pp. 354; 1018*). These allow the detection of small subunit ribosomal RNA from mixed populations. In addition, probes can detect specific groups of microorganisms such as the iron- and manganese-oxidizing sheathed bacteria by the use of 16S rRNA-based probes.

Many newer and more sensitive procedures are now available, including the use of radioactive substrates and sophisticated techniques to measure the viability and activity of individual microorganisms. Hybridization techniques can be used to "probe" colonies or single cells to determine if they contain specific DNA or RNA sequences. The technique of whole-cell hybridization has progressed to the point that "subcluster-specific" probes have been developed. These allow the simultaneous detection of different microbial types in the same preparation (*see figure 29.9, p. 643*).

In most studies employing these molecular approaches to analyze complex microbial communities, nucleic acids have been extracted from the sample, followed typically by cloning and further genomic and phylogenetic analyses. The specific source of the nucleic acids that are being studied is not known. Because of

[a]Major uses are noted with two plus signs (++) and minor uses are noted with one plus (+); minimal or no use noted with (–).

improvements in the sensitivity of the polymerase chain reaction (*see section 14.3*), it is possible to study nucleic acids recovered from individual cells after isolating them with **optical tweezers** (a laser beam is used to drag a microbe away from its neighbors) or a **micromanipulator.** In the micromanipulator procedure, a desired cell or cellular organelle is drawn up into a fine capillary after direct observation (**figure 28.35**). PCR amplification of nucleic acids from an isolated cell or organelle allows one to obtain sequence data for use in phylogenetic analysis (*see chapter 19*). For example, it has been possible to establish the phylogenetic relationship of a mycoplasma recovered from the flagellate *Koruga bonita* (**figure 28.36**).

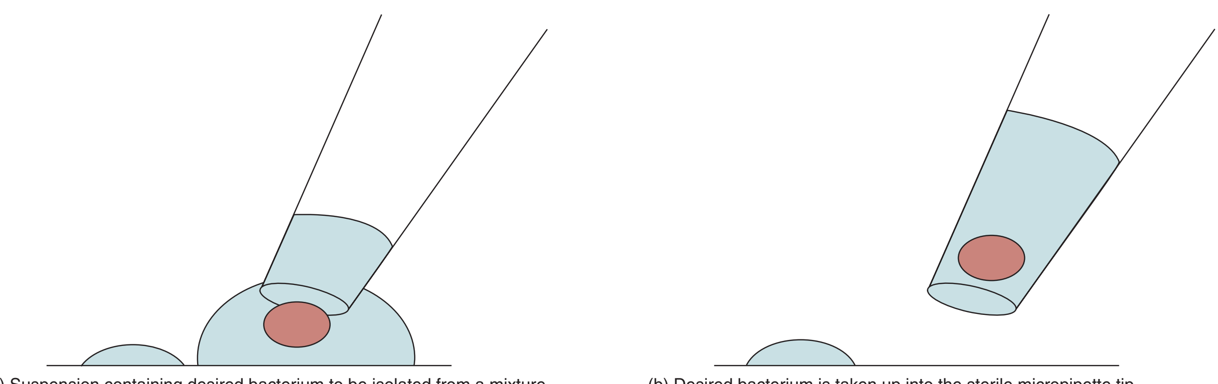

Figure 28.35 Recovery of Single Cells or Cell Organelles from Complex Natural Mixtures Using Micromanipulation. By use of an inverted phase-contrast microscope and a micromanipulator, a microorganism can be recovered for direct molecular analysis. (**a**) The bacterium to be isolated is placed below the micromanipulator tip (diameter 5 to 10 µm) and a slight vacuum is drawn. (**b**) The desired single bacterium is drawn up into the micropipette tube and is ready for molecular analysis.

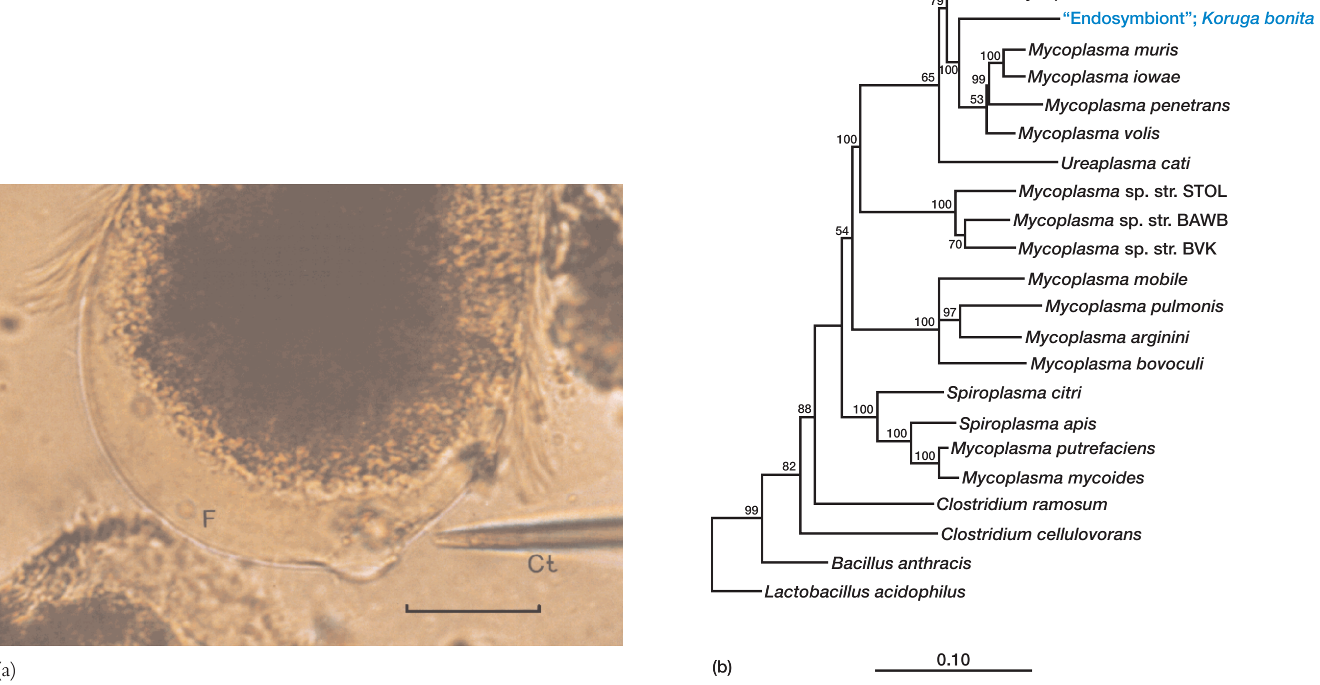

Figure 28.36 Combining Micromanipulation for Isolation of Single Cells or Organelles with the Polymerase Chain Reaction (PCR). (**a**) Recovery of an endosymbiotic mycoplasma from single cell of the flagellate *Koruga bonita* by micromanipulation (bar = 10 µM) and (**b**) phylogenetic analysis of the recovered mycoplasma following PCR amplification and sequencing of the PCR products, with the bar indicating 10% estimated sequence divergence. *Lactobacillus acidophilus* is the outgroup reference. This approach makes it possible to link a specific microorganism or organelle, isolated from a natural environment, to its molecular sequence and phylogenetic information. Flagellate (F), capillary tube (Ct).

With this single cell-based approach, it is now possible to link specific microbial structures observed under the microscope to the phylogenetic information contained in that cell or organelle. This should improve our understanding of the role of individual microorganisms in complex microbial assemblages.

Symbioses and microbial ecology involve complex relationships, the subtlety of which are only beginning to be understood. This involves not only finding out what microorganisms are there (the first formidable challenge) but also determining what the organisms are doing and how they are interacting at various temporal and spatial scales. These tasks are central to understanding microbial associations with other organisms and the environment, which is the essence of microbial ecology.

1. Why are "classic" microscopic and physical methods still used for the study of microorganisms when molecular techniques are available?
2. What are optical tweezers and micromanipulators?
3. What time scales can be used when studying the activity of microorganisms?
4. What is a genosensor or microarray system?

Summary

1. Most microorganisms that can be observed in complex natural assemblages under a microscope cannot be grown at the present time. Molecular techniques are making it possible to obtain information on these uncultured microorganisms.
2. Microbial ecology is the study of microorganisms' interactions with their living and nonliving environments. Symbiosis is a narrower term that means "together life," the study of organism-organism interactions.
3. A microorganism functions in a physical location that can be described as its microenvironment. The resources available in a microenvironment and their time of use by a microorganism describe the niche. Pores are important microenvironments that can protect bacteria from predation.
4. One organism may grow on the surface of another organism as an ectosymbiont or inside another organism as an endosymbiont. Organisms may have other organisms on their surface and inside them at the same time, an ecto/endosymbiosis.
5. Positive interactions (**figure 28.1**) include mutualism (mutually beneficial and obligatory), protocooperation (mutually beneficial, not obligatory), and commensalistic (product of one organism can be used beneficially by another organism). Negative interactions include predation (use and ingesting/killing a larger or smaller prey), parasitism (a longer-term internal maintenance of another organism or acellular infectious agent), and amensalism (a microbial product can inhibit another organism). Competition involves organisms competing for space or a limiting nutrient. The quality of these interactions can change, depending on the environment and the characteristics of the particular organisms.
6. Mutual advantage is central to positive organism-organism interactions. These interactions can be based on material transfers related to energetics, cell-to-cell communication, or physical protection. With several important mutualistic interactions, chemolithotrophic microorganisms play a critical role in making organic matter available for use by an associated organism (e.g., endosymbionts in *Riftia*).
7. Predation and parasitism are closely related. Predation has many positive effects on populations of predators and prey. These include the microbial loop (returning minerals immobilized in organic matter to mineral forms for reuse by chemotrophic and photosynthetic primary producers), protection of prey from heat and damaging chemicals, and possibly aiding pathogenicity, as with *Legionella.*
8. A consortium is a physical association of organisms that have a mutually beneficial relationship based on positive interactions.
9. Syntrophism simply means growth together. It does not require physical contact but only a mutually positive transfer of materials, such as interspecies hydrogen transfer.
10. The rumen is an excellent example of a mutualistic interaction between a ruminant and its complex microbial community. In this microbial community, complex plant materials are broken down to simple organic compounds that can be absorbed by the animal, as well as forming waste gases such as methane that are released to the environment (**figure 28.8**).
11. Protocooperative interactions are beneficial for both organisms but are not obligatory (**figure 28.9**). Important examples are marine animals, including *Alvinella, Rimicarus,* and *Eubostrichus,* that involve interactions with hydrogen sulfide–oxidizing chemotrophs.
12. These varied positive and negative interactions occur in complex biological systems and lead to feedback responses of varied members of a biological community.
13. Microbes can be present as individual cells, as populations of similar organisms, or as mixtures of populations or communities. These populations and communities can be parts of self-regulating ecosystems.
14. Microorganisms—functioning with plants, animals, and the environment—play important roles in nutrient cycling, which is also termed biogeochemical cycling. Assimilatory processes involve incorporation of nutrients into the organism's biomass during metabolism; dissimilatory processes, in comparison, involve the release of nutrients to the environment after metabolism (**figure 28.18**)
15. Biogeochemical cycling involves oxidation and reduction processes, and changes in the concentrations of gaseous cycle components, such as carbon, nitrogen, and sulfur can result from microbial activity.
16. Microorganisms serve as primary producers that accumulate organic matter (**figure 28.32**). Energy sources include hydrogen, sulfide, and methane. In addition, many chemoheterotrophs decompose the organic matter that primary producers accumulate and carry out mineralization, the release of inorganic nutrients from organic matter.
17. Major organic compounds used by microorganisms differ in structure, linkage, elemental composition, and susceptibility to degradation under aerobic and anaerobic conditions. Lignin is degraded only under aerobic conditions, a fact that has important implications in terms of carbon retention in the biosphere.
18. In terms of effects on humans, metals can be considered in three broad groups: (1) the noble metals, which have antimicrobial properties but which do not have negative effects on humans; (2) metals such as mercury and lead, from which toxic organometallic compounds can be formed; and (3) certain other metals, which are antimicrobial in ionic form, such as copper and zinc. The second of these groups is of particular concern.
19. Biofilms, or layers of microorganisms, are widespread and are formed on a wide variety of living and nonliving surfaces (**figure 28.28**). These are important in disease occurrence and the survival of pathogens. Biofilms can develop to form complex layered ecosystems.
20. Most disease-causing bacteria from the intestinal tract of humans and other higher organisms do not survive in the environment. At lower temperatures, however, increased survival can occur.

21. Decreased species diversity usually occurs in extreme environments, and many microorganisms that can function in such habitats, called extremophiles, have specialized growth requirements. For them, extreme environments can be required environments.
22. Many approaches can be used to study microorganisms in the environment (**table 28.8**). These include nutrient cycling, biomass, numbers, activity, and community structure analyses. It is now possible to study the genetic characteristics of microorganisms that cannot be grown in the laboratory.
23. Methods presently being used make it possible to study presence, types, and activities of microorganisms in their natural environments (including soils, waters, plants, and animals). Although most microorganisms that can be observed still cannot be grown, molecular techniques are making it possible to obtain information on these noncultured microorganisms.
24. Optical tweezers and micromanipulators can be used to recover individual cells or cell organelles from complex microbial communities. This makes it possible to obtain genomic and phylogenetic information from specific individual microbial cells for use in studies of microbial ecology (**figure 28.36**).

Questions for Thought and Review

1. It is evident that some microorganisms have a wide range of electron donors and acceptors that they can use, and others use only single oxidants and reductants. What are the advantages and disadvantages of each strategy?
2. Why might microorganisms prefer to grow in association with other microorganisms, as in biofilms, when they can have better access to nutrients as single cells?
3. Why is mutualism in association with multicellular organisms a major strategy of microorganisms? Why have these especially developed with sulfide and simple hydrocarbon-based systems?
4. What types of unique information do microscopic and molecular techniques provide and not provide?
5. How might you show that a microorganism found in a particular extreme environment is actually growing there?
6. Why is predation such a very important part of microbial ecology? Can a predator ever completely eliminate all of its prey?
7. How might you attempt to grow a microorganism in the laboratory to increase its chances of being a strong competitor when placed back in a natural habitat?
8. Considering the possibility of microorganisms functioning at temperatures approaching 120°C, what do you think the limiting factor for microbial growth at higher temperatures will be and why?
9. Where in their bodies do most people have noble metals? Why have these been used with more success than materials such as ceramics, which have been tested over many decades?
10. Compare the degradation of lignin and cellulose by microorganisms. What different environmental factors are required for these important polymers to be degraded?
11. Considering the intensive searches for unique microorganisms that have been carried out all over the world, where can we look for new microbes?

Critical Thinking Questions

1. Compare and contrast diversity among microorganisms with diversity among macroorganisms.
2. Describe a naturally occurring niche on this planet that you believe is inhospitable to microbial life. Explain, in light of what is known about extremophiles, why you believe this environment will not support microbial life.

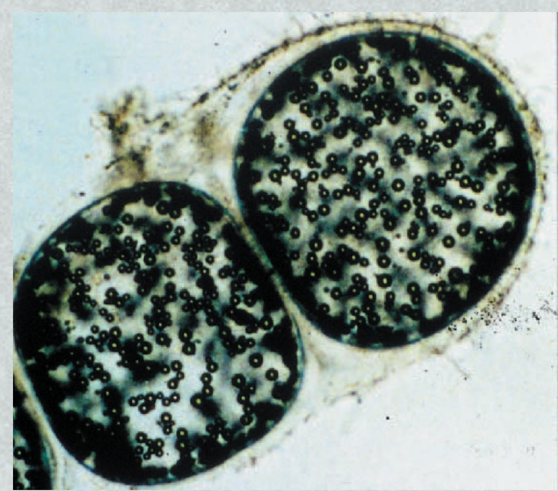
CHAPTER 29

Microorganisms in Aquatic Environments



New procaryotes are discovered at locations where reduced and oxidized nutrients mix. This giant bacterium, *Thiomargarita namibiensis,* about 100 to 300 μm in diameter, accumulates sulfur from sediments in its refractive sulfur granules and nitrate from overlying waters to support its growth. *Thiomargarita,* which resembles a string of pearls, is found off the coast of Namibia.

Concepts

1. Oxygen diffuses through water at a slow rate, in comparison with the rate at which it diffuses through air; this is a defining characteristic of water as an environment for microbial growth and functioning.
2. Oxygen, once it is dissolved in water, can be used by microorganisms at a faster rate than it can be replenished. This leads to the creation of anaerobic zones. If light penetrates into these anaerobic zones, unique groups of photosynthetic microorganisms can arise. Specialized microbial communities also develop at the interface between anoxic and oxic regions.
3. Aquatic environments, both marine and freshwater, include vast volumes of cold water and ice. In addition to fresh water stored in glaciers and the polar regions, sea ice covers approximately 7% of the world's surface. Together with the cold (2 to 3°C), high pressure waters of the Earth's oceans, these cold environments are important sites of microbial survival and functioning.
4. Aquatic environments allow development of many unique types of microorganisms. These include microbes at deep hydrothermal vents and hydrocarbon seeps, and other microorganisms that exploit surfaces by gliding motility and attachment. Other microorganisms link spatially separated resources such as nitrate and sulfide. New microorganisms continue to be discovered in aquatic environments.
5. The biogeochemical cycles of carbon, nitrogen, sulfur, and phosphorus for lakes and marine environments involve interactions over both local and vast distances.
6. Phytoplankton (photosynthetic procaryotic and eucaryotic organisms) form the basis of primary production in most marine and freshwater environments. The phytoplankton release dissolved and particulate organic matter, which is used by heterotrophic bacteria, a portion of which are consumed by predators, releasing materials that are recycled for use by the phytoplankton, creating a microbial loop. Iron and nitrogen can limit these activities in different marine environments.
7. Disease-causing microorganisms, as well as organic materials, are constantly being added to waters. These can be transported over large distances, especially in rapidly moving rivers, lakes, and marine environments. Atmospheric-borne dusts and other materials, including pollutants, can be carried to the farthest regions of the oceans, freshwater bodies, and ice-covered regions of the world.
8. Many important human pathogens, such as *Shigella, Vibrio,* and *Legionella,* are found in waters. These can occur normally or can survive for various intervals after addition to waters. Often protozoa provide protection for such pathogens, especially when the protozoa are associated with biofilms.
9. Aquatic environments can serve as reservoirs and transmission routes for disease-causing microorganisms. A major goal of aquatic system management is to control pathogen survival and transfer.
10. Water is an important reservoir for the survival and dissemination of protozoa and viruses. These cannot be reliably controlled by chlorination. Protozoan pathogens include *Cyclospora* and *Giardia.*
11. The biological use of organic wastes follows regular and predictable sequences. Once these sequences are understood, more efficient sewage treatment systems can be created.
12. Sewage treatment can be carried out using large vessels where mixing and aeration can be controlled (conventional treatment). Constructed wetlands, where aquatic plants and their associated microorganisms are used, now are finding widespread applications in the treatment of liquid wastes.
13. Indicator organisms, which usually die off at slower rates than many disease-causing microorganisms, can be used to evaluate the microbiological quality of water.
14. Groundwater is an important source of drinking water, especially in suburban and rural areas. In too many cases, this resource is being contaminated by disease-causing microorganisms, especially from septic tanks.

Water is a very good servant, but it is a cruel master.

—John Bullein

Of all the water found on Earth, 97% is marine. Most of this water is at a temperature of 2 to 3°C and devoid of light; 62% is under high pressure (>100 atm). Microscopic phytoplankton and associated bacteria create a complex food web that can extend over long distances and extreme depths. The marine environment seems so vast that it will not be able to be affected by pollution; however, in coastal areas human activities are increasingly disrupting microbial processes and damaging water quality.

Fresh waters, although a small part of the waters on Earth, are extremely important as a source of drinking water. In many locations the contamination of surface and subsurface waters by domestic and industrial wastes causes environmental problems.

Marine and freshwater environments create unique niches for many specialized microorganisms needing habitats with a continuous water phase.

29.1 Aquatic Environments and Microorganisms

A major factor in aquatic environments is the movement of materials, whether they be gaseous, solid, or in the dissolved phase. These changes in concentration are part of the world of aquatic microorganisms; these microorganisms are able to respond rapidly to select their most suitable environment.

The mixing and movement of nutrients, O_2, and waste products that occur in freshwater and marine environments are the dominant factors controlling the microbial community. For example, in deep lakes or oceans, organic matter from the surface can sink to great depths, creating nutrient-rich zones where decomposition takes place. Gases and soluble wastes produced by microorganisms in these deep marine zones can move into overlying waters and stimulate the activity of other microbial groups. Similar processes take place on a lesser scale in nutrient-rich lakes, biofilms, and in microbial mats (*see pp. 620–22*) where gradients are established on a scale of micrometers.

Aquatic environments have varied surface areas and volumes. They are found in locations as diverse as the human body; drinks and beverages; and the usual places one would expect—rivers, lakes, and the oceans. They also occur in water-saturated zones in materials we usually describe as soils! These environments can range from alkaline to extremely acidic. The temperatures within which microorganisms function in aquatic environments can range from −5 to −15°C at the lower range, to at least 113°C in geothermal areas. Some of the most intriguing microbes have come from the study of high-temperature environments, including the now-classic studies of T. D. Brock and his coworkers at Yellowstone National Park which led to the discovery of *Thermus aquaticus,* the source of *Taq* polymerase (*see p. 326*). Hyperthermophilic microorganisms, including *Pyrolobus fumarii,* also have been isolated from hydrothermal vents in deep marine environments.

A goal of microbiologists is to isolate and culture unique marine microorganisms, especially in the search to find new antibiotic-producing microorganisms (**Box 29.1**). New techniques to collect microorganisms without changing temperature or pres-

New Agents in Medicine: The Sea as the New Frontier

Most currently available antibiotics have been derived from soil microorganisms, primarily from the actinomycetes, but also from a lesser number of nonfilamentous gram-positive bacteria and fungi (*see section 35.2*). Over 100 products are in use as antibiotics, antitumor agents, and agrochemicals.

In recent years, with the need for additional compounds for use in medicine, marine microorganisms are receiving increased attention. Some of the newer chemicals that have been discovered are microalgal metabolites. There also is an interest in the culture of symbiotic marine microorganisms, including *Prochloron,* which are associated with macroscopic hosts. A variety of interesting compounds of unknown origin have been discovered. Many are assumed to be of microbial origin, but more work will be needed to establish this. Many biologists feel that marine microorganisms may provide unique bioactive compounds, including marine toxins, which do not occur in terrestrial microorganisms. There is a worldwide effort to better characterize the marine microbial community and to harness these often poorly studied organisms for modern medicine. Often the first challenge is to culture these organisms.

Examples of recent discoveries include goniodomin A, a macrolide antifungal agent isolated from *Goniodoma* (*Gonyaulax*) sp. (see **Box figure,** part *a*) and didemnin B, a strong antiviral and antitumor agent (see Box figure, part *b*). This latter compound is produced by members of the genus *Prochloron.*

sure are now available. For example, Japanese and American scientists have constructed equipment to culture microorganisms that grow at 1,000 atm without decompressing them.

Gases and Aquatic Microorganisms

In aquatic environments the distance (on a microbial scale) from an air bubble or the water surface limits oxygen diffusion. Thus aquatic environments are termed **low oxygen diffusion environments.** The flux rate for oxygen through water is approximately 1/4,000 of that which would occur if the microorganisms were in direct association with a gas phase (**figure 29.1**).

Oxygen not only diffuses slowly through waters, its solubility is further decreased at higher temperatures and with lower pressure (**table 29.1**). Because of limited solubility and the low oxygen diffusion in waters, oxygen can be used by aerobic microorganisms faster than it can be replenished. This frequently leads to the formation of **hypoxic** or **anoxic** zones in aquatic environments. These zones allow specialized anaerobic microbes, both chemotrophic and phototrophic, to grow in the lower regions of lakes where light can penetrate. In contrast, if the microorganisms are functioning in an extremely thin water film and oxygen-containing air is close to them, they are in **high oxygen diffusion environments.** Examples include soils, which will be discussed in chapter 30.

Low oxygen diffusion environments, which will be discussed in this chapter, can range from an ice cube in a cocktail glass to Arctic and Antarctic ice sheets (the latter make up 7% of the world's surface) and the vastness of marine and freshwater systems.

The second major gas in water, CO_2, plays many important roles in chemical and biological processes. The carbon dioxide-bicarbonate-carbonate equilibrium can control the pH in weakly buffered waters, or it can be controlled by the pH of strongly buffered waters. As shown in **figure 29.2,** the pH of distilled water, which is not buffered, is determined by the dissolved CO_2 in equilibrium with the air, and is approximately 5.0 to 5.5. In comparison, water strongly buffered at pH 8.0 contains CO_2 absorbed from the air, which is present primarily as bicarbonate (HCO_3^-). When autotrophic microorganisms such as algae use CO_2, the pH of many waters will be increased.

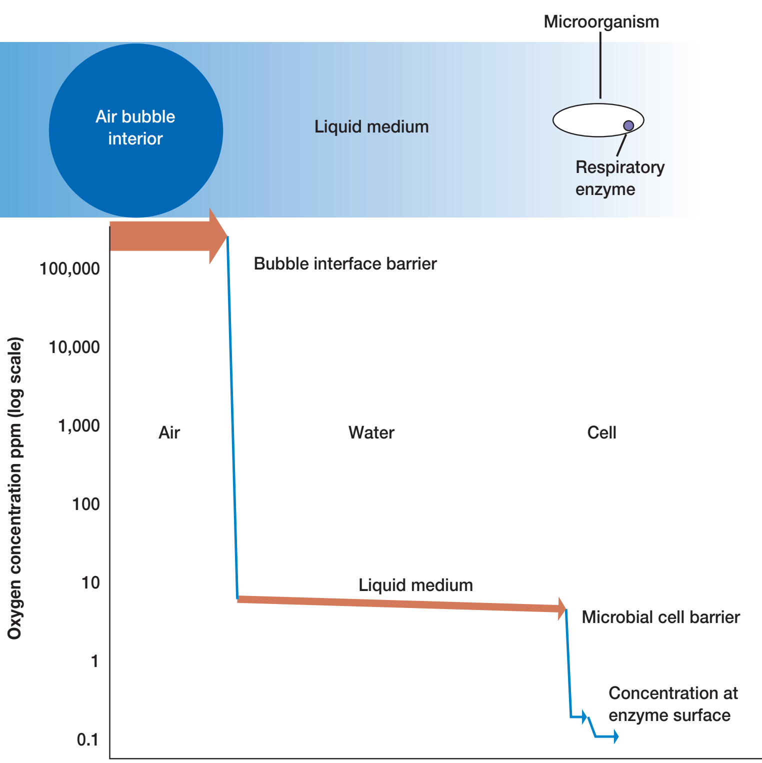

Figure 29.1 Oxygen Transfer in Water Is Limited. Oxygen diffuses at a high rate through air and at approximately 1/4,000 this rate through water. The wide arrow size represents the rapid oxygen flux rate through the air; the decrease in the intensity of the blue color indicates the oxygen concentration. After rapid diffusion through air, oxygen crosses the air/water barrier and then diffuses at a lower rate (the narrow arrow) and lower concentration through the water to the point at which it is used by a microorganism. The oxygen concentration (ppm) is expressed on a logarithmic scale, and the oxygen present at an enzyme can be less than one-millionth of that occurring in the air.

Table 29.1 The Effects of Water Temperature and Elevation on Dissolved O_2 Levels (mg/liter) in Water

	Elevation above Sea Level (Meters)			
Temperature (°C)	**0**	**1,000**	**2,000**	**3,000**
0	14.6	12.9	11.4	10.2
5	12.8	11.2	9.9	8.9
10	11.3	9.9	8.8	7.9
15	10.0	8.9	7.9	7.1
25	9.1	8.1	7.1	6.4
30	8.2	7.3	6.4	5.8
35	7.5	6.6	5.9	5.3
40	6.9	6.1	5.4	4.9

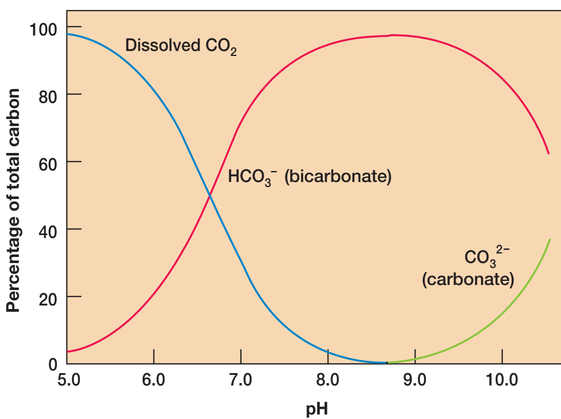

Figure 29.2 The Relationship of pH to Dissolved CO_2. Atmospheric gases can affect the physical characteristics of water. The pH of water is influenced by the amount of dissolved carbon dioxide in the water, and also by the equilibrium of the dissolved carbon dioxide with bicarbonate and carbonate ions.

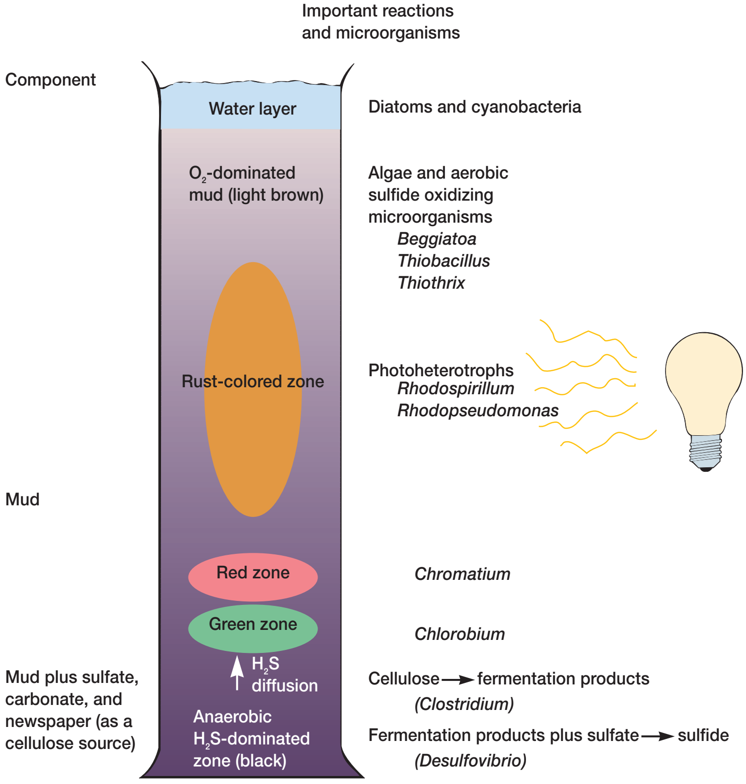

Figure 29.3 The Winogradsky Column. A microcosm in which microorganisms and nutrients interact over a vertical gradient. Fermentation products and sulfide migrate up from the reduced lower zone, and oxygen penetrates from the surface. This creates conditions similar to those in a lake with nutrient-rich sediments. Light is provided to stimulate the penetration of sunlight into the anaerobic lower region, which allows photosynthetic microorganisms to develop.

Other gases also are important in aquatic environments. These include nitrogen gas, used as a nitrogen source by nitrogen fixers; hydrogen, which is both a waste product and a vital substrate; and methane (CH_4). These gases vary in their water solubility, and methane is the least soluble of the three. Methane thus is an example of an ideal microbial waste product: once it is produced under anaerobic conditions, it leaves the microorganism's environment by diffusing up in the water column and being released to the atmosphere. This eliminates the problem of toxic waste accumulation that occurs with many microbial metabolic products, such as organic acids and ammonium ion.

1. What is an important defining characteristic of an aquatic environment?
2. Why is it critical to consider not only concentration but also flux rates of gases in waters?
3. How are anoxic zones created in aquatic environments?
4. How much oxygen, in milligrams per liter, is dissolved in water at normal room temperature and pressure? What are the effects of higher temperature and decreased pressure on oxygen solubility?
5. Why is carbon dioxide (CO_2) such a critical gas in aquatic environments? Consider both chemical equilibria and microbial processes.

Nutrients in Aquatic Environments

Nutrient concentrations in aquatic environments can vary from extremely low, in the range of micrograms of organic matter per liter, to levels approaching those in laboratory culture media, creating gradients that microorganisms exploit. High nutrient levels are found in polluted environments and sewage treatment plants, for example. With changes in nutrient levels, shifts between low-nutrient responsive and high-nutrient responsive microorganisms can occur. Nutrient turnover rates also vary. In marine environments the turnover time for nutrient processing may range from hundreds to thousands of years. In contrast, marsh and estuarine areas may have rapid rates of nutrient turnover, and a complex, diverse microbial community of rapidly responding microorganisms is present.

As noted in chapter 28, chemotrophically based marine and freshwater ecosystems are important recent discoveries, whether these occur in deep "black smoker" areas (*see pp. 126, 599–601*), in subsurface cave systems, or in shallower methane seep areas.

The **Winogradsky column,** usually constructed using a glass graduated cylinder, illustrates many interactions and gradients that occur in aquatic environments (**figure 29.3**). In this glass cylinder a layer of reduced mud is mixed with sodium sulfate, sodium carbonate, and shredded newspaper—a cellulose source—and additional

mud and water are placed in the column, which is then incubated in the light. A series of reactions occurs as the column begins to mature, with particular members of the microbial community developing in specific microenvironments in response to chemical gradients.

In the bottom of the column, cellulose is degraded to fermentation products by the genus *Clostridium* (*see section 23.3*). With these fermentation products available as reductants and using sulfate as an oxidant, *Desulfovibrio* produces hydrogen sulfide (*see section 22.4*). The hydrogen sulfide diffuses upward toward the oxygenated zone, creating a stable hydrogen sulfide gradient. In this gradient the photoautotrophs *Chlorobium* and *Chromatium* develop as visible olive green and purple zones. These microorganisms use hydrogen sulfide as an electron source, and CO_2, from sodium carbonate, as a carbon source. Above this region the purple nonsulfur bacteria of the genera *Rhodospirillum* and *Rhodopseudomonas* can grow. These photoheterotrophs use organic matter as an electron donor under anaerobic conditions and function in a zone where the sulfide level is lower. Both O_2 and hydrogen sulfide may be present higher in the column, allowing specially adapted microorganisms to function. These include *Beggiatoa* and *Thiothrix,* which use reduced sulfur compounds as a reductant and O_2 as an oxidant. In the upper portion of the column, diatoms and cyanobacteria may be visible. Green and purple photosynthetic bacteria (pp. 468–71, 487–88, 498–501); Cyanobacteria (pp. 471–76)

These commensalistic microorganisms, which develop sequentially, are dependent on the reductant originally provided as the cellulose or plant materials. When this reductant is exhausted, the column gradually becomes oxidized and the sulfide-dependent photosynthetic microorganisms and other anaerobes can no longer maintain themselves in the microcosm.

1. What are the sources of energy that support microbially based ecosystems in freshwater and marine environments?
2. What are the reasons for adding cellulose, sodium sulfate, and sodium carbonate to the Winogradsky column? Discuss this in relation to microbial groups that respond to these materials or their products.
3. What major microbial genera occur in the bottom of the Winogradsky column?

Nutrient Cycles in Aquatic Environments

The major source of organic matter in illuminated surface waters is photosynthetic activity, primarily from **phytoplankton** [Greek *phyto,* plant and *planktos,* wandering]. A common planktonic genus is *Synechococcus,* which can reach densities of 10^4 to 10^5 cells per milliliter at the ocean surface. Picocyanobacteria (very small cyanobacteria) may represent 20 to 80% of the total phytoplankton biomass upon which grazers depend.

As they grow and fix carbon dioxide to form organic matter, the phytoplankton acquire needed nitrogen and phosphorus from the surrounding water. The nutrient composition of the water affects the final carbon-nitrogen-phosphorus (C:N:P) ratio of the phytoplankton, which is termed the **Redfield ratio,** named for the aquatic biologist A. C. Redfield. A commonly used value for this ratio is 106 parts C, 16 parts N, and 1 part P. This ratio is important for following nutrient dynamics, especially mineralization and immobilization processes, and for studying factors that limit microbial growth, especially the sensitivity of oceanic photosynthesis to atmospheric additions of nitrogen, sulfur, and iron.

Once the phytoplankton have grown, much of the organic matter fixed by these minute photosynthetic organisms then enters the **microbial loop** (**figure 29.4**). In the microbial loop, organic matter is recycled to carbon dioxide and minerals. Dissolved organic matter (DOM) released by the phytoplankton is used by the heterotrophic bacteria. The DOM is transformed to bacteria, which become part of the particulate organic matter (POM) pool.

These bacteria are then consumed and digested by a series of increasingly larger predators, including protozoa and metazoan zooplankters, releasing the carbon as CO_2 and the other nutrients in mineral forms to be cycled through the phytoplankton again. This results in the rapid cycling of nutrients at a stage between the primary producers and the higher consumers such as fish, leading to a decrease in ecosystem productivity. It has been suggested that this loss of carbon through the microbial loop is relatively greater in low-nutrient (oligotrophic) than in higher-nutrient (**copiotrophic**) environments.

It is important to note that the microbial loop operates best in aerobic environments where both photosynthetic microorganisms are active and the top consumers can function. If too much organic matter is added to a water, an anaerobic foul-smelling body of water is created that will not support top consumers such as fish. Once a body of water reaches this point, only major remediation efforts to limit nutrient inputs will restore it to its original condition and allow fish and other oxygen-requiring aquatic animals to survive.

Confined animal agriculture, especially when carried out near estuarine and coastal areas, can result in massive inputs of organic matter to waters that affect aquatic oxygen levels and the functioning of the microbial loop. One pig produces wastes equivalent to three to four people, and millions of tons of manure are produced per year in various confined beef cattle, hog, and poultry operations in the United States and elsewhere in the world.

1. What does the term phytoplankton mean?
2. Describe the Redfield ratio and its use.
3. What is the microbial loop? What role do protozoans play in this "loop"?
4. Define the terms oligotrophic and copiotrophic.

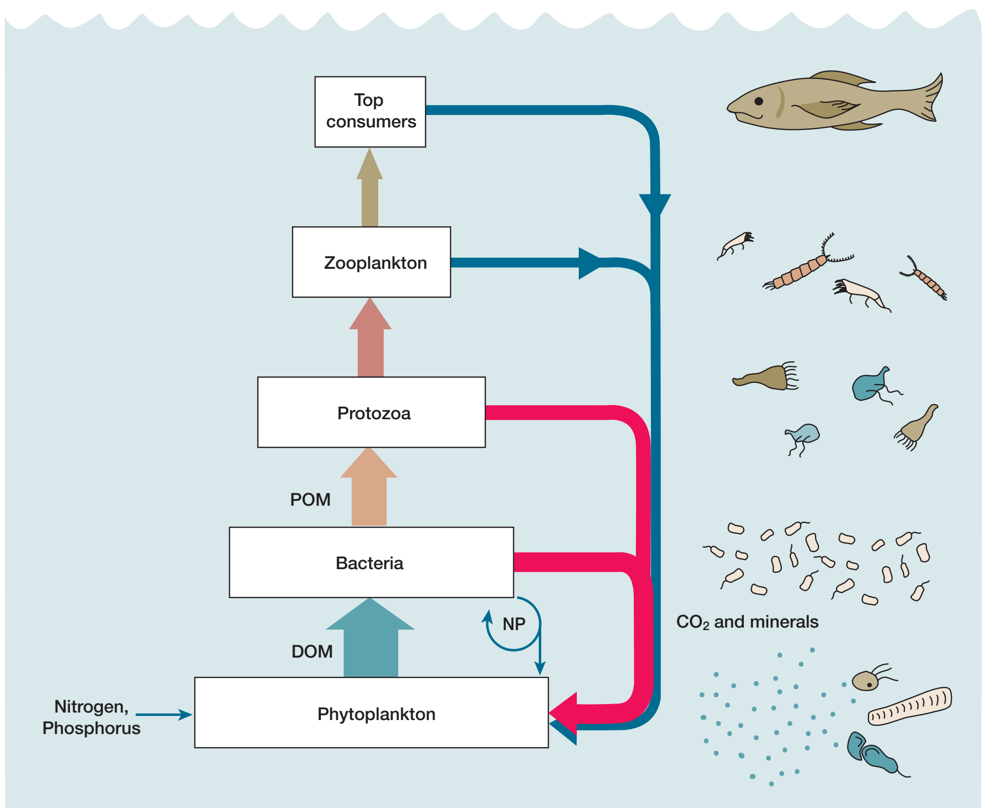

Figure 29.4 The Microbial Loop. A simplified view of the microbial loop, as it occurs in waters, is noted in red. In this loop a large portion of the organic matter synthesized by the phytoplankton during photosynthesis is released as dissolved organic matter (DOM). This DOM is used by the bacteria, which become part of the particulate organic matter (POM) pool. A portion of these bacteria are then used as a food source by protozoa. After digestion by the protozoa, a portion of the nutrients contained in the bacteria and protozoa is mineralized and "looped back" to the phytoplankton, making it unavailable to the higher trophic levels of the ecosystem. Arrow sizes representing the relative materials flows and organisms types (not to scale) are shown. Nitrogen (N), phosphorus (P).

29.2 The Microbial Community

Water provides an environment for a wide variety of microorganisms to survive and function (**table 29.2**). Microbial diversity depends on available nutrients, their varied concentrations (ranging from extremely low to very high levels), the transitions from aerobic to anaerobic zones, and the mixing of oxidants and reductants in this dynamic environment. In addition, the penetration of light into many anaerobic zones creates environments for certain types of photosynthetic microorganisms. Although important microorganisms found in aquatic environments have been discussed in the previous chapters on microbial diversity, it is important to discuss specific adaptations of microbes to these particular aquatic environments.

Table 29.2 Important Procaryotic Genera Found Primarily in Marine and Freshwater Environments

Group	Genera
Photoautotrophs	*Chlorobium* *Chloroherpeton* *Chromatium* *Pelodictyon* *Thiodictyon* *Thiopedia*
Photoheterotrophs	*Chloroflexus* *Heliobacterium* *Heliothrix* *Rhodocyclus* *Rhodomicrobium* *Rhodopseudomonas* *Rhodospirillum*
Chemoheterotrophs	*Blastobacter* *Caulobacter* *Flexibacter* *Flexithrix* *Gemmobacter* *Hyphomicrobium* *Leucothrix* *Sphaerotilus*
Chemolithoautotrophs	*Beggiatoa*[b] *Gallionella* *Thioploca*[b] *Thiothrix*[b] *Thiovulum*

Rothe, et al., "The Phylogenetic Position of the Budding Bacteria *Blastobacter aggregatus* and *Gemmobacter aquatilis"* in *Archives of Microbiology,* 147:92–99, 1987.

[a]Many are mixotrophs.

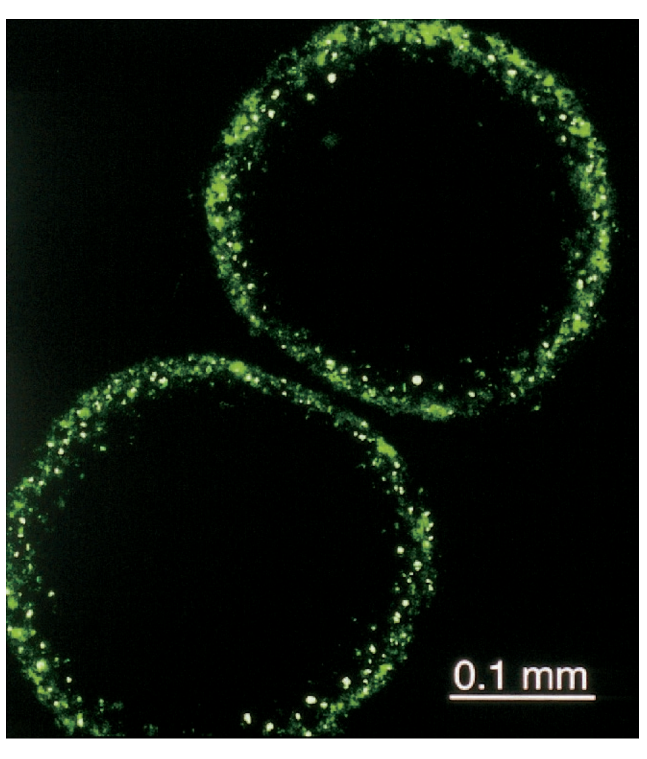

Figure 29.5 ***Thiomargarita namibiensis,* the World's Known Largest Bacterium.** This procaryote, usually 100 to 300 µm in diameter as shown here, occasionally reaches a size of 0.75 mm (larger than a period on this page), 100 times the size of a common bacterium. This unique bacterium uses sulfide from bottom sediments as an energy source and nitrate, which is found in the overlying waters, as an electron acceptor.

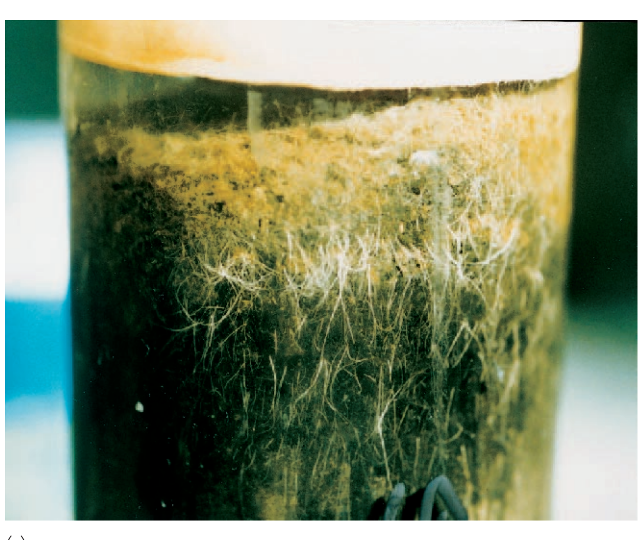
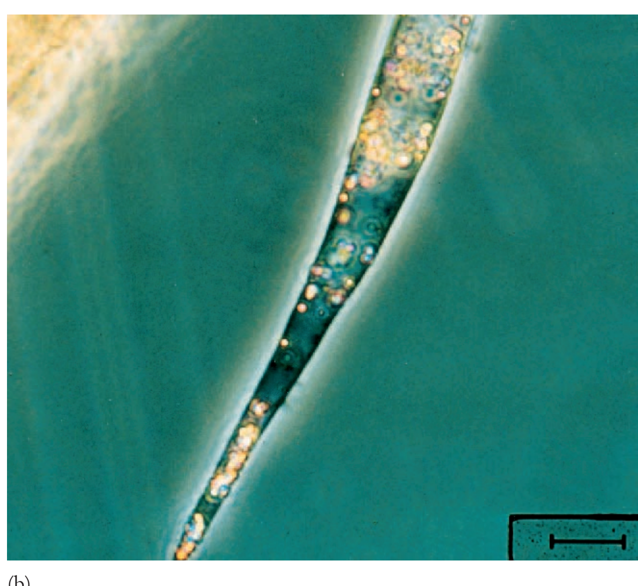
One of the most exciting findings in the last few years is the presence of extremely high levels of **ultramicrobacteria** or **nanobacteria** in aquatic environments, particularly the genus *Sphingomonas,* which easily can pass through a 0.2 µm membrane filter. These cells, which have a volume of less than 0.08 μm^3, have been found to be the dominant bacteria in marine systems (and in soils, as will be discussed in the next chapter); they may approach 10^{12} to 10^{13} cells per gram or milliliter of material. They can make up the dominant microbial biovolume in many environments, as has been shown in the northern Pacific Ocean region. These ultramicrobacteria are so small that they are not grazed as efficiently by heterotrophic nanoflagellates, giving them a unique survival advantage.

Another unusual marine microbe, found off the coast of Namibia on the west coast of Africa, is *Thiomargarita namibiensis* (**figure 29.5;** *see also Box 3.1*), which means the "sulfur pearl of Namibia." This microorganism is considered to be the world's largest bacterium! The individual cells are usually 100 to 300 µm in diameter (750 µm cells occasionally occur) and sulfide and nitrate are used as the reductant and oxidant, respectively. In this case the nitrate, from the overlying seawater, penetrates the anaerobic sulfide-containing muds only during storms. When this short-term mixing occurs, the *Thiomargarita* takes up and stores the nitrate in a huge internal vacuole, which can take up 98% of the organism's volume. The vacuolar nitrate can approach a concentration of 800 mM. The elemental sulfur granules appear near the cell edge in a thin layer of cytoplasm. Between the storms, the organism lives using the stored nitrate as an oxidant. These unique bacteria are important in sulfur and nitrogen cycling in these environments.

A critical adaptation of microorganisms in aquatic systems is the ability to link and use resources that are in separate locations, or that are available at the same location only for short intervals such as during storms. One of the most interesting bacteria linking widely separated resources is *Thioploca* spp., which lives in bundles surrounded by a common sheath (**figure 29.6**). These microbes are found in upwelling areas along the coast of Chile, where oxygen-poor but nitrate-rich waters are in contact with sul-



(a)



(b)

Figure 29.6 ***Thioploca*** **the "Spaghetti Bacterium."** ***Thioploca*** (sulfur braid) is an unusual microorganism that links separated resources of sulfide from the mud and nitrate from the overlying water. (**a**) Bundles that join the aerobic surface and the lower anaerobic mud. (**b**) An individual *Thioploca,* showing the elemental sulfur globules and tapered ends. Bar = 40 µm.

fide-rich bottom muds. The individual cells are 15 to 40 µm in diameter and many centimeters long, making them one of the largest bacteria known. They form filamentous sheathed structures, and the individual cells can glide 5 to 15 cm deep into the sulfide-rich sediments. These unique microorganisms are found in vast fields off the coast of Chile and are "the largest communities of visible bacteria in the world."

Other microorganisms take advantage of surfaces in aquatic systems. These include sessile microorganisms of the genera *Sphaerotilus* and *Leucothrix* and the prosthecate and budding bacteria of the genera *Caulobacter* and *Hyphomicrobium.* There are also a wide range of aerobic gliding bacteria such as the genera *Flexithrix* and *Flexibacter,* which move over surfaces where organic matter is adsorbed. These organisms are characterized by their exploitation of surfaces and nutrient gradients. They are obligate aerobes, although sometimes they can carry out denitrification, as occurs in the genus *Hyphomicrobium.* In addition, bacteria may be primarily colonizers of submerged surfaces, allowing subsequent development of a more complex biofilm. Budding bacterium (pp. 490–92); Sheathed bacteria (pp. 496–97); Gliding bacteria (pp. 482–83)

Microscopic fungi, which usually are thought to be terrestrial organisms living in soils and on fruits and other foods, also grow in freshwater and marine environments. Zoosporic fungi that are adapted to an aquatic existence include both the oomycetes, which have motile asexual reproductive spores with two flagella, and the chytrids, which have motile asexual reproductive spores with a single whiplash flagellum (*see chapter 25*). Most chytrids are important because of their role in decomposing dead organic matter, but they also cause potato wart disease and parasitize invertebrates, particularly nematodes and mosquitoes. In addition, many chytrids attack algae (**figure 29.7**).

Recently chytrids have been reported to live in the skin cells of amphibians, and these have been associated with die-offs of frogs and toads in many parts of the world, including the United States, Australia, and Central America. The chytrid *Batrachochytrium dendrobatidis* is one of the major zoosporic fungi that has been associated with amphibian mortalities.

Another important group includes filamentous fungi that can sporulate under water. These hypomycetes include the **Ingoldian fungi,** named after C. T. Ingold. In 1942 Ingold discovered fungi that produce unique tetraradiate forms (**figure 29.8*a***). The ecology of these aquatic fungi is very interesting (figure 29.8*b*). The tetraradiate conidium forms on a vegetative mycelium, which grows inside decomposing leaves. Released tetraradiate conidia are transported by the water and often are present in surface foam. When they contact leaves, the conidia attach and establish new centers of growth. These uniquely adapted fungi contribute significantly to the processing of organic matter, especially leaves. Often aquatic insects will feed only on leaves that contain fungi. Without fungal processing, the insects are not interested!

One of the most interesting recent discoveries regarding the marine environment is the presence of large numbers of archaea. By use of rRNA sequence comparisons (*see chapter 19*), it has

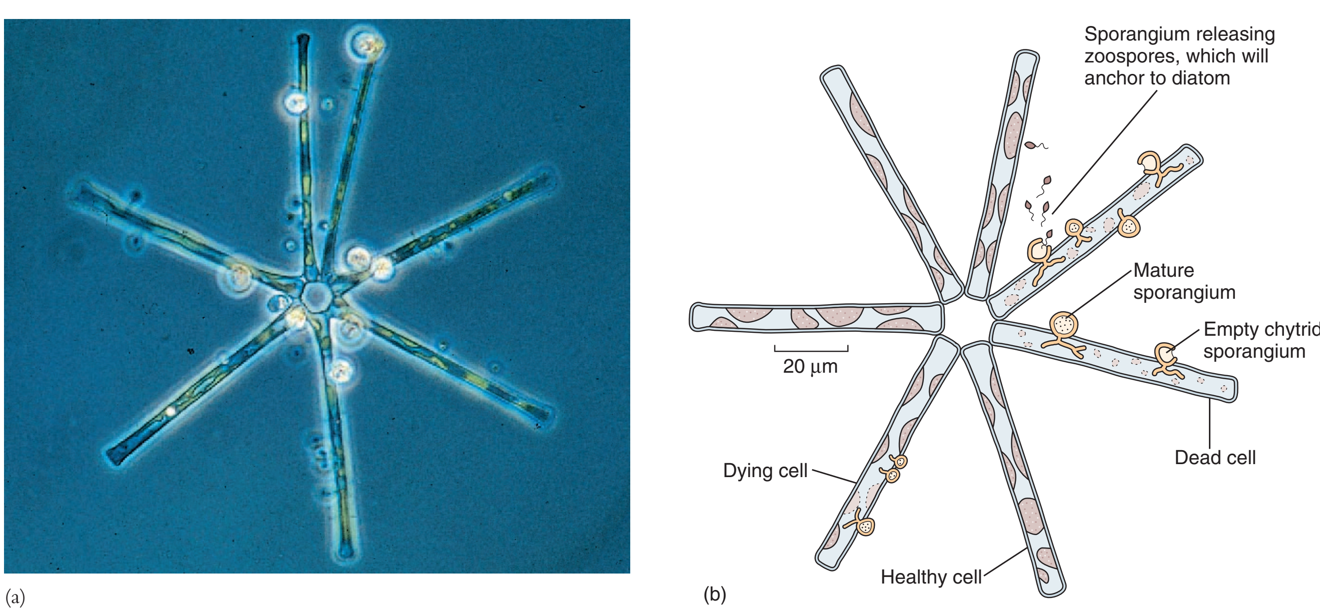


Figure 29.7 Chytrids and Aquatic Environments. Chytrids play important roles in aquatic environments. (**a**) The infection of the diatom by the chytrid *Rhizophydium* is shown in the photograph, and (**b**) in the illustration showing details of the parasitism process.

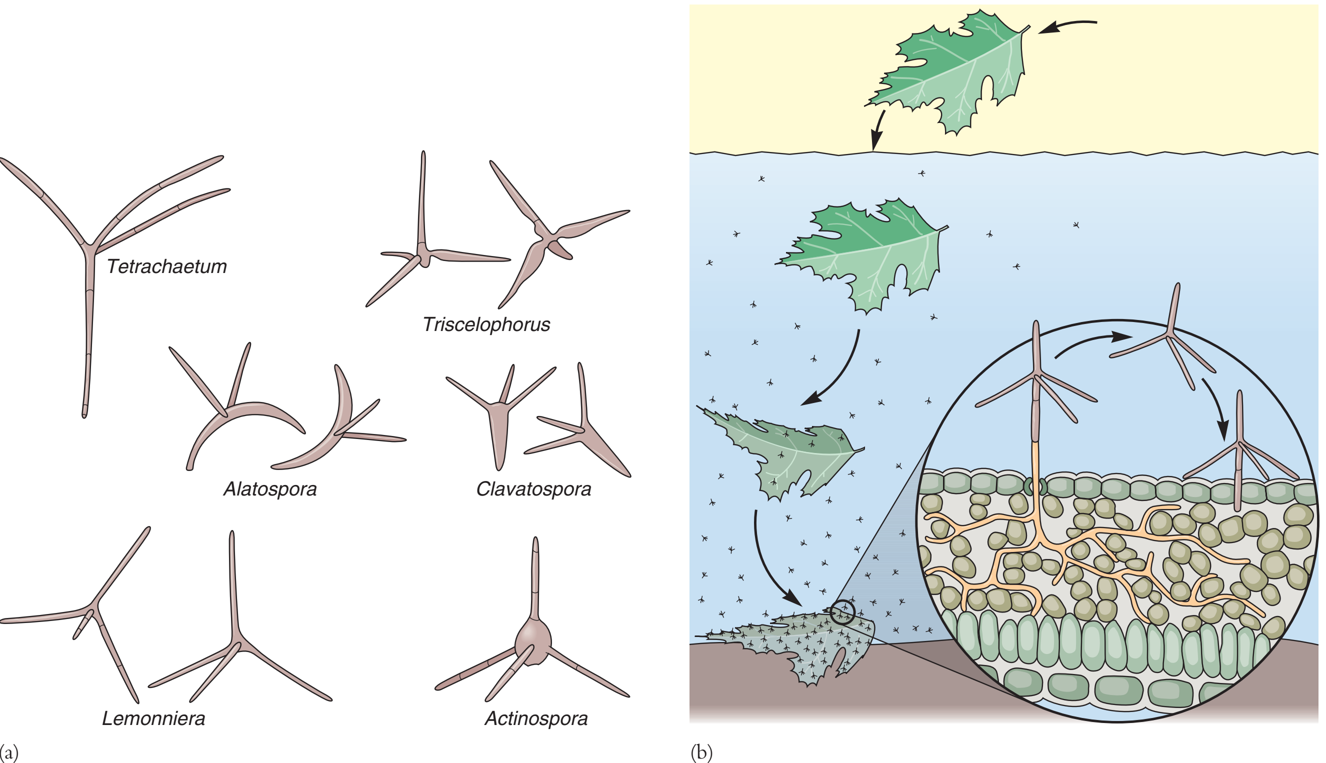

Figure 29.8 Ingoldian Fungi. These fungi, named after C. T. Ingold, are capable of sporulation under water. These aquatic fungi play important roles in the processing of complex organic matter, such as leaves, which fall into streams and lakes. These microbes include types with tetraradiate conidia (**a**). The tetraradiate conidia are produced as aerial structures (**b**) from the mycelium, which is growing inside the decomposing leaf. The new tetraradiate conidium then can be released and attaches to a leaf surface, repeating the process and accelerating leaf decomposition.

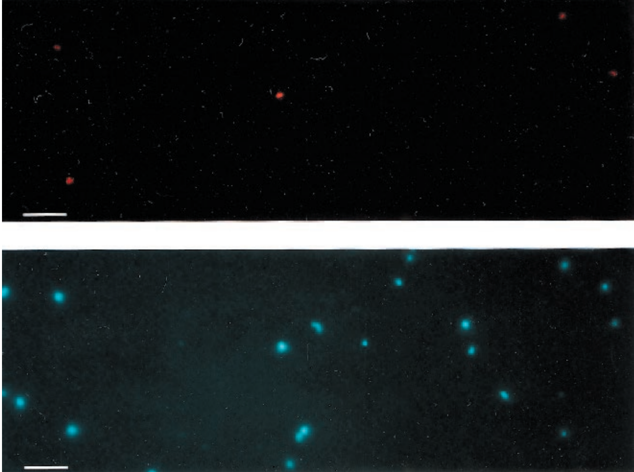

Figure 29.9 Detection of Archaea in the Ocean with Probes. Fluorescent-labeled probes and selective barrier filters can be used to detect archaea (top plate) as a part of a mixed population of procaryotes (bottom plate) in deep marine water samples using microscopy. Bar = 5 μm.

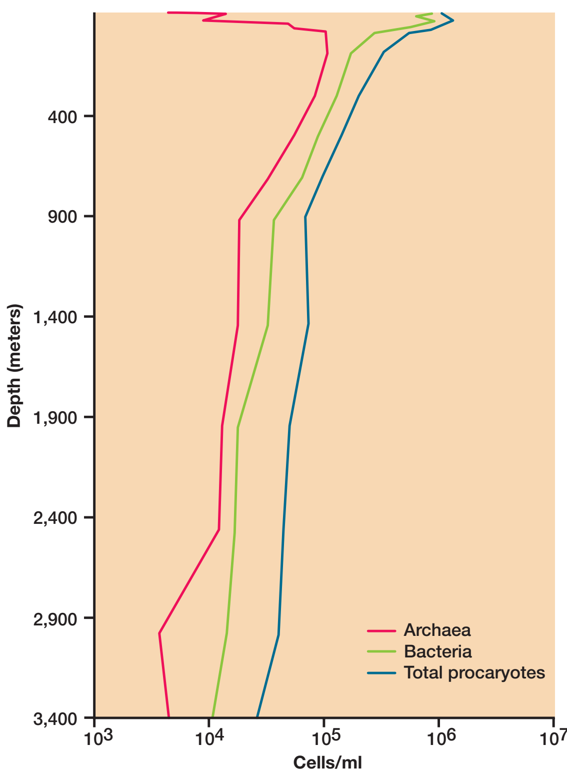

Figure 29.10 Archaea Are Plentiful in Ocean Depths. The distribution of group I archaea and bacteria, together with an estimate of total procaryotes, over a depth of 3,400 meters are shown at a Pacific Ocean location. These results indicate that archaea make up a significant part of the observable picoplankton below the surface zone.

been determined that approximately 1/3 of the oceanic picoplankton (cells smaller than 2 μm) are archaea, particularly crenarchaeans, organisms normally associated with hostile environments (hot springs, deep marine "black smoker" areas, saline and thermoacidophilic regions).

Planktonic archaea and bacteria are present in both freshwater and marine environments, and deep in the ocean. Using fluorochrome labeled probes in a fluorescent in situ hybridization (FISH) technique, it is possible to detect these different microbial groups in the same sample by the use of different exciting wavelengths (**figure 29.9**). Bacterial concentrations are higher in the surface zone, but below 100 meters archaea form a greater portion of the total population (**figure 29.10**). More than 90% of the cells react to the stains and can be detected by the use of different probes and wavelengths.

Aquatic environments also harbor large populations of viruses. These are present at 10-fold higher concentrations than the bacteria, and most are bacteriophages. These **virioplankton** are an important part of the aquatic microbial community. They may influence the functioning of the microbial loop, be involved in horizontal gene transfer between procaryotes, and control microbial community diversity.

Microorganisms are constantly mixing and being added to waters. Aquatic microorganisms are released to the atmosphere and returned to other aquatic locations by air movement, a part of aerobiology. In rivers, microorganisms can be moved thousands of miles from high mountain areas to the ocean; in lakes, flushing and turnover can occur; and in marine environments, movement and cycling of waters can occur over centuries. Microorganisms associated with detritus, animals, and fish carcasses also move with their substratum. Occasionally, carcasses of large animals such as whales will drop to the ocean floor over thousands of meters of water depth. The carcass of a dead whale lands on the ocean floor, creating new opportunities for scavengers and microorganisms (**figure 29.11**). The mobile scavenger stage lasts 0-6 months (figure 29.11*a*); the sulfophilic state lasts 1 to 2 years, with sulfides released from bones allowing chemoautotrophic microbial growth (29.11*b*); and finally after 2 to 3 years, the enrichment opportunist stage occurs (figure 29.11*c*). These transfers result in the continuous inoculation of oceans, especially, with microorganisms from other regions of the Earth.

Dust and sediment from distant terrestrial areas also continually fall on all waters and ice-covered regions, due to wind and storms, another important part of aerobiological processes. Through these atmospheric transport processes, microorganisms are constantly being mixed across all regions of the Earth. In this regard, recent studies indicate that microorganisms cultured from sediments at the bottom of the deep ocean are similar to those from surface soils. Another example is airborne dust from the sub-Saharan region of Africa, which has been linked to the massive die-off of corals in the Caribbean due to fungi and algae contained in soils that have drifted around the world in the atmosphere.

1. Discuss the unusual structure and function of *Thioploca.* What environment is this organism found in?
2. What does *Thiomargarita* mean? Where would one go to find this interesting microorganism?
3. Give the genera of sessile and prosthecate bacteria that are important in aquatic environments.
4. What are chytrids? Why might they be important in aquatic environments?
5. Describe Ingoldian fungi. How do they function in aquatic environments, and what is unique about their shape? What does the term tetraradiate mean?
6. What levels of archaea are found in aquatic environments? How have these been detected?
7. How are microorganisms moved within and between various water bodies?

29.3 Marine Environments

In terms of sheer volume, the marine environment represents a major portion of the biosphere and contains 97% of the Earth's water. Much of this is in the deep sea at a depth greater than 1,000 meters, representing 75% of the ocean's volume. The ocean has been called a "high-pressure refrigerator," with most of the volume below 100 meters at a constant 3°C temperature. The ocean, at its greatest depth, is slightly more than 11,000 meters deep or equivalent to almost 29 Empire State Buildings (each 1,250 feet or 381 meters in height) stacked on top of one another! The pressure in the marine environment increases approximately 1 atm/10 meters in depth, and pressures are in the vicinity of 1,000 atm at the greatest ocean depths (**figure 29.12**).

A series of pressure relationships is observed among the bacteria growing in this vertically differentiated system. Some bacteria are barotolerant and grow between 0 and 400 atm, but best at normal atmospheric pressure. Many other bacteria are **barophiles** [Greek, *baro,* weight and *philein,* to love] and prefer higher pressures. Moderate barophiles grow optimally at 400 atm, but still grow at 1 atm; extreme barophiles grow only at higher pressures. Pressure differences influence many biological processes including cell division, flagellar assembly, DNA replication, membrane transport, and protein synthesis. Porins, outer membrane proteins that form channels for diffusion of materials into the periplasm (*see figure 3.23*), also function most effectively at specific pressures. Pressure and microbial growth (p. 129)

Most nutrient cycling in oceans occurs in the top 300 meters where light penetrates. Light allows phytoplankton to grow and fall as a "marine snow" to the seabed. This "trip" can take a month or longer. Most of the organic matter that falls below the 300 meter zone is decomposed, and only 1% of photosynthetically derived material reaches the deep-sea floor unaltered. Because low inputs of organic matter occur in the deep sea, the ability of microorganisms to grow under oligotrophic conditions becomes important (*see section 6.5*).

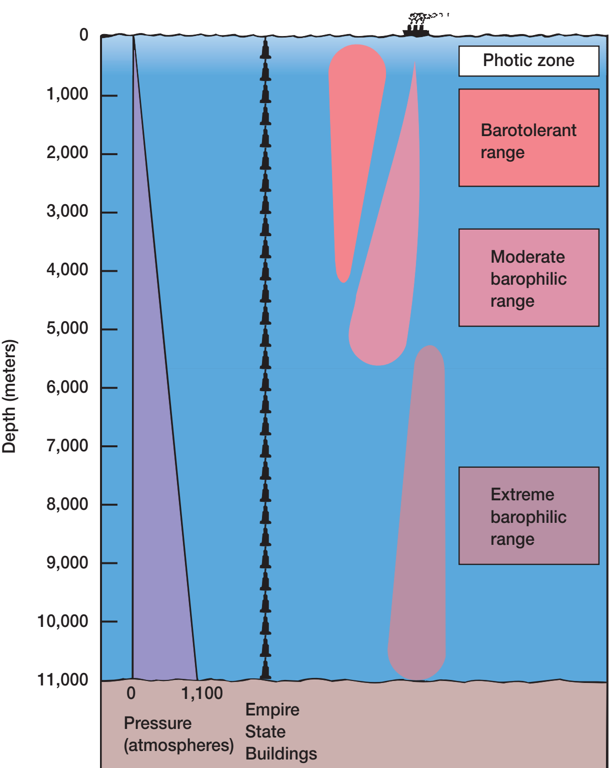

Figure 29.12 The Deep Marine Environment. Microorganisms with specialized pressure relationships are found at various depths. The relative activity and depth relationships of barotolerant, moderate barophilic, and extreme barophilic microorganisms are noted schematically. The pressure can approach 1,100 atmospheres at the deepest ocean depths. The depths are given in meters and "stacked" Empire State Buildings for perspective. Light penetrates only into a relatively shallow surface layer, creating the photic zone.

The carbon cycle within the ocean environment is only poorly understood (**figure 29.13**), but clearly microorganisms can profoundly influence the cycle. It is estimated that the large amount of dissolved organic carbon (DOC) in the ocean has a mean age of greater than 1,000 years. Organic matter in deep ocean waters has a similarly long residence time. Besides DOC, massive deposits of methane hydrate occur in ocean sediments. Under the low-temperature, high-pressure conditions found at the ocean floor below 500 meters, methane accumulates in latticelike cages of crystalline water. There may be up to 10,000 billion metric tons of carbon present as methane hydrate worldwide, 80,000 times the world's current known natural gas reserves.

The nitrogen and sulfur cycles also function at an "ocean scale" and have potentially significant effects on global-level processes, which have not been appreciated until recently. Large volumes of the ocean's water have lower oxygen levels, leading to denitrification and a decrease in the nitrate-phosphate ratio in the water. As a consequence, nitrogen fixation may be favored and increase the nitrogen level in the water. It appears that nitrogen, and not phosphorus, often can limit biological activity in many marine environments. The ocean sulfur cycle also has widespread effects on global processes. Dimethylsulfide (DMS), an algal osmolite, can be released to the atmosphere and comprises 90% of the volatile sulfur compounds in the sulfur cycle. When DMS is oxidized, its end products can influence the acidity of the atmosphere, as well as the Earth's temperature and cloud formation.

Additional cold-temperature microorganisms include those involved in the production and use of methane. As already noted, methane hydrates are found at low temperatures and high pressures in many marine regions of the world. The procaryotes that consume these methane hydrates serve as a food source for ice worms, *Hesiocaeca methanicola.* Archaea, as a part of complex microbial communities, appear to metabolize methane deposits at low hydrogen levels under sulfate reducing conditions. The process is called **reverse methanogenesis.**

Much of the marine environment is covered by sea ice that may comprise up to 7% of the world's surface at the winter maxima at the north and south poles! Microorganisms actually grow and reproduce at the interface between the ice and the seawater. **Figure 29.14** shows an ice core taken from the lower zone of an ice sheet at the seawater-ice interface; a band of microorganisms is clearly visible in the ice profile. Pockets of salt brine also form in this region, creating additional environments with varied temperatures, salinities, nutrient concentrations, and light levels for these cold-adapted microorganisms. The microbes that have been recovered from these ice cores have been given intriguing generic names: these include *Polaromonas, Marinobacter, Psychroflexus, Iceobacter, Polibacter,* and *Psychromonas antarcticus.*

Increased human populations and the urban development occurring in coastal areas around the world is taxing the seemingly inexhaustible ability of oceans to absorb and process pollutants. Coastal areas that have limited mixing with ocean waters (e.g., the Baltic Sea, Long Island Sound, Chesapeake Bay, the Mediterranean) are showing signs of nutrient enrichment and microbial pollution. One example is shellfish contamination by runoff waters from urbanized coastal areas. Only a few years ago shellfish could be harvested without delay after major rainfalls; now, one week or longer is needed to allow dieback of polluting microorganisms. This economically impacts individuals who depend on harvesting of shellfish for a livelihood.

In the Gulf of Mexico, at the Mississippi River delta, releases of nutrients from states that drain into this river have stimulated microbial growth and oxygen depletion. This has created a "dead zone," a hypoxic or anoxic region, that is larger than the state of New Jersey. The lowered oxygen levels occurring in this rich shellfish area have damaged the economy of these aquaculture-dependent regions.

Another problem that relates to ocean waters and water mixing in coastal areas is the occurrence of red tides (*see Box 26.2*). This has major economic effects when shellfish cannot be harvested or consumed. Recently the occurrence of algal blooms and red tides in the Pacific Ocean off the central California coast has resulted in the die-off of dolphins. The major algal genus responsible for the

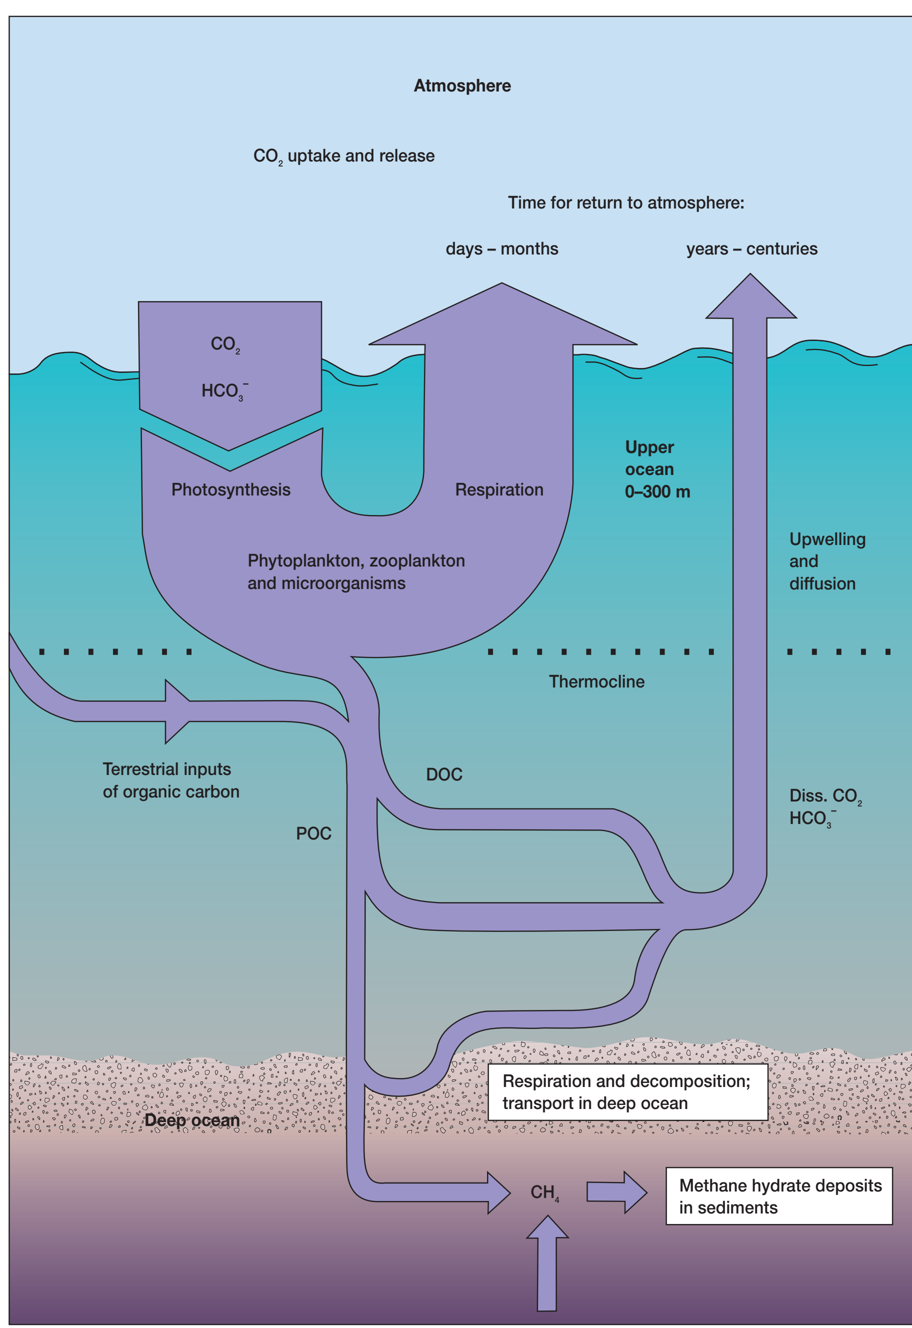

Figure 29.13 Carbon Cycling in the Ocean Environment. Microorganisms in the oceans can influence global carbon cycling and ocean-atmosphere interactions. Most carbon processing occurs in the surface water zone, with particulate organic carbon (POC), dissolved organic carbon (DOC), and methane hydrate (in sediments) being major carbon pools. The ocean also contains bicarbonate and dissolved CO_2 (diss. CO_2) that come from the atmosphere and the degradation of organic carbon. Methane hydrate allows microorganisms and associated animals such as ice worms to develop.

Figure 29.14 Sea ice as a Habitat for Microorganisms. Sea ice allows the development of complex microbial communities. The bottom of a sea ice core from the Antarctic, which is in contact with the underlying seawater, is shown. The dark band (see arrow) is the sea ice microbial community.

widespread loss of these aquatic animals is *Pseudo-nitzschia.* The key link is anchovies. This fish, consumed by the dolphins, feeds on algae that contain a high concentration of a neurotoxin, domoic acid; this toxin has been detected in the sick and dead dolphins.

Algae may cause problems other than red tides. An excellent example is *Pfiesteria piscicida,* a dinoflagellate (*see pp. 579–80*) that has produced major fish kills from Maryland southward along the U.S. Atlantic coast. It even can cause dizziness and loss of memory in people exposed to its toxins. *Pfiesteria* has an exceptionally complex life cycle that probably involves at least 24 stages (**figure 29.15**)! This primitive protisfan alga is a fish predator. Its flagellated vegetative cell stage can detect fish compounds in the water and then literally attack the approaching fish. *Pfiesteria* produces at least two powerful toxins: one that stuns the fish and another that causes the characteristic lesions (**figure 29.16**). This dinoflagellate apparently once used other algae as its primary food source, but now has become a killer of fish, eels, crabs, and other animals. Increased nutrient levels are suspected as the cause of its increasing prevalence.

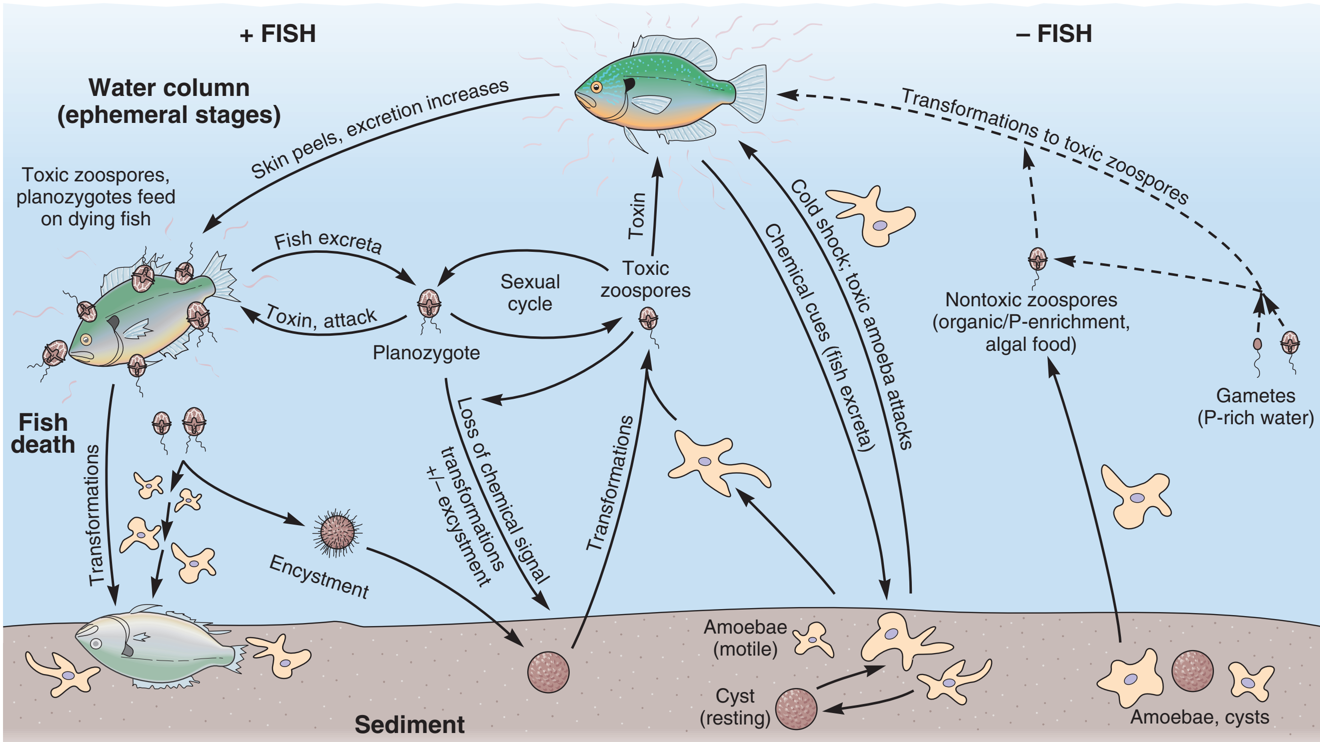

Figure 29.15 Basic Life Cycle of *Pfiesteria piscicida.* The cycle can occur with (+) and without (−) the presence of a fish in the overlying waters.

Figure 29.16 ***Pfiesteria* Lesions.** Lesions on menhaden resulting from parasitism by the dinoflagellate *Pfiesteria piscicida.* Note that the worker is using thick gloves—humans also are susceptible to these toxins, which can cause dizziness, loss of memory, and impaired motor function.

Global-level movements of air also affect marine microorganisms. The atmospheric movement of soils and industrial activities influence phytoplankton growth and their Redfield ratio (p. 638). In the northern Pacific, the water is iron-limited, and iron is being added to these waters by desertification and dust storms in central Asia, thus increasing primary production. In contrast, the northern Atlantic Ocean is nitrogen-limited, and a transition from N- to P-limitation is occurring with increased depositions of atmospheric nitrogen from human activities. The N:P ratio in the deep North Atlantic is increasing and altering the phytoplankton Redfield ratio.

1. What portion of the water in the world is marine?
2. Why is sea ice an important habitat for microorganisms? Where are the microorganisms mostly located?
3. What microbially produced volatile sulfur compound can influence the weather?
4. Where are methane hydrates found, and what is reverse methanogenesis?
5. What is hypoxia or anoxia? What are possible causes?
6. Microbiological quality of waters in marine coastal areas is important. What are some major concerns?
7. What link has been found recently between algae, anchovies, and dolphins?
8. What is unique about *Pfiesteria?*
9. How can atmospheric processes influence nutrient limitation in marine waters?

29.4 Freshwater Environments

Most fresh water that is not locked up in ice sheets, glaciers, or groundwaters is found in lakes and rivers. These provide microbial environments that are different from the larger oceanic systems in many important ways. For example, in lakes, mixing and water exchange can be limited. This creates vertical gradients over much shorter distances. Changes in rivers occur over distance and/or time as water flows through river channels.

Lakes

Lakes vary in nutrient status. Some are **oligotrophic** or nutrient-poor (**figure 29.17*a***), others are **eutrophic** or nutrient-rich (figure 29.17*b*). Nutrient-poor lakes remain aerobic throughout the year, and seasonal temperature shifts do not result in distinct oxygen stratification. In contrast, nutrient-rich lakes usually have bottom sediments that contain organic matter. In thermally stratified lakes the **epilimnion** (warm, upper layer) is aerobic, while the **hypolimnion** (deeper, colder, bottom layer) often is anaerobic (particularly if the lake is nutrient-rich). The epilimnion and hypolimnion are separated by a zone of rapid temperature decrease called the **thermocline,** and there is little mixing of water between the two layers. In the spring and fall, the aerobic surface water and the anaerobic subsurface water will turn over as the result of differences in temperature and specific gravity. After such mixing occurs, motile bacteria and algae migrate within the water column to again find their most suitable environment.

When sufficiently large amounts of nutrients are added to water, **eutrophication** (nutrient enrichment) takes place and stimulates the growth of plants, algae, and bacteria (*see figure 21.11*). Because nitrogen and phosphorus frequently limit microbial growth in freshwater habitats, the addition of nitrogen and phosphorus compounds has a particularly large impact on freshwater systems. Depending on the body of water and the rate of nutrient addition, eutrophication may either require many centuries or occur very rapidly.

If phosphorus is added to oligotrophic fresh water, cyanobacteria play the major role in nutrient accumulation, even in the absence of extra nitrogen. Several genera, notably *Anabaena, Nostoc,* and *Cylindrospermum,* can fix nitrogen under aerobic conditions (*see section 21.3*). The genus *Oscillatoria,* using hydrogen sulfide as an electron donor for photosynthesis, can fix nitrogen under anaerobic conditions. Even with both nitrogen and phosphorus present, cyanobacteria still can compete with algae. Cyanobacteria function more efficiently with higher pH conditions (8.5 to 9.5) and higher temperatures (30 to 35°C). Eucaryotic algae, in comparison, generally prefer a more neutral pH and have lower optimum temperatures. By using CO_2 at rapid rates, cyanobacteria also increase the pH, making the environment less suitable for eucaryotic algae.
Algae (chapter 26); Cyanobacteria (pp. 471–76)

Cyanobacteria have additional competitive advantages. Many produce hydroxamates, which bind iron, making this important trace nutrient less available for the eucaryotic algae. Cyanobacteria also often resist predation because of their production of toxins. In addition, some synthesize odor-producing compounds that affect the quality of drinking water.

Both cyanobacteria and algae can contribute to massive blooms in strongly eutrophied lakes (*see figure 21.11*). This problem may continue for many years, until the nutrients are eventually lost from the lake by normal water passage or by precipitation

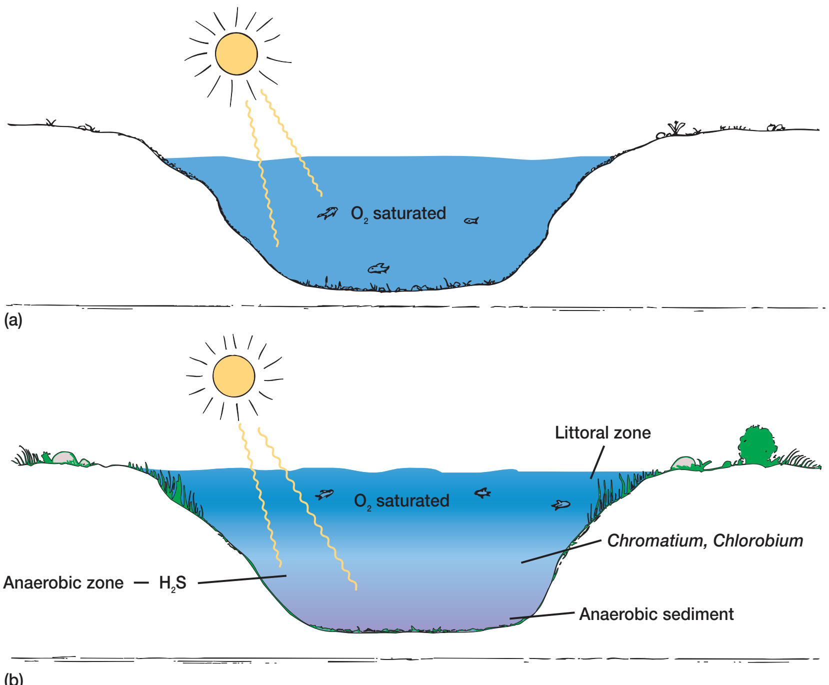

Figure 29.17 Oligotrophic and Eutrophic Lakes. Lakes can have different levels of nutrients, ranging from low nutrient to extremely high nutrient systems. The comparison of (**a**) an oligotrophic (nutrient-poor) lake, which is oxygen saturated and has a low microbial population, with (**b**) a eutrophic (nutrient-rich) lake. The eutrophic lake has a bottom sediment layer and can have an anaerobic hypolimnion. Sulfur photosynthetic microorganisms can develop in this anaerobic region.

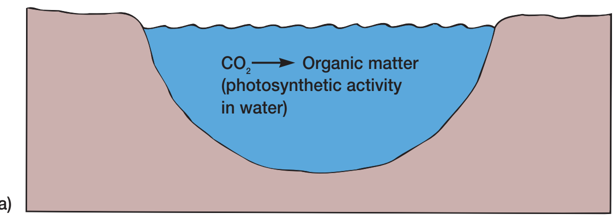
of nutrients in bottom sediments. Lake management can improve the situation by removing or sealing bottom sediments or adding coagulating agents to speed sedimentation.

1. What terms can be used to describe the different parts of a lake?
2. Why are cyanobacteria so important in waters that have been polluted by phosphorus additions?
3. What are some important effects of eutrophication on lakes?

Streams and Rivers

Streams and rivers present a different situation from lakes in that there is sufficient horizontal water movement to minimize vertical stratification; in addition, most of the functional microbial biomass is attached to surfaces. Only in the largest rivers will a greater relative portion of the microbial biomass be suspended in the water. Depending on the size of the stream or river, the source of nutrients may vary. The source may be in-stream production based on photosynthetic microorganisms (**figure 29.18*a***). Nutrients also may come from outside the stream, including runoff sediment from riparian areas (the edge of a river), or leaves and other organic matter falling directly into the water (figure 29.18*b*). Chemoorganotrophic microorganisms metabolize the available organic material and provide an energy base for the ecosystem. Under most conditions the amounts of organic matter added to streams and rivers will not exceed the system's oxidative capacity, and productive, aesthetically pleasing streams and rivers will be maintained.



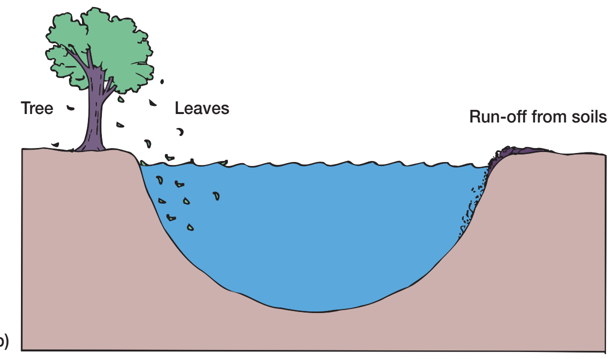


Figure 29.18 Organic Matter Sources for Lakes and Rivers. Organic matter used by microorganisms in lakes and rivers can be synthesized in the water, or can be added to the water from outside. (**a**) Within-stream sources of organic matter, primarily photosynthesis, and (**b**) sources of organic matter which enter streams and rivers from outside the water. Stream cross sections are shown.

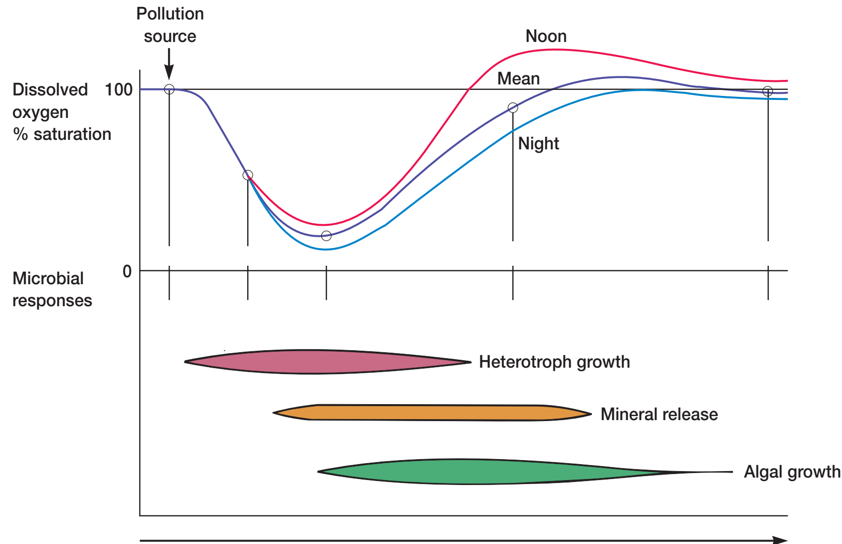

Figure 29.19 The Dissolved Oxygen Sag Curve. Microorganisms and their activities can create gradients over distance and time when nutrients are added to rivers. An excellent example is the dissolved oxygen sag curve, caused when organic wastes are added to a clean river system. During the later stages of self-purification, the phototrophic community will again become dominant, resulting in diurnal changes in river oxygen levels.

The capacity of streams and rivers to process such added organic matter is, however, limited. If too much organic matter is added, the water may become anaerobic. This is especially the case with urban and agricultural areas located adjacent to streams and rivers. The release of inadequately treated municipal wastes and other materials from a specific location along a river or stream represents a **point source of pollution.** Such point source additions of organic matter can produce distinct and predictable changes in the microbial community and available oxygen, creating an oxygen sag curve (**figure 29.19**). Runoff from fields and feedlots, which causes algal blooms in eutrophic water bodies, is an example of a **nonpoint source of pollution.**

When the amount of organic matter added is not excessive, the algae will grow using the minerals released from the organic matter. This leads to the production of O_2 during the daylight hours, and respiration will occur at night farther down the river, resulting in **diurnal oxygen shifts.** Eventually the O_2 level approaches saturation, completing the self-purification process.

Along with the stresses of added nutrients, removal of silicon from rivers by the construction of dams and trapping of sediments causes major ecological disturbances. For example, construction of the dam at the "iron gates" on the Danube (600 miles above the Black Sea) has led to a decrease in silicon to 1/60th of the previous concentration. This decreased silicon availability then inhibits the growth of diatoms (*see pp. 577–78)* because the ratio of silicon to nitrate has been altered (silicon is required for diatom frustule formation). With this shift in resources, Black Sea diatoms are not able to grow and immobilize nutrients. The result has been a 600-fold increase in nitrate levels and a massive development of toxic algae. Thus the delicate balance of rivers can be altered in unexpected ways by dams (there are over 36,000 dams in the world, and more being built, including in China), leading to effects on aquatic microbiological processes and whole ecosystems.

With the damaging effects of dams now being recognized, there is a growing trend to attempt to breach these structures to restore normal water and sediment movements, and to allow fish migration into upper regions of rivers where they often have been excluded for decades.

Microorganisms in Freshwater Ice

Fresh waters include glaciers, as well as vast ice sheets in the Arctic and Antarctic polar regions. These regions, although far away from most people, are important as habitats for microorganisms. Of particular interest are deep frozen lakes in the Antarctic region. An excellent example is the McMurdo Dry Valley Lakes, which have 3 to 6 meter thick ice layers with windblown sediments occupying various levels in the ice profile. In the summer, melting of the ice in these sediment-containing zones provides an opportunity for microbial growth. There is interest in studying ice-inhabiting microorganisms from the north and south poles. Are they isolated and different populations? Do some of them show biogeographic distribution?

One of the most interesting deep-frozen habitats lies above Lake Vostok in the Antarctic, where cores have been taken to a depth of 3,600 meters (11,800 feet) in ice that has been frozen for over 420,000 years. The actual Lake Vostok lies below another 120 meters of ice. The lake itself has a size similar to that of Lake Ontario, but it is deeper, being 500 meters in depth. Scientists are actively searching for microorganisms in these unique older freshwater frozen environments. It is hoped that it will be possible to link microbial communities and the time of their deposition.

1. What is an oxygen sag curve, and what changes in a river lead to these effects?
2. What are point and nonpoint pollution? Give examples.
3. Why might dams influence microorganisms and microbial processes in rivers?
4. What is unique about Lake Vostok in the Antarctic?

Table 29.3 Water-Based Microbial Pathogens That Can Be Maintained in the Environment Independent of Humans

Organism	Reservoir	Comments
Bacteria		
Aeromonas hydrophila	Free-living	Sometimes associated with gastroenteritis, cellulitis, and other diseases
Campylobacter	Bird and animal reservoirs	Major cause of diarrhea; common in processed poultry; a microaerophile
Helicobacter pylori	Free-living, not known	Can cause type B gastritis, peptic ulcers, gastric adenocarcinomas
Legionella pneumophila	Free-living and associated with protozoa	Found in cooling towers, evaporators, condensers, showers, and other water sources
Leptospira	Infected animals	Hemorrhagic effects, jaundice
Mycobacterium	Infected animals and free-living	Complex recovery procedure required
Pseudomonas aeruginosa	Free-living	Swimmer's ear and related infections
Salmonella enteriditis	Animal intestinal tracts	Common in many waters
Vibrio cholera	Free-living	Found in many waters and estuaries
Vibrio parahaemolyticus	Free-living in coastal waters	Causes diarrhea in shellfish consumers
Yersinia enterocolitica	Frequent in animals and in the environment	Waterborne gastroenteritis
Protozoa		
Acanthamoeba	Sewage sludge disposal areas	Can cause granulomatous amebic encephalitis (GAE); keratitis, corneal ulcers
Cryptosporidium	Many species of domestic and wild animals	Causes acute enterocolitis; important with immunologically compromised individuals; cysts resistant to chemical disinfection; not antibiotic sensitive
Cyclospora cayetanensis	Waters—does not withstand drying; possibly other reservoirs	Causes long-lasting (43 days average) diarrheal illness; infection self-limiting in immunocompetent hosts; sensitive to prompt treatment with Bactrim
Giardia lamblia	Beavers, sheep, dogs, cats	Major cause of early spring diarrhea; important in cold mountain water
Naegleria fowleri	Warm water (hot tubs), swimming pools, lakes	Inhalation in nasal passages; central nervous system infection; causes primary amebic meningoencephalitis (PAM)

29.5 Waters and Disease Transmission

Since the beginning of recorded history water has been recognized as a potential carrier of disease. In order to protect his health, Alexander the Great (356–323 B.C.) had his personal drinking water carried in silver urns. Clearly the association between noble heavy metals such as silver and the prevention of waterborne diseases was early established through chance observation. The connection between a freshwater supply and the health of an urban population was recognized by the time of the Roman Empire (27 B.C.). However, much of the technology for the protection of the water supply was subsequently lost until the middle of the nineteenth century.

With increased use of waters by humans, especially as a receptacle for the disposal of human wastes, the effects of added organic matter and pathogens is of continuing concern for human health.

Waterborne Pathogens and Water Purification

Many important human pathogens are maintained in association with living organisms other than humans, including many wild animals and birds. Some of these bacterial and protozoan pathogens can survive in water and infect humans. As examples, *Vibrio vulnificus, V. parahaemolyticus,* and *Legionella* are of continuing concern. When waters are used for recreation or are a source of seafood that is consumed uncooked, the possibility for disease transmission certainly exists. A waterborne infection may have serious consequences for immunologically compromised individuals.

Some major waterborne diseases are summarized in **table 29.3.** Waterborne bacterial and viral pathogens are extensively discussed in sections 38.4 and 39.4. The protozoan pathogens *Giardia, Cryptosporidium* are described in section 40.2; *Cyclospora* is discussed on page 653.

Another waterborne protozoan disease of increasing concern worldwide is primary amebic meningoencephalitis (PAM), an infection of the central nervous system caused by *Naegleria fowleri.* The disease usually occurs in children or young adults who have been swimming in lakes or pools or have been waterskiing. After nasal infection the protozoan reaches the brain and initiates an inflammatory response. The result usually is fatal. Warm water and heated industrial effluents promote the growth of this protozoan.

Protozoan diseases (pp. 950–58); Food-borne and waterborne viral diseases (pp. 891–93); Food-borne and waterborne bacterial diseases (pp. 926–33)

Water purification is a critical link in controlling disease transmission in waters. As shown in **figure 29.20,** water purification can involve a variety of steps, depending on the type of impurities in the raw water source. For example, if the raw water contains large amounts of iron and manganese, which will often precipitate when water is exposed to air, it may be necessary to aerate the water and employ other methods to remove these ions early in the purification sequence. Usually municipal water supplies are purified by a process that consists of at least three or four

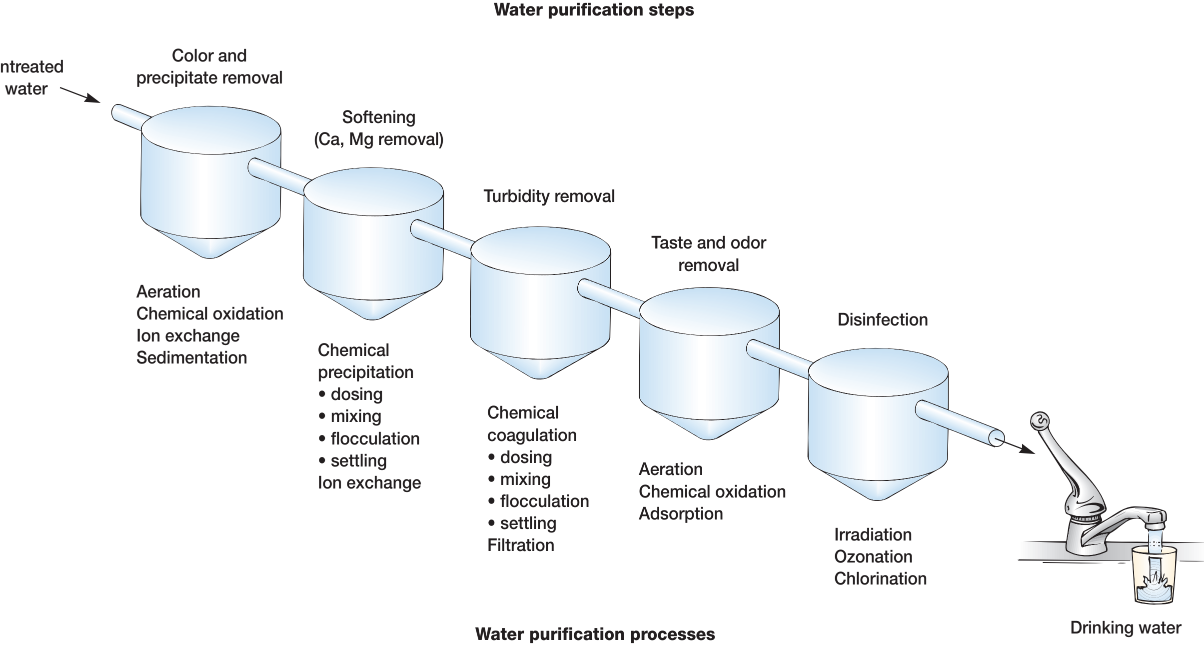

Figure 29.20 Water Purification. Several alternatives can be used for drinking water treatment depending on the initial water quality. A major concern is disinfection: chlorination can lead to the formation of disinfection byproducts (DBPs), including potentially carcinogenic trihalomethanes (THMs).

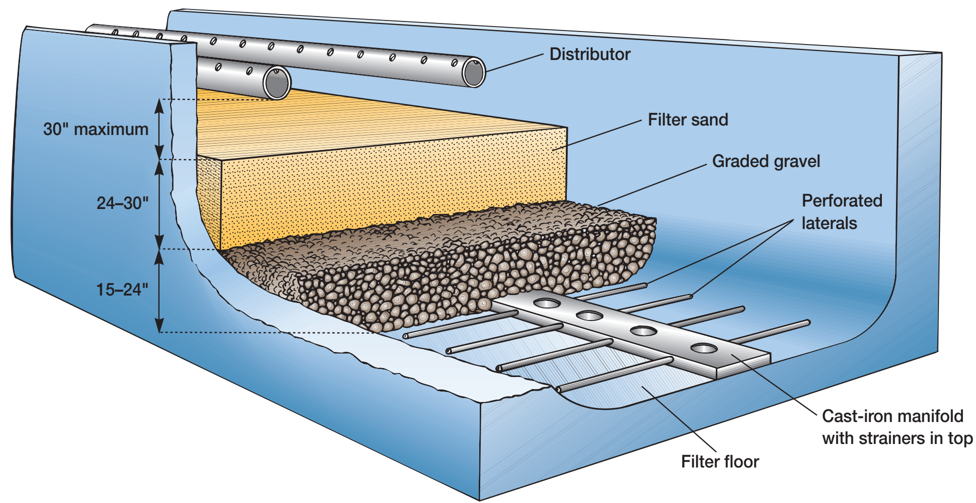

Figure 29.21 Water Filtration. Physical filtration is an important step in drinking water treatment. This is a cross section of a typical sand filter showing layers of sand and graded gravel.

steps. If the raw water contains a great deal of suspended material, it often is first routed to a **sedimentation basin** and held so that sand and other very large particles can settle out. The partially clarified water is then mixed with chemicals such as alum and lime and moved to a **settling basin** where more material precipitates out. This procedure is called **coagulation** or flocculation and removes microorganisms, organic matter, toxic contaminants, and suspended fine particles. After these steps the water is further purified by passing it through a filtration unit (**figure 29.21**). **Rapid sand filters,** which depend on the physical trap-

Box 29.2

Waterborne Diseases, Water Supplies, and Slow Sand Filtration: The Return of a Time-Tested Concept in Drinking Water Treatment

Slow sand filtration, in which drinking water is passed through a sand filter that develops a layer of microorganisms on its surface, has had a long and interesting history. After London's severe cholera epidemic of 1849, Parliament, in an act of 1852, required that the entire water supply of London be passed through slow sand filters before use.

The value of this process was shown in 1892, when a major cholera epidemic occurred in Hamburg, Germany, and 10,000 lives were lost. The neighboring town, Altona, which used slow sand filtration, did not have a cholera epidemic. Slow sand filters were installed in many cities in the early 1900s, but the process fell into disfavor with the advent of rapid sand filters, chlorination, and the use of coagulants such as alum. Slow sand filtration, a time-tested process, is regaining favor because of its filtration effectiveness and lower maintenance costs. Slow sand filtration is particularly effective for the removal of *Giardia* from waters. For this reason slow sand filtration is used in many mountain communities where *Giardia* is a problem.

ping of fine particles and flocs are usually used for this purpose. This filtration removes up to 99% of the remaining bacteria. After filtration the water is treated with a disinfectant. This step usually involves chlorination, but ozonation is becoming increasingly popular. When chlorination is employed, the chlorine dose must be large enough to leave residual free chlorine at a concentration of 0.2 to 2.0 mg/liter. A concern is the creation of **disinfection by-products (DBPs)** such as **trihalomethanes (THMs)** that are formed when chlorine reacts with organic matter. Some of these compounds may be carcinogens.

The preceding purification process effectively removes or inactivates disease-causing bacteria and indicator organisms (coliforms). Unfortunately, however, the use of coagulants, rapid filtration, and chemical disinfection often does not consistently and reliably remove *Giardia lamblia* cysts, *Cryptosporidium* oocysts, *Cyclospora,* and viruses. *Giardia,* a cause of human diarrhea, is now recognized as the most common identified waterborne pathogen in the United States. The protozoan, first observed by Leeuwenhoek in 1681, has trophozoite and cyst forms. The disease often is called "backpacker's diarrhea" and is transmitted primarily through untreated stream water or undependable municipal water supplies. More consistent removal of *Giardia* cysts, which are about 7 to 10 by 8 to 12 μm in size, can be achieved with **slow sand filters.** This treatment involves the slow passage of water through a bed of sand in which a microbial layer covers the surface of each sand grain. Waterborne microorganisms are removed by adhesion to the gelatinous surface microbial layer (**Box 29.2**). *Giardia* (pp. 589, 953–54)

In the last few years, *Cryptosporidium* has become of even greater concern than *Giardia.* This protozoan parasite is smaller than *Giardia* and is even more difficult to remove from water. *Cryptosporidium* is discussed in section 40.2.

Another newly emerging protozoan human pathogen is *Cyclospora.* This coccidian protozoan is larger than *Cryptosporidium* and has two sporocysts, each with two sporozoites (*Cryptosporidium* has four sporozoites in its oocysts). *Cyclospora* causes cyclosporiasis, a self-limiting diarrhea that lasts from 19 to 43 days and can be accompanied by nausea, vomiting, cramps, and fever. *Cyclospora* has recently been implicated in the occurrence of diarrheal diseases due to fecal contamination of imported fruits and vegetables.

Viruses in drinking water also must be destroyed or removed. Coagulation and filtration do reduce virus levels about 90 to 99%. Further inactivation of viruses by chemical oxidants, high pH, and photooxidation may yield a reduction as great as 99.9%. None of these processes, however, is considered to provide sufficient protection. New standards for virus inactivation are being developed. Bacteriophages (*see chapter 17*), which can be easily grown and assayed, now are being used as disinfection surrogates. If sufficient log reductions of bacteriophage infectivity occur with a given disinfection process, it is assumed that viruses capable of infecting humans will be reduced to satisfactory levels.

With the increased concern for drinking water quality in the United States, an Information Collection Rule (ICR) has been initiated. This program has been designed to assess the threat of these pathogens to the waters of cities with populations over 100,000.

1. Which important bacterial pathogens can be transmitted by waters?
2. What disease is caused by *Naegleria fowleri?* What is the route of entry to the human body?
3. What steps are usually taken to purify drinking water?
4. Why is chlorination, although beneficial in terms of bacterial pathogen control, of environmental concern?
5. Which important waterborne pathogens are not controlled reliably by chlorination?

Sanitary Analysis of Waters

Monitoring and detection of indicator and disease-causing microorganisms are a major part of sanitary microbiology. Bacteria from the intestinal tract generally do not survive in the aquatic environment, are under physiological stress, and gradually lose their ability to form colonies on differential and selective media.

Their die-out rate depends on the water temperature, the effects of sunlight, the populations of other bacteria present, and the chemical composition of the water. Procedures have been developed to attempt to "resuscitate" these stressed coliforms before they are identified using selective and differential media.

A wide range of viral, bacterial, and protozoan diseases result from the contamination of water with human fecal wastes (*see chapters 38, 39, and 40*). Although many of these pathogens can be detected directly, environmental microbiologists have generally used **indicator organisms** as an index of possible water contamination by human pathogens. Researchers are still searching for the "ideal" indicator organism to use in sanitary microbiology. The following are among the suggested criteria for such an indicator:

1. The indicator bacterium should be suitable for the analysis of all types of water: tap, river, ground, impounded, recreational, estuary, sea, and waste.
2. The indicator bacterium should be present whenever enteric pathogens are present.
3. The indicator bacterium should survive longer than the hardiest enteric pathogen.
4. The indicator bacterium should not reproduce in the contaminated water and produce an inflated value.
5. The assay procedure for the indicator should have great specificity; in other words, other bacteria should not give positive results. In addition, the procedure should have high sensitivity and detect low levels of the indicator.
6. The testing method should be easy to perform.
7. The indicator should be harmless to humans.
8. The level of the indicator bacterium in contaminated water should have some direct relationship to the degree of fecal pollution.

Coliforms, including *Escherichia coli,* are members of the family *Enterobacteriaceae.* These bacteria make up approximately 10% of the intestinal microorganisms of humans and other animals (*see figure 31.2*) and have found widespread use as indicator organisms. They lose viability in fresh water at slower rates than most of the major intestinal bacterial pathogens. When such "foreign" enteric indicator bacteria are not detectable in a specific volume (100 ml) of water, the water is considered **potable** [Latin *potabilis,* fit to drink], or suitable for human consumption. The Enterobacteriaceae (pp. 505–7)

The coliform group includes *E. coli, Enterobacter aerogenes,* and *Klebsiella pneumoniae.* Coliforms are defined as facultatively anaerobic, gram-negative, nonsporing, rod-shaped bacteria that ferment lactose with gas formation within 48 hours at 35°C. The original test for coliforms that was used to meet this definition involved the presumptive, confirmed, and completed tests, as shown in **figure 29.22.** The presumptive step is carried out by means of tubes inoculated with three different sample volumes to give an estimate of the **most probable number (MPN)** of coliforms in the water. The complete process, including the confirmed and completed tests, requires at least 4 days of incubations and transfers.

Unfortunately the coliforms include a wide range of bacteria whose primary source may not be the intestinal tract. To deal with this difficulty, tests have been developed that allow waters to be tested for the presence of **fecal coliforms.** These are coliforms derived from the intestine of warm-blooded animals, which can grow at the more restrictive temperature of 44.5°C.

To test for coliforms and fecal coliforms, and more effectively recover stressed coliforms, a variety of simpler and more specific tests have been developed. These include the membrane filtration technique, the **presence-absence (P-A) test** for coliforms and the related Colilert **defined substrate test** for detecting both coliforms and *E. coli.*

The **membrane filtration technique** (*see figure 6.6*), has become a common and often preferred method of evaluating the microbiological characteristics of water. The water sample is passed through a membrane filter. The filter with its trapped bacteria is transferred to the surface of a solid medium or to an absorptive pad containing the desired liquid medium. Use of the proper medium allows the rapid detection of total coliforms, fecal coliforms, or fecal streptococci by the presence of their characteristic colonies (**figure 29.23;** *see also figure 6.7*). Samples can be placed on a less selective resuscitation medium, or incubated at a less stressful temperature, prior to growth under the final set of selective conditions. An example of a resuscitation step is the use of a 2 hour incubation on a pad soaked with lauryl sulfate broth, as is carried out in the LES Endo procedure. A resuscitation step often is needed with chlorinated samples, where the microorganisms are especially stressed. The advantages and disadvantages of the membrane filter technique are summarized in **table 29.4.** Membrane filters have been widely used with water that does not contain high levels of background organisms, sediment, or heavy metals.

More simplified tests for detecting coliforms and fecal coliforms are now available. The presence-absence test (P-A test) can be used for coliforms. This is a modification of the MPN procedure, in which a larger water sample (100 ml) is incubated in a single culture bottle with a triple-strength broth containing lactose broth, lauryl tryptose broth, and bromcresol purple indicator. The P-A test is based on the assumption that no coliforms should be present in 100 ml of drinking water. A positive test results in the production of acid (a yellow color) and constitutes a positive presumptive test requiring confirmation.

To test for both coliforms and *E. coli,* the related Colilert defined substrate test can be used. A water sample of 100 ml is added to a specialized medium containing *o*-nitrophenyl-β-D-galactopyranoside (**ONPG**) and 4-methylumbelliferyl-β-D-glucuronide (**MUG**) as the only nutrients. If coliforms are present, the medium will turn yellow within 24 hours at 35°C due to the hydrolysis of ONPG, which releases *o*-nitrophenol, as shown in **figure 29.24.** To check for *E. coli,* the medium is observed under long-wavelength UV light for fluorescence. When *E. coli* is present, the MUG is modified to yield a fluorescent product. If the test is negative for the presence of coliforms, the water is considered acceptable for human consumption. The main change from previous standards is the requirement to have waters free of coliforms and fecal coliforms. If coliforms are present, fecal coliforms or *E. coli* must be tested for.

Molecular techniques are now used routinely to detect coliforms in waters and other environments, including foods.

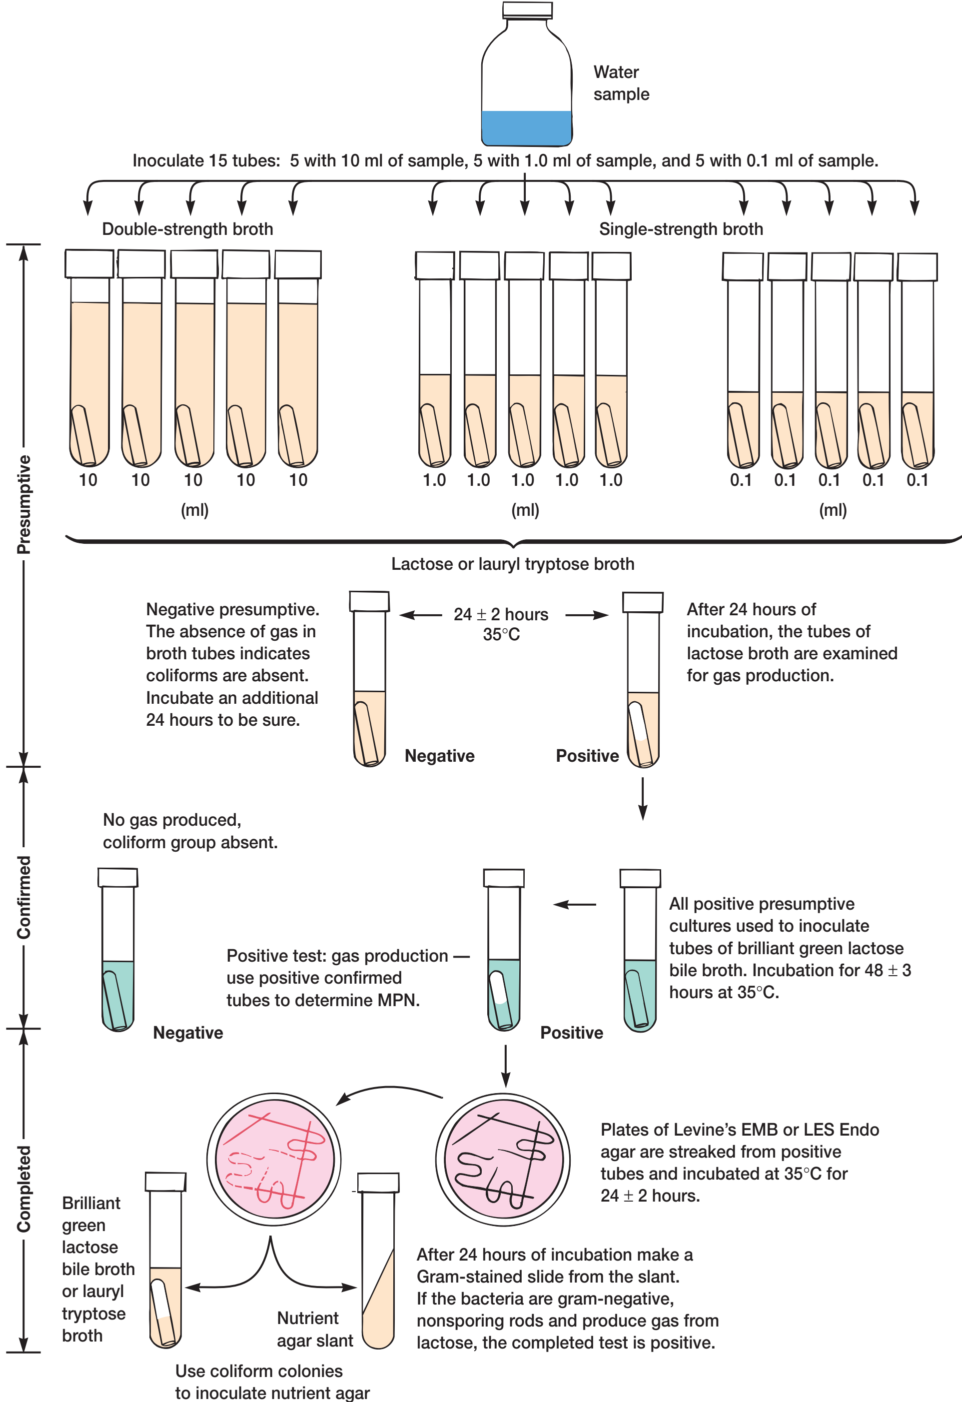

Figure 29.22 The Multiple-Tube Fermentation Test. The multiple-tube fermentation technique has been used for many years for the sanitary analysis of water. Lactose broth tubes are inoculated with different water volumes in the presumptive test. Tubes that are positive for gas production are inoculated into brilliant green lactose bile broth in the confirmed test, and positive tubes are used to calculate the most probable number (MPN) value. The completed test is used to establish that coliform bacteria are present.

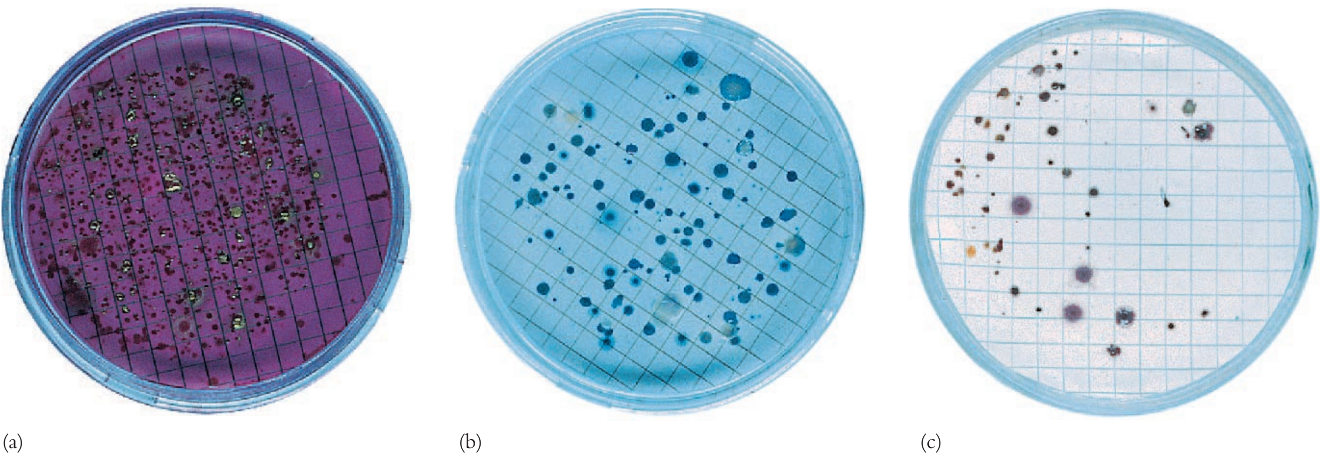

(a) (b) (c)

Figure 29.23 Coliform and Enterococcal Colonies. Membrane filters made it possible to more rapidly test waters for the presence of coliforms, fecal coliforms, and fecal enterococci by the use of differential media. (**a**) Coliform reactions on an Endo medium. (**b**) Fecal coliform growth on a bile salt medium (m-FC agar) containing aniline blue dye. (**c**) Fecal enterococci growing on an azide-containing medium (KF agar) with TTC, an artificial electron acceptor, added to allow better detection of colonies.

Table 29.4 Advantages and Disadvantages of the Membrane Filter Technique for Evaluation of the Microbial Quality of Water

Advantages

- Good reproducibility
- Single-step results often possible
- Filters can be transferred between different media
- Large volumes can be processed to increase assay sensitivity
- Time savings are considerable
- Ability to complete filtrations on site
- Lower total cost in comparison with MPN procedure

Disadvantages

- High-turbidity waters limit volumes sampled
- High populations of background bacteria cause overgrowth
- Metals and phenols can adsorb to filters and inhibit growth

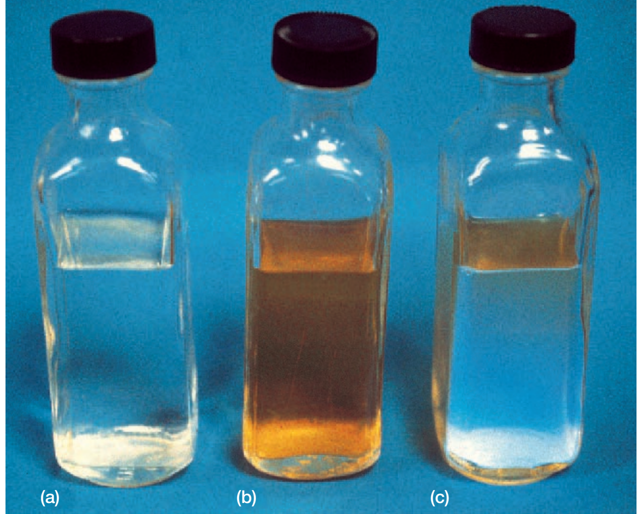

Figure 29.24 The Defined Substrate Test. This much simpler test is now being used to detect coliforms and fecal coliforms in single 100 ml water samples. The medium uses ONPG and MUG (see text) as defined substrates. (**a**) Uninoculated control. (**b**) Yellow color due to the presence of coliforms. (**c**) Fluorescent reaction due to the presence of fecal coliforms.

16 S rRNA gene-targeted primers for coliforms have been developed. Using these primers, it is possible to detect one colony-forming unit (CFU) of *E. coli* per 100 ml of water, if an eight-hour enrichment step precedes the use of the PCR amplification. This allows the differentiation of nonpathogenic and enterotoxigenic strains, including the shiga-toxin producing *E. coli* O157:H7. The PCR technique (pp. 326–27)

In the United States a set of general guidelines for microbiological quality of drinking waters has been developed, including standards for coliforms, viruses, and *Giardia* (**table 29.5**). If unfiltered surface waters are being used, one coliform test must be run each day when the waters have higher turbidities.

Other indicator microorganisms include **fecal enterococci.** The fecal enterococci are increasingly being used as an indicator

Table 29.5 Current Drinking Water Standards in the United States.

Agent	Allowable Maximum Contaminant Level Goal (MCLG) or Maximum Contaminant Level (MCL)
Coliforms	MCLG = 0 MCL = No more than 5% positive total coliform samples/month for water systems that collect > 40 samples/month. For water systems that collect < 40 routine samples/month, no more than 1 can be coliform positive. Every sample that has total coliforms must be analyzed for fecal coliforms. There cannot be any fecal coliforms.
Giardia lamblia	MCLG = 0
Legionella	MCLG = 0
Viruses (enteric)	MCLG = 0

Source: Environmental Protection Agency, USA, 24 July, 2000.

of fecal contamination in brackish and marine water. In salt water these bacteria die back at a slower rate than the fecal coliforms, providing a more reliable indicator of possible recent pollution. The genus *Enterococcus* (pp. 531–33)

1. What is an indicator organism, and what properties should it have?
2. How is a coliform defined? How does this definition relate to presumptive, confirmed, and completed tests?
3. How does one differentiate between coliforms and fecal coliforms in the laboratory?
4. In what type of environment is it better to use fecal enterococci rather than fecal coliforms as an indicator organism?
5. What are the advantages and disadvantages of membrane filters for microbiological examinations of water?
6. Why has the defined substrate test with ONPG and MUG been accepted as a test of drinking water quality?

29.6 Wastewater Treatment

Waters often contain high levels of organic matter from industrial and agricultural wastes (e.g., from food processing, petrochemical and chemical plants, and plywood plant resin wastes), and from human wastes. It is necessary to remove organic matter by the process of wastewater treatment. Depending on the effort given to this task, it may still produce waters containing nutrients and some microorganisms, which can be released to rivers and streams.

The treatment of human waste–impacted waters, with the many pathogens that may be present, is one of the most important factors in maintaining an advanced society. In fact, the use of modern sewage treatment, together with chlorination, has led to major reductions in the worldwide spread of pathogens. This often unappreciated technology thus is at the front line of maintaining a healthy society. When sewage treatment systems break down, as often occurs with natural disasters or civil unrest, long-forgotten diseases such as cholera reappear.

Measuring Water Quality

To measure carbon removal in these wastewater treatment processes, several approaches can be used. Carbon removal can be measured (1) as **total organic carbon (TOC),** (2) as chemically oxidizable carbon by the **chemical oxygen demand (COD)** test, or (3) as biologically usable carbon by the **biochemical oxygen demand (BOD)** test. The TOC includes all carbon, whether or not it is usable by microorganisms. This is carried out by oxidizing the organic matter in a sample at high temperature in an oxygen stream and measuring the resultant CO_2 by infrared or potentiometric techniques. The COD gives a similar measurement, except that lignin often will not react with the oxidizing chemical, such as permanganate, that is used in this procedure. The BOD test, in comparison, measures only the portion of the total carbon that can be oxidized by microorganisms in a 5-day period under standard conditions.

The biochemical oxygen demand is an indirect measure of organic matter in aquatic environments. It is the amount of dissolved O_2 needed for microbial oxidation of biodegradable organic matter. When O_2 consumption is measured, the O_2 itself must be present in excess and not limit oxidation of the nutrients (**table 29.6**). To achieve this, the waste sample is diluted to assure that at least 2 mg/liter of O_2 are used while at least 1 mg/liter of O_2 remains in the test bottle. Ammonia released during organic matter oxidation can also exert an O_2 demand in the BOD test, so nitrification or the **nitrogen oxygen demand (NOD)** is often inhibited by 2-chloro-6-(trichloromethyl) pyridine (nitrapyrin). In the normal BOD test, which is run for 5 days at 20°C on untreated samples, nitrification is not a major concern. However, when treated effluents are analyzed, NOD can be a problem.

In terms of speed, the TOC is fastest, but less informative in terms of biological processes. The COD is slower and involves the use of wet chemicals with higher waste chemical disposal costs. The TOC, COD, and BOD provide different but

Table 29.7 Major Steps in Primary, Secondary, and Tertiary Treatment of Wastes

Treatment Step	Processes
Primary	Removal of insoluble particulate materials by settling, screening, addition of alum and other coagulation agents, and other physical procedures
Secondary	Biological removal of dissolved organic matter
	Trickling filters
	Activated sludge
	Lagoons
	Extended aeration systems
	Anaerobic digesters
Tertiary	Biological removal of inorganic nutrients
	Chemical removal of inorganic nutrients
	Virus removal/inactivation
	Trace chemical removal

complementary information on the carbon in a water sample. It is critical to note that these measurements, concerned with carbon and carbon removal, do not directly address concerns for removal of minerals such as nitrate, phosphate, and sulfate from waters. These minerals are having worldwide impacts on cyanobacterial and algal growth in lakes, rivers, and the oceans by contributing to the process of eutrophication. The removal of dissolved organic matter and possibly inorganic nutrients, plus inactivation and removal of pathogens, are important parts of wastewater treatment.

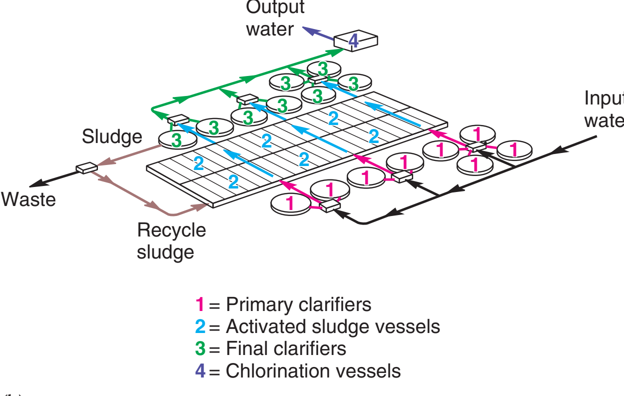
1. What are TOC, COD, and BOD and how are these similar and different?
2. What factors can lead to a nitrogen oxygen demand (NOD) in a water?
3. What components should limit the reactions in a BOD test, and what components should not limit reaction rates? Why?
4. What minerals can contribute to eutrophication?

Water Treatment Processes

The aerobic self-purification sequence that occurs when organic matter is added to lakes and rivers can be carried out under controlled conditions in which natural processes are intensified. This often involves the use of large basins (conventional sewage treatment) where mixing and gas exchange are carefully controlled. Purification also can be carried out using constructed wetlands where natural reed and aquatic plant communities (and their associated microorganisms) process dissolved nutrients. Such procedures can be effective in minimizing environmental degradation of valuable water resources and in destroying potential human pathogens.

Conventional **wastewater treatment** normally involves primary, secondary, and tertiary treatment, as summarized in **table 29.7.**

(a)



(b)

Figure 29.25 An Aerial View of a Modern Conventional Sewage Treatment Plant. Sewage treatment plants allow natural processes of self-purification that occur in rivers and lakes to be carried out under more intense, managed conditions in large concrete vessels. (**a**) A plant in New Jersey. (**b**) A diagram of flows in the plant.

Primary treatment can physically remove 20 to 30% of the BOD that is present in particulate form. In this treatment, particulate material is removed by screening, precipitation of small particulates, and settling in basins or tanks. The resulting solid material is usually called **sludge.**

An aerial photograph of a modern sewage treatment plant is shown in **figure 29.25*a*,** and a schematic of this plant is shown in figure 29.25*b*. The sequence of physical removal of settleable solids (primary treatment) and secondary treatment (biological transformation of dissolved organic matter to microbial biomass and carbon dioxide) is shown, together with the final clarifiers. The final clarifiers separate the newly formed microbial biomass (sewage sludge) from the processed water stream, which can be returned to the receiving body of water. At the end of the process, the water is usually chlorinated (itself an emerging environmental and human health problem) before it is released.

© The McGraw–Hill Companies, 2002

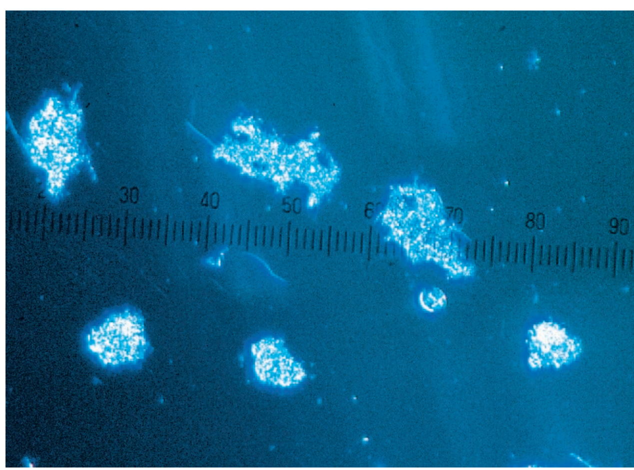
Secondary treatment is used after primary treatment for the biological removal of dissolved organic matter. About 90 to 95% of the BOD and many bacterial pathogens are removed by this process. Several approaches can be used in secondary treatment to biologically remove dissolved organic matter. All of these techniques involve similar microbial activities. Under aerobic conditions, dissolved organic matter will be transformed into additional microbial biomass plus carbon dioxide. When microbial growth is completed, under ideal conditions the microorganisms will aggregate and form a settleable stable floc structure. Minerals in the water also may be tied up in microbial biomass. When microorganisms grow, flocs can form (**figure 29.26**). As shown in figure 29.26*a,* a healthy settleable floc will be compact. In contrast, poorly formed floc can have a network of filamentous microbes that will retard settling (figure 29.26*b*).

When these processes occur with lower O_2 levels or with a microbial community that is too young or too old, unsatisfactory floc formation and settling can occur. The result is a **bulking sludge,** caused by the massive development of filamentous bacteria such as *Sphaerotilus* and *Thiothrix,* together with many poorly characterized filamentous organisms. These important filamentous bacteria (*see pp. 496, 502*) form flocs that do not settle well, and thus produce effluent quality problems.

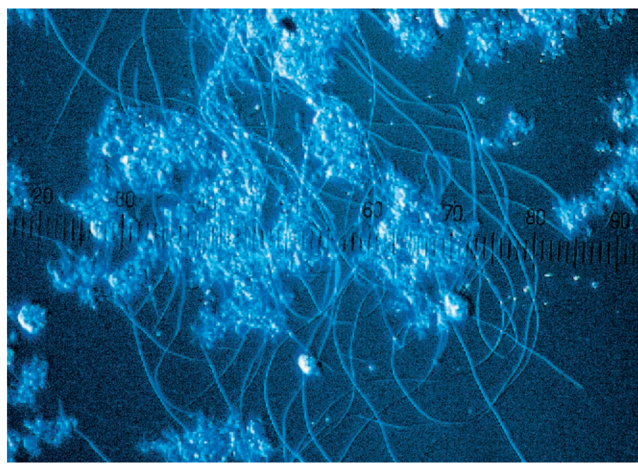
An aerobic **activated sludge** system (**figure 29.27*a***) involves a horizontal flow of materials with a recycle of sludge—the active biomass that is formed when organic matter is oxidized and degraded by microorganisms. Activated sludge systems can be designed with variations in mixing. In addition, the ratio of organic matter added to the active microbial biomass can be varied. A low-rate system (low nutrient input per unit of microbial biomass), with slower growing microorganisms, will produce an effluent with low residual levels of dissolved organic matter. A high-rate system (high nutrient input per unit of microbial biomass), with faster growing microorganisms, will remove more dissolved organic carbon per unit time, but produce a poorer quality effluent.

Aerobic secondary treatment also can be carried out with a **trickling filter** (figure 29.27*b*). The waste effluent is passed over rocks or other solid materials upon which microbial films have developed, and the microbial community in these films degrades the organic waste. A sewage treatment plant can be operated to produce less sludge by employing the **extended aeration** process (figure 29.27*c*). Microorganisms grow on the dissolved organic matter, and the newly formed microbial biomass is eventually consumed to meet maintenance energy requirements. This requires extremely large aeration basins and extended aeration times. In addition, with the biological self-utilization of the biomass, minerals originally present in the microorganisms are again released to the water.

All aerobic processes produce excess microbial biomass, or sewage sludge, which contains many recalcitrant organics. Often the sludges from aerobic sewage treatment, together with the materials settled out in primary treatment, are further treated by **anaerobic digestion** (**figure 29.28**). Anaerobic digesters are



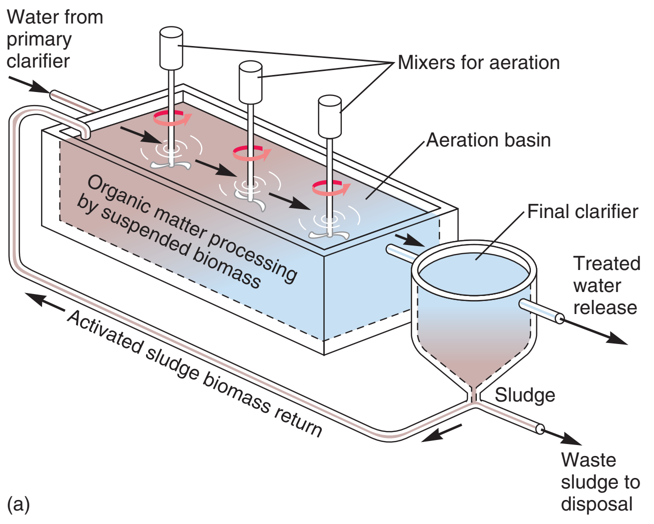
(a)

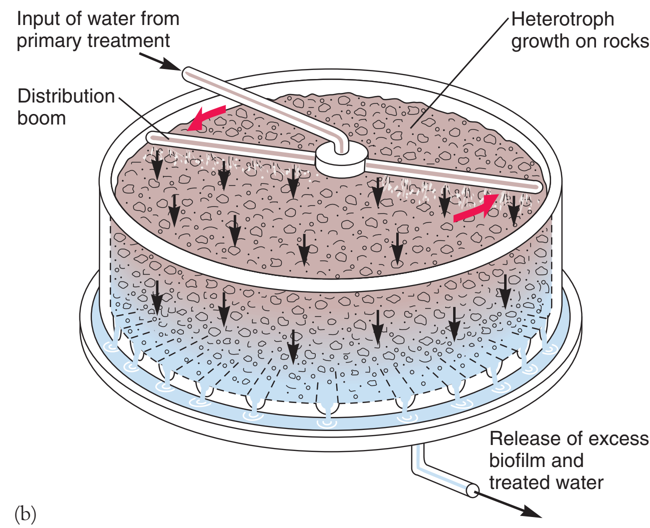


(b)

Figure 29.26 Proper Floc Formation in Activated Sludge. Microorganisms play a critical role in the functioning of activated sludge systems. The operation is dependent on the formation of settleable flocs (**a**). If the plant does not run properly, poorly settling flocs (**b**) can form due to such causes as low aeration, sulfide, and acidic organic substrates. These flocs do not settle properly because of their open or porous structure. As a consequence, the organic material is released with the treated water and lowers the quality of the final effluent.

large tanks designed to operate anaerobically with continuous input of untreated sludge and removal of the final, stabilized sludge product. Methane is vented and often burned for heat and electricity production. This digestion process involves three steps: (1) the fermentation of the sludge components to form organic acids, including acetate; (2) production of the methanogenic substrates: acetate, CO_2, and hydrogen; and finally, (3) methanogenesis by the methane producers. These methanogenic processes,





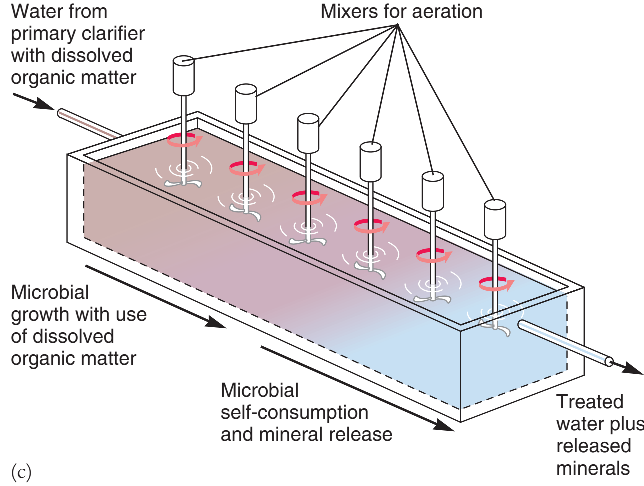


Figure 29.27 Aerobic Secondary Sewage Treatment. (**a**) Activated sludge with microbial biomass recycling. The biomass is maintained in a suspended state to maximize oxygen, nutrient, and waste transfer processes. (**b**) Trickling filter, where waste water flows over biofilms attached to rocks or other solid supports, resulting in transformation of dissolved organic matter to new biofilm biomass and carbon dioxide. Excess biomass and treated water flow to a final clarifier. (**c**) An extended aeration process, where aeration is continued beyond the point of microbial growth, allows the microbial biomass to self-consume due to microbial energy of maintenance requirements. (The extended length of the reactor allows this process of biomass self-consumption to occur.) Minerals originally incorporated in the microbial biomass are released to the water as the process occurs.

Figure 29.28 High-Efficiency Anaerobic Bioreactors Used for Sludge Digestion and Methane Production. These "egg-shaped" units are so well insulated that they maintain their temperature (39°C) without outside heating, and the methane can be burned to provide electricity. These reactors are located at Kiel, Germany.

Box 29.3

Sewage Sludge, Long-Term Concerns with Land and Water Disposal: An Environmental Challenge

Sewage treatment plants have allowed large cities to develop near rivers and lakes and still maintain the quality of the water. Large quantities of sludge are produced during sewage treatment and are usually subjected to anaerobic digestion. This process transforms complex organic matter (including microorganisms that grew in the aerobic treatment process) to methane and CO_2. At the same time heavy metals are concentrated in the residual sludge, and viable cysts of free-living protozoa may be present.

The sludge is disposed of on land or, in large urban areas near the ocean, by dumping at designated disposal sites in coastal waters. When such sludges are dumped offshore, free-living protozoa of the genus *Acanthamoeba* may be released in the water, where they may infect bathers. *Acanthamoeba* infections are more widespread than usually is recognized, and the organisms can be common contaminants in water that tests negative for coliforms and fecal coliforms.

The use of water-based waste disposal systems has, of course, allowed major improvements in urban living and the retirement of chamber pots to museums. A product of this advancement in public health is sewage sludge. NIMBY (not in my backyard) has been the usual means of managing this problem.

Table 29.8 Sequential Reactions in the Anaerobic Biological Use of Organic Wastes

Process Step	Substrates	Products	Major Microorganisms
Fermentation	Organic polymers	Butyrate, propionate, lactate, succinate, ethanol, acetate,[a] H_2,[a] CO_2[a]	*Clostridium* *Bacteroides* *Peptostreptococcus* *Peptococcus* *Eubacterium* *Lactobacillus*
Acetogenic reactions	Butyrate, propionate, lactate, succinate, ethanol	Acetate, H_2, CO_2	*Syntrophomonas* *Syntrophobacter* *Acetobacterium*
Methanogenic reactions	Acetate	$CH_4 + CO_2$	*Methanosarcina* *Methanothrix*
	H_2 and HCO_3^-	CH_4	*Methanobrevibacter* *Methanomicrobium* *Methanogenium* *Methanobacterium* *Methanococcus* *Methanospirillum*

[a]Methanogenic substrates produced in the initial fermentation step.

summarized in **table 29.8,** involve critical balances between oxidants and reductants. To function most efficiently, the hydrogen concentration must be maintained at a low level. If hydrogen and organic acids accumulate, methane production can be inhibited, resulting in a stuck digester. Methanogenic archaea (pp. 458–61)

Anaerobic digestion has many advantages. Most of the microbial biomass produced in aerobic growth is used for methane production. The resulting sludge occupies less volume and can be dried easily. However, heavy metals and other environmental contaminants are often concentrated in the sludge. There may be longer-term environmental and public health effects from disposal of this material on land or in water (**Box 29.3**).

The sludge resulting from anaerobic digestion, instead of being disposed of on soil or added to waters, can be further treated under aerobic conditions in the sewage treatment plant. This removes more pathogens and oxidizes smelly ammonium and sulfide to odorless oxidized forms. The combined process takes advantage of the complementary nature of microbial growth under sequential anaerobic-aerobic conditions.

Tertiary treatment purifies wastewaters more than is possible with primary and secondary treatments. The goal is to remove such pollutants as nonbiodegradable organic material (e.g., polychlorinated biphenyls), heavy metals, and minerals. It is particularly important to remove nitrogen and phosphorus compounds

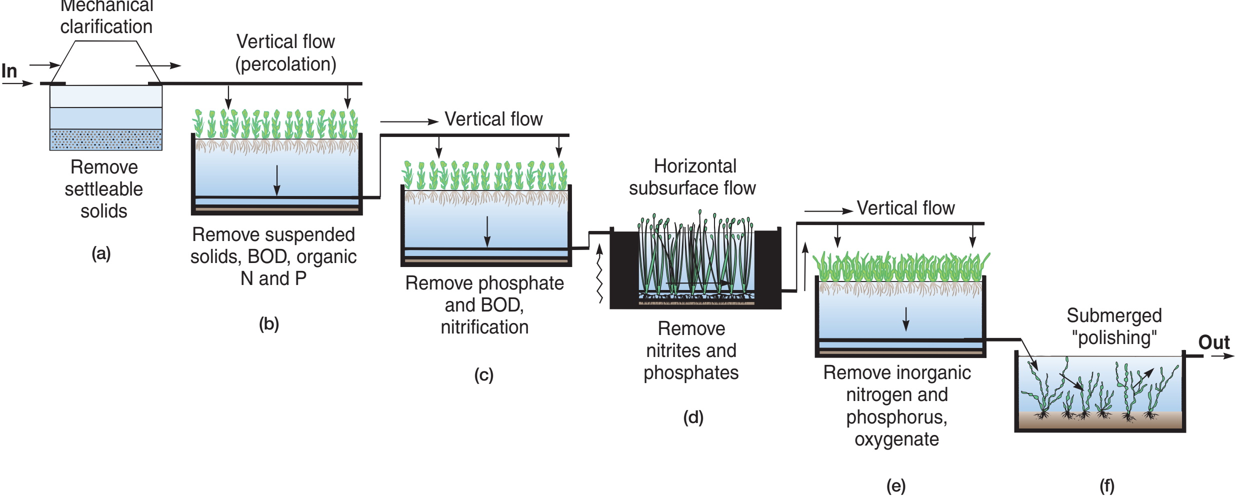

Figure 29.29 Constructed Wetland for Wastewater Treatment. Multistage constructed wetland systems can be used for organic matter and phosphate removal. Free-floating macrophytes (**b,c,e**), such as duckweed and water hyacinth, can be used for a variety of purposes. Emergent macrophytes (**d**) such as bulrush, allow surface flow as well as vertical and horizontal subsurface flow. Submerged vegetation (**f**), such as waterweed, allows final "polishing" of the water. These wetlands also can be designed for nitrification and metal removal from waters.

that can promote eutrophication. Organic pollutants can be removed with activated carbon filters. Phosphate usually is precipitated as calcium or iron phosphate (for example, by the addition of lime). Excess nitrogen may be removed by "stripping," volatilization as NH_3 at high pHs. Ammonia itself can be chlorinated to form dichloramine, which is then converted to molecular nitrogen. In some cases, biological processes also are used to remove nitrogen and phosphorus. A widely used process for nitrogen removal is denitrification (*see p. 190*). Here nitrate, produced under aerobic conditions, is used as an electron acceptor under conditions of low oxygen with organic matter added as an energy source. Nitrate reduction yields nitrogen gas and nitrous oxide (N_2O) as the major products. For phosphorus removal, aerobic and anaerobic conditions are used alternately in a series of treatments, and phosphorus accumulates in specially adapted microbial biomass as polyphosphate. Tertiary treatment is expensive and usually not employed except where necessary to prevent obvious ecological disruption.

Anaerobic and aerobic treatment processes often are used together in a carefully designed sequence as a part of tertiary treatment. Linked aerobic and anaerobic processes now are designated by the acronym AAO, which means anaerobic-anoxic-oxic. The complete sequence has three stages: (1) the anaerobic (A) processing of waste, (2) treatment of this product with added nitrate under anoxic conditions (A) to promote denitrification, and (3) "polishing" the effluent under aerobic (oxic) conditions (O) before release to the environment.

Wetlands are a vital natural resource and a critical part of our environment, and increasingly efforts are being made to protect these fragile aquatic communities from pollution. Surprisingly a major means of treatment of wastes is the use of **constructed wetlands** where the basic components of natural wetlands (soils, aquatic plants, waters) are used as a functional waste treatment system. Constructed wetlands now are increasingly employed in the treatment of liquid wastes and for bioremediation (*see pp. 1012–14*). This system uses floating, emergent, or submerged plants, as shown in **figure 29.29.** The aquatic plants provide nutrients in the root zone, which can support microbial growth. Especially with the emergent plants, the root zone can be maintained in an anaerobic state in which sulfide, synthesized by *Desulfovibrio* using root zone organic matter as an energy source, can trap metals. Such emergent plant systems have found wide applications in the processing of waters from abandoned mines.

The different aquatic plant types and their associated microorganisms can be used in integrated systems to remove organic matter, inorganic nutrients, and metals from waters. Constructed wetlands also are being used to treat acid mine drainage (AMD) in many parts of the world. Higher-strength industrial wastes also can be treated.

Another method of effluent processing is simple surface flow soil treatment. In this approach liquid waste is allowed to flow across a planted or plowed field, where aerobic microbial processing of the waste can occur. This is becoming a widespread practice, with the increases in confined animal agriculture that are occurring in many areas. Whether dealing with beef cattle, hogs, or poultry, these large commercial operations produce massive pollution, especially when these facilities are placed near estuarine and coastal areas.

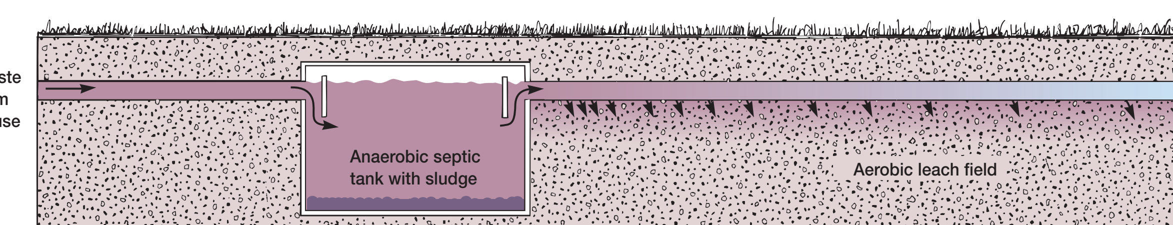

Figure 29.30 The Septic Tank Home Treatment System. This system combines an anaerobic waste liquefaction unit (the septic tank) with an aerobic leach field. Biological oxidation of the liquefied waste takes place in the leach field, unless the soil becomes flooded.

1. Explain how primary, secondary, and tertiary treatment are accomplished.
2. What is bulking sludge? Name several important microbial groups that contribute to this problem.
3. What are the steps of organic matter processing that occur in anaerobic digestion? Why is acetogenesis such an important step?
4. After anaerobic digestion is completed, why is sludge disposal still of concern? How can it be further treated to improve its quality?
5. Why might different aquatic plant types be used in constructed wetlands?

29.7 Groundwater Quality and Home Treatment Systems

Groundwater, or water in gravel beds and fractured rocks below the surface soil, is a widely used but often unappreciated water resource. In the United States groundwater supplies at least 100 million people with drinking water, and in rural and suburban areas beyond municipal water distribution systems, 90 to 95% of all drinking water comes from this source.

The great dependence on this resource has not resulted in a corresponding understanding of microorganisms and microbiological processes that occur in the groundwater environment. Increasing attention is now being given to predicting the fate and effects of groundwater contamination on the chemical and microbiological quality of this resource. Pathogenic microorganisms and dissolved organic matter are removed from water during subsurface passage through adsorption and trapping by fine sandy materials, clays, and organic matter. Microorganisms associated with these materials—including predators such as protozoa—can use the trapped pathogens as food. This results in purified water with a lower microbial population.

This combination of adsorption-biological predation is used in home treatment systems (**figure 29.30**). Conventional **septic tank** systems include an anaerobic liquefaction and digestion step that occurs in the septic tank itself (the tank functions as a simple anaerobic digester). This is followed by organic matter adsorption and entrapment of microorganisms in the aerobic leach-field environment where biological oxidation occurs. A septic tank may not operate correctly for several reasons. It will not function properly if the retention time of the waste in the septic tank is too short. Retention time decreases when the flow is too rapid or when excessive sludge has accumulated in the septic tank. As a result undigested solids move into the leach field, gradually plugging the system. If the leach field floods and becomes anaerobic, biological oxidation does not occur, and effective treatment ceases.

When a suitable soil is not present and the septic tank outflow drains too rapidly to the deeper subsurface, problems can occur. Fractured rocks and coarse gravel materials provide little effective adsorption or filtration. This may result in the contamination of well water with pathogens and the transmission of disease. In addition, phosphorus from the waste will not be retained effectively and may pollute the groundwater. This often leads to nutrient enrichment of ponds, lakes, and rivers as the subsurface water enters these environmentally sensitive water bodies.

Subsurface zones (*see section 30.8*) also can become contaminated with pollutants from other sources. Land disposal of sewage sludges, illegal dumping of septic tank pumpage, improper toxic waste disposal, and runoff from agricultural operations all contribute to groundwater contamination with chemicals and microorganisms. Deep-well injection of industrial wastes has raised questions about the longer-term fate and effects of these materials.

Many pollutants that reach the subsurface will persist and may affect the quality of groundwater for extended periods. Much research is being conducted to find ways to treat groundwater in place—**in situ treatment.** Microorganisms and microbial processes are critical in many of these remediation efforts (*see chapter 42*).

1. In rural areas, approximately what percentage of the water used for human consumption is groundwater?
2. What factors can limit microbial activity in subsurface environments? Consider the energetic and nutritional requirements of microorganisms in your answer.
3. How, in principle, are a septic tank system and a leach-field system supposed to work? What factors can reduce the effectiveness of this system?

Summary

1. The largest portion of waters on the Earth is marine (97%). Most of this is cold (2 to 3°C) and at high pressure. Fresh waters are a minor but important part of the Earth's waters.
2. The movement of materials in aquatic environments extends over long distances and occurs at varied rates. Mixing and diffusion are critical processes in creating unique environments for different microorganisms.
3. Oxygen solubility and diffusion rates in waters are limited; waters are low oxygen diffusion rate environments, in comparison with soils (**figure 29.1**). Carbon dioxide, nitrogen, hydrogen, and methane are also important gases for microbial functioning in waters.
4. If sufficient organic matter is present, heterotrophic microorganisms can use this dissolved O_2 more rapidly than it can be replenished. Respiration or decomposition of algal and cyanobacterial blooms also can cause O_2 depletion.
5. Nutrient concentrations in waters can vary, and diffusion produces unique environments for microorganisms by creating gradients. The Winogradsky column is a model laboratory system that allows gradients and unique microbial communities to develop (**figure 29.3**).
6. The nutrient composition of the ocean influences the C:N:P ratio of the phytoplankton, which is called the Redfield ratio. This ratio is important for predicting nutrient cycling in oceans. Atmospheric additions of minerals, including iron and nitrogen, affect this ratio and global-level oceanic processes.
7. The microbial loop is an important part of the food web in waters (**figure 29.4**). This results from bacterial growth on organic matter released by the phytoplankton, followed by use of the bacteria as a prey by protozoa. The nutrients in a portion of these bacterial prey are then released in mineral forms, making them again available for use by the phytoplankton.
8. The marine microbial community is dominated, in terms of numbers and biomass, by ultramicrobacteria or nanobacteria. Archaea are important components of the microbial community. Viruses are present at high concentrations in many waters, and occur at 10-fold higher levels than the bacteria. In marine systems they may play a major role in controlling cyanobacterial development and nutrient turnover.
9. Many unusual microbial groups are found in waters, especially when oxidants and reductants can be linked. These include *Thioploca* and *Thiomargarita,* both of which are found in coastal areas where nutrient mixing occurs. *Thiomargarita* is the world's largest known bacterium (**figure 29.5**).
10. Aquatic fungi are important parts of the aquatic microbial community. These include the chytrids (**figure 29.7**), with a motile zoosporic stage, and the Ingoldian fungi (**figure 29.8**), which often have tetraradiate structures. Both of these are uniquely adapted to an aquatic existence, and the chytrids may contribute to disease in amphibians.
11. Microorganisms and their metabolic products interact with the atmosphere and are important in the field of aerobiology.
12. Barophiles are important in deep marine environments. These include barotolerant, barophilic, and extreme barophilic procaryotes.
13. Materials can move in aquatic environments over extended distances and depths. This may include animal and human wastes, carcasses, and plant detritus. Dust is transported over wide distances. All of these processes result in the constant introduction of new organisms.
14. The global cycles of carbon, nitrogen, phosphorus and sulfur are influenced by microbial processes that occur in the vast regions of the world's oceans. This is especially important for the sulfur cycle, where dimethylsulfide (DMS) release from algae can lead to changes in the acidity of the atmosphere and cloud formation.
15. Eutrophication can be caused by nutrient releases from rural and urban areas. Sources of nitrogen and phosphorus are particularly important in eutrophication. These mineral additions and the growth of photosynthetic microorganisms can lead to widespread hypoxia and anoxia in coastal and estuarine areas.
16. Lakes can be oligotrophic (low-nutrient) and eutrophic (high-nutrient) environments (**figure 29.17**). The addition of organic matter, especially with the microbial use and release of N and P, can lead to eutrophication.
17. In rivers the addition of organic matter can produce dissolved O_2 sag curves and diurnal O_2 changes in the latter stages of self-purification (**figure 29.19**). This occurs with materials added from point sources.
18. Much of the marine environment is covered by sea ice. Specially adapted microbial communities are found at the ice-water interface. Deep Antarctic lakes (such as Lake Vostok) and dry valley frozen lakes provide unique environments for microbes. In an environment such as Lake Vostok, the microorganisms may have been held in the ice for 420,000 years or more.
19. Water purification can involve the use of sedimentation, coagulation, chlorination, and rapid and slow sand filtration (**figure 29.20**). Chlorination may lead to the formation of organic disinfection by-products, including trihalomethane (THM) compounds, which are potential carcinogens.
20. *Cryptosporidium, Cyclospora,* viruses, and *Giardia* are of concern, as conventional water purification and chlorination will not always assure their removal and inactivation to acceptable limits.
21. Indicator organisms are used to indicate the presence of pathogenic microorganisms. Most probable number (MPN) and membrane filtration procedures are employed to estimate the number of indicator organisms present. Presence-absence (P-A) tests for coliforms and defined substrate tests for coliforms and *E. coli* allow 100 ml water volumes to be tested with minimum time and materials.
22. Molecular techniques based on the polymerase chain reaction (PCR) can be used to detect waterborne Shiga-toxin producing *E. coli* O157:H7 in 8 hours, when a preenrichment step is used.
23. The biochemical oxygen demand (BOD) test is an indirect measure of organic matter that can be oxidized by the aerobic microbial community. In this assay, oxygen should never limit the rate of reaction. The chemical oxygen demand (COD) and total organic carbon (TOC) tests provide information on carbon that is not biodegraded in the 5-day BOD test.
24. Conventional sewage treatment is a controlled intensification of natural self-purification processes, and it can involve primary, secondary, and tertiary treatment (**figure 29.27**).
25. Constructed wetlands involve the use of aquatic plants (floating, emergent, submerged) and their associated microorganisms for the treatment of liquid wastes (**figure 29.29**). These systems are being used in a wide range of environments. Domestic wastes, industrial effluents, and acid mine drainage (AMD) can be treated.
26. Home treatment systems operate on general self-purification principles. The septic tank (**figure 29.30**) provides anaerobic liquefaction and digestion whereas the aerobic leach field allows oxidation of the soluble effluent.
27. Groundwater is an important resource that can be affected by pollutants from septic tanks and other sources. This vital water source must be protected and improved.

Questions for Thought and Review

1. Why might you describe the interaction of many microorganisms with oxygen as a “love-hate” relationship? How do these microorganisms deal with this important gas?
2. How might you measure the activity of nanobacteria or ultramicrobacteria, in spite of the fact that they are so difficult to culture and observe?
3. What are the functional strategies of organisms such as *Thioploca* and *Thiomargarita?* Where would you go to find similar organisms, and how would you search for them?
4. You wish to study the characteristics of microorganisms from a 10,000 meter depth in the ocean. What effects might decompression have on these organisms, and what type of equipment would you design to work with them under their natural conditions?
5. Discuss the advantages and disadvantages for microorganisms that become attached to surfaces.
6. With sea ice being such an important environment for specialized microorganisms, what might be the global-level effects of these microbial communities?
7. Why are levels of virus particles so high in many marine environments? Consider the requirements for viral replication. How old do you think these viral particles might be and why?
8. How might one manage waters to control *Pfiesteria piscicida?*
9. How might it be possible to rejuvenate an aging eutrophic lake? Consider physical, chemical, and biological approaches.
10. You wish to develop a constructed wetland for removal of metals from a stream at one site, and at another site, you wish to treat acid mine drainage. How might you approach each of these problems?
11. What are the linkages between nutrient cycling in the oceans and soils?
12. Why are indicator organisms still being used despite the fact that methods are available for the direct isolation of most pathogens that might occur in water?
13. What alternatives, if any, can one use for protection against microbiological infection when swimming in polluted recreational water? Assume that you are part of a water rescue team.
14. What are possible alternatives that could be used to eliminate N and P releases from sewage treatment systems? What suggestions could you make that might lead to new technologies?

Critical Thinking Questions

1. If we were able to decrease or increase the activity of the microbial loop in the ocean, which should be done and why? Would either shift be desirable?
2. There have been numerous “fish kills” in the waters of the Chesapeake Bay region recently. Fishermen blame poultry farmers (poultry waste disposal) and the overuse and subsequent runoff of residential fertilizers by homeowners. What components in poultry waste and fertilizer can create an ecological imbalance that would result in hundreds of dead fish floating in inlet waterways?

CHAPTER 30

Microorganisms in Terrestrial Environments

Terrestrial plants and filamentous fungi have developed long-term relationships that benefit both partners. The tips of pine tree roots are usually surrounded by dense fungal sheaths that are part of a hyphal network which extends out into the soil. The plant supplies organic matter to maintain the fungus, and the fungus, in turn, provides the plant with nutrients and water.

Outline

30.1 Soils as an Environment for Microorganisms 669
30.2 Microorganisms in the Soil Environment 670
30.3 Microorganisms and the Formation of Different Soils 672
- Tropical and Temperate Region Soils 672
- Cold Moist Area Soils 673
- Desert Soils 673
- Geologically Heated Hyperthermal Soils 674

30.4 Soil Microorganism Associations with Vascular Plants 674
- Microorganisms on the Outside of Plants 674
- Microorganism Growth within Plants 675
- Tripartite and Tetrapartite Associations 685

30.5 Soils, Plants, and Nutrients 686
30.6 Soils, Plants, and the Atmosphere 688
30.7 Microorganisms and Plant Decomposition 690
30.8 The Subsurface Biosphere 691
30.9 Soil Microorganisms and Human Health 693
30.10 Understanding Microbial Diversity in the Soil 693

Concepts

1. Terrestrial [Latin *terra,* earth] environments are dominated by inert solid materials. Organic substances, including microorganisms, are usually a minor part of a soil.
2. Water, when present, will be predominantly in thin water films on particle surfaces. Microorganisms in these water films have good contact with gases in air, including oxygen.
3. Oxygen is much more accessible to microorganisms in soils because its flux into thin water films is not limited by a large continuous water bulk phase. The flux rate of oxygen in air is approximately 4000 times faster than in water.
4. Microorganisms growing in such higher oxygen flux environments have developed complex physical and physiological mechanisms to deal with potentially toxic oxygen species. Fungi even develop structures impermeable to oxygen.
5. Soils can have isolated water-saturated zones that become anaerobic. These may be considered as isolated aquatic environments surrounded by high-oxygen flux zones.
6. There is a great variety of terrestrial environments: dry, cold, temperate, tropical, and geothermally heated zones.
7. Insects, nematodes, and other soil animals interact with microorganisms to influence nutrient cycling and other processes.
8. The subsurface supports a varied and diverse microbial community. These microorganisms are maintained by nutrient sources such as materials leaching from the surface, decomposition of buried plant remains, and methane synthesis.
9. Fungi play important roles in the functioning of plants. They occur inside and on the surfaces of plants, and can have positive and negative effects. Most plant roots are infected with fungi.
10. Soil microorganisms interact with plants and the atmosphere. Critical microbial products are nitrous oxide and methane, both greenhouse gases. In addition, microorganisms produce chloromethane and cyanide, usually considered as anthropogenic pollutants.

They [the leaves] that waved so loftily, how contentedly, they return to dust again and are laid low, resigned to lie and decay at the foot of the tree and afford nourishment to new generations of their kind, as well as to flutter on high!

—*Henry D. Thoreau*

Soils are dynamic and develop over time. This process may take decades and even centuries; the organic matter in soils can be thousands of years old. Because of changes in plant growth, temperature, rainfall, disturbance and erosion, a soil that has taken hundreds of years to form can be quickly degraded if the microbial community is activated. For example, this can occur when a bog soil is drained, which increases oxygen access to the accumulated organic matter. In most soils the major producers of organic matter are the vascular plants, although algae, cyanobacteria, and photosynthetic bacteria also can contribute to these processes, especially in desert crust environments.

Soil is the habitat for a variety of organisms, including bacteria, fungi, protozoa, insects, nematodes, worms, and many other animals. Viruses also are present in soils. This complex biological community contributes to the formation, maintenance, and in some situations, the degradation and disappearance of soils.

30.1 Soils as an Environment for Microorganisms

Soils have been formed, and continue to be formed, in a wide variety of environments. These environments range from Arctic tundra regions, where approximately 11% of the world's soil carbon pool is stored, to Antarctic dry valleys, where there are no vascular plants. In addition, deeper subsurface zones, where plant roots and their products cannot penetrate, also have microbial communities. Microbial activities in these environments can lead to the formation of minerals such as dolomite; microbial activity also occurs in deep continental oil reservoirs, in stones, and even in rocky outcrops. These microbes are dependent on energy sources from algae, nutrients in rainfall, and dust.

Most soils are dominated by inorganic geological materials, which are modified by the biotic community, including the microorganisms and plants, to form soils. A major characteristic of soils is that they are typically not water saturated, making it possible for oxygen to penetrate into the passages and pores. Soils also can contain isolated regions which are water saturated, and these isolated regions become "mini" aquatic environments.

An important defining characteristic of a soil, from a microbial viewpoint, is that the microorganisms are in close physical contact with oxygen; they are located in thin water films on the particle surfaces where oxygen is present at high levels and can be easily replenished from the gaseous phase. When microorganisms use oxygen, it can be replenished rapidly by diffusion, thus maintaining the microbes under aerobic conditions. Oxygen diffusion through air in the soil occurs about 4,000 times faster than it does through water (**figure 30.1**). As shown in this figure, the oxygen concentrations and flux rates in pores and channels is high, whereas within water-filled zones the oxygen flux rate is much lower. As an example, particles as small as about 2.0 mm can be aerobic on the outside and anaerobic on the inside. Even in oxygen-saturated zones, microbial-scale aquatic environments can be created that are "hot spots" for anaerobic processes.

Depending on the physical characteristics of the soil, rainfall or irrigation may rapidly change a soil from being ideal, in terms of having reoxygenating thin water films, to an environment with isolated pockets of water, which are "miniaquatic" habitats. If this process of flooding continues, a water-logged soil can be created that is more like a lake sediment.

Shifts in water content and gas fluxes also affect the concentrations of CO_2, CO, and other gases present in the soil atmosphere, as noted in **table 30.1.** These changes will be accentuated in the smaller pores where many bacteria are found. At lower depths less oxygen is available, especially in wetter, less permeable soils. Another factor that affects the levels of oxygen and CO_2 in a soil are plant roots. The roots of plants growing in normal aerated soils also consume oxygen and release CO_2, influencing the concentrations of these gases in the root environment.

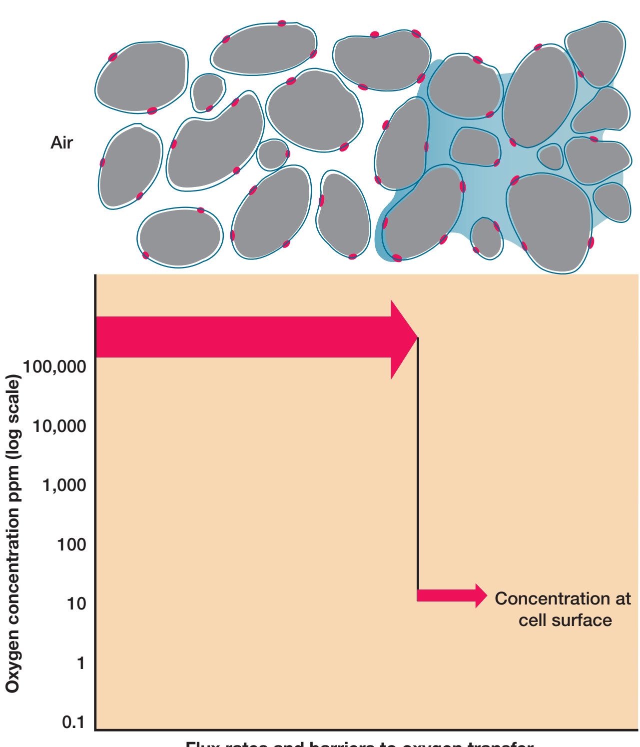

Figure 30.1 Oxygen Concentrations and Fluxes in a Soil. Microorganisms in thin water films on the surface of soil particles have good access to oxygen. In comparison, microbes in isolated water volumes have limited oxygen fluxes, creating miniaquatic environments.

Table 30.1 Concentrations of Oxygen and Carbon Dioxide in the Atmosphere of a Tropical Soil under Wet and Dry Conditions

	Oxygen Content (%)		*Carbon Dioxide Content (%)*	
Soil Depth (cm)	**Wet**	**Dry**	**Wet**	**Dry**
10	13.7	20.7	6.5	0.5
25	12.7	19.8	8.5	1.2
45	12.2	18.8	9.7	2.1
90	7.6	17.3	10.0	3.7
120	7.8	16.4	9.6	5.1

Note: Normal air contains approximately 21% oxygen and 0.035% carbon dioxide.

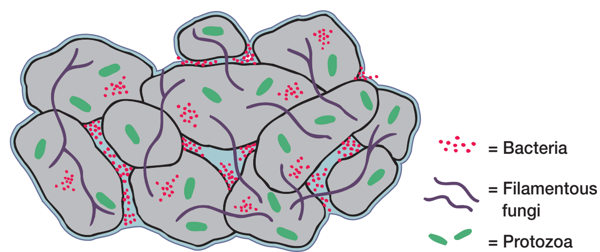

Figure 30.2 The Microenvironment—The World of Microorganisms in Soil. Bacteria tend to be present as isolated microcolonies on surfaces and in pores, which are covered by thin water films. Filamentous fungi are able to grow on and between these aggregated particles, or peds. Protozoa move in water films and graze on bacteria, especially when they are not protected in soil pores.

1. Why are Arctic tundra soils important in terms of carbon storage?
2. Contrast differences in oxygen flux rates and concentrations in a soil with those in a miniaquatic environment.
3. How do the concentrations of oxygen and carbon dioxide differ between the atmosphere and the soil interior?

30.2 Microorganisms in the Soil Environment

If we look at a soil in greater detail (**figure 30.2**), the bacteria and fungi use different functional strategies to take advantage of this complex physical matrix. Most soil bacteria are located on the surfaces of soil particles and require water and nutrients that must be located in their immediate vicinity. Bacteria are found most frequently on surfaces within smaller soil pores (2 to 6 μm in diameter). Here they are probably less liable to be eaten by protozoa, unlike bacteria that are located on the exposed outer surface of a sand grain or organic matter particle.

Terrestrial filamentous fungi bridge across open areas between soil particles or aggregates called **peds,** and are exposed to high levels of oxygen (figure 30.2). These fungi will tend to darken and form oxygen-impermeable structures including sclerotia and hyphal cords. This is particularly important for the functioning of basidiomycetes, which form such structures as an oxygen sealing mechanism. Within these structures, the filamentous fungi move nutrients and water over great distances, including across air spaces, a unique part of their functional strategy. These oxidatively polymerized, oxygen-impermeable hyphal boundaries do not usually occur in fungi growing in aquatic environments. Basidiomycetes (pp. 561–64)

A wide variety of insects and animals also are present in soils, and these often use the fungi and bacteria as food sources, as well as processing plant residues. The earthworms, with their ability to mix and ingest soils, add bacteria and enzymes from their intestine to their soil casts, a process that has major effects on the soil structure and the soil microbial community. Earth-

Table 30.2 Easily Cultured Gram-Positive Irregular Branching and Filamentous Bacteria Common in Soils

Bacterial Group	Representative Genera	Comments and Characteristics
Coryneforms	*Arthrobacter*	Rod-coccus cycle
	Cellulomonas	Important in degradation of cellulose
	Corynebacterium	Club-shaped cells
Mycobacteria	*Mycobacterium*	Acid-fast
Nocardioforms	*Nocardia*	Rudimentary branching
Actinomycetes	*Streptomyces*	Aerobic filamentous bacteria
	Thermoactinomyces	Higher temperature growth

worms, along with many other soil insects and animals, use filamentous fungi as a food source, and this can result in decreased fungal development in a soil. Earthworms also assist in mixing soil organic materials, creating the deep soils found in grasslands. In forest areas, which lack as many earthworms, a more distinct organic matter layer will be formed that is separated from the underlying inorganic layer. The fungi (chapter 25)

The microbial populations in soils can be very high. In a surface soil the bacterial population can approach 10^8 to 10^9 cells per gram dry weight of soil as measured microscopically. Fungi can be present at up to several hundred meters of hyphae per gram of soil. We tend to think that soil fungi are small like the mushrooms sprouting from our lawns. This is natural because most of the fungal thallus lies beneath the soil surface, but such a view sometimes is quite inaccurate. A case in point is the fungus *Armillaria bulbosa,* which lives associated with tree roots in hardwood forests. An individual *Armillaria* clone that covers about 30 acres has been discovered in the Upper Peninsula of Michigan. It is estimated to weigh a minimum of 100 tons (an adult blue whale may weigh 150 tons) and be at least 1,500 years old. Thus some fungal mycelia are among the largest and most ancient living organisms on Earth.

It is important to remember, when discussing soils and their microorganisms, that only a minor portion (approximately 10%) of the microscopically observable organisms making up this biomass have been cultured. In terms of biotechnology and basic ecology, the microorganisms that have not been cultured may provide a valuable genetic resource for basic and applied research. We are gradually learning more about these uncultured microorganisms through the use of molecular techniques. For example, novel groups of the *Crenarchaeota* (*see pp. 456–58*) have been discovered in forest soil and the ocean by extracting microbial DNA and amplifying it with the polymerase chain reaction. Examination of soils from different areas of the world continues to yield surprises. Recent molecular studies of Siberian tundra soils have uncovered considerable unexplored microbial diversity, as most of the recovered bacteria are not related to any known species. Microorganisms are present and prolific in subsurface environments, including oil reservoirs. Hyperthermophilic archaea have been found in such harsh subsurface environments and are probably indigenous to these poorly understood regions of our world.

OH, CH_3, CH_3

trans-1,10-dimethyl-*trans*-9-decalol

Figure 30.3 Geosmin. The structure of geosmin, the major chemical produced by actinomycetes and cyanobacteria that gives soils their characteristic odor.

The gram-positive bacteria, which show varied degrees of branching and mycelial development, are an important and less studied part of the soil microbial community. They include the coryneforms, the nocardioforms, and the true filamentous bacteria or actinomycetes (**table 30.2**). These bacteria play a major role in the degradation of hydrocarbons, older plant materials, and soil humus. In addition, some members of these groups actively degrade pesticides. The filamentous actinomycetes, primarily of the genus *Streptomyces,* produce an odor-causing compound called **geosmin,** which gives soils their characteristic earthy odor (**figure 30.3**). Actinobacteria (chapter 24)

As with aquatic environments (*see chapter 29*), microorganisms are constantly being added to soils from waters, wind, dust, plants, and animal sources. Most of these added microorganisms will not survive, either being outcompeted by indigenous microbes or being consumed by predators such as the protozoa.

The microbial community in soil makes important contributions to biogeochemical cycling and the carbon, nitrogen, sulfur, iron, and manganese cycles (*see chapter 28*). Because the soil is primarily an oxidized environment, the inorganic forms of these elements will tend to be in the oxidized state. If there are localized water-saturated, lower oxygen-flux environments, the biogeochemical cycles will shift toward reduced species. Biogeochemical cycles, (section 28.3)

Soil microorganisms can be categorized with respect to organic matter processing on the basis of both (1) their preference for either easily available or more resistant substrates and (2) the substrate concentrations they require. At higher nutrient-level levels, some microorganisms such as *Pseudomonas* respond rapidly to the addition of easily usable substrates such as sugars and amino acids. Indigenous forms tend to use native organic matter to a greater extent. These include the genus *Arthrobacter* and many soil actinomycetes. A less understood part of the microbial community grows in oligotrophic environments, defined as those that contain less than 15 mg/liter of organic matter. Physiological and genetic studies on microbial responses in such low-nutrient environments are under way. As discussed in this book, microbes have many strategies to deal with survival in such low-nutrient environments, and this presents special technical problems when studying them. Arthrobacter (pp. 542–43)

Soil insects and other animals such as earthworms also contribute to organic matter transformations in soils. These organisms carry out decomposition, often leading to the release of minerals, and physically "reducing" the size of organic particles such as plant litter. This increases the surface area and makes organic materials more available for use by bacteria and fungi. These organisms also mix substrates with their internal gut microflora and enzymes, and this contributes substantially to decomposition.

Protozoa also can influence nutrient cycling by feeding on "palatable" microorganisms. This process of **microbivory,** or use of microorganisms as a food source, results in higher rates of nitrogen and phosphorus mineralization, thus increasing the availability of nutrients for plant growth. Protozoa (chapter 27)

A significant part of the biological activity of soils arises from enzymes released by plants, insects, and other animals, and from lysed microorganisms. These free enzymes contribute to many hydrolytic degradation reactions, such as proteolysis; catalase and peroxidase activities also have been detected. Apparently these free enzymes associate with clays and humic materials, which helps to protect them from denaturation and microbial degradation.

A microbial loop regenerates nutrients in soils as it does in aquatic environments. In this process carbon and nutrients fixed by plants will be turned over rapidly by bacteria and predatory protozoa and will not be available for transfer to higher trophic levels in the food web. Protozoa, predominantly the naked amoebae that glide over surfaces, are the major protozoan predators. In waters the major predators are ciliates and flagellates.

1. What are the differences in preferred soil habitats between bacteria and filamentous fungi?
2. How can earthworms, nematodes, and insects influence microbial communities?
3. What types of archaeans have been detected in soils?
4. Does the microbial loop function in soils?

30.3 Microorganisms and the Formation of Different Soils

Soils form under various environmental conditions. When newly exposed geologic materials begin to weather, as after a volcanic event or a simple soil disturbance, microbial colonization occurs. If only subsurface materials are available, phosphorus may be present, but nitrogen and carbon must be imported by physical or biological processes. Under these circumstances many cyanobacteria, which can fix atmospheric nitrogen and carbon, are active in pioneer-stage nutrient accumulation.

Once they are formed, most soils are rich sources of nutrients. Nutrients are found in organic matter, microorganisms, soil insects, and other animals. Plants grow, senesce, and die—and at each of these phases, they provide nutrients for soil organisms. Different plant parts vary in their nutrient content and biomasses. In addition, the turnover times for the various plant parts are quite different. The components in the plant-soil system with the lowest carbon-nitrogen ratios (most nutrient-rich) are soil organic matter, microorganisms, soil insects, and other soil animals. The soil organic matter contains the greatest portion of the carbon and nitrogen in a typical soil, but with its slow turnover time (100 to 1,000 years and longer), most of this nutrient resource is not immediately available for plant or microbial use. The major types of soils that can be formed are shown in **figure 30.4.**

Tropical and Temperate Region Soils

In moist tropical soils, with their higher mean temperatures, organic matter is decomposed very quickly, and the mobile inorganic nutrients can be leached out of the surface soil environment, causing a rapid loss of fertility. To limit nutrient loss, many tropical plants have root systems that penetrate the rapidly decomposing litter layer. As soon as organic material and minerals are released during decomposition, the roots can take them up to avoid losses in leaching. Thus it is possible to "recycle" nutrients before they are lost with water movement through the soil (figure 30.4*a*). With deforestation, the nutrients are not recycled, leading to their loss from the soil and decreased soil fertility.

Tropical plant-soil communities are often used in **slash-and-burn agriculture.** The vegetation on a site is chopped down and burned to release the trapped nutrients. For a few years, until the minerals are washed from the soils, crops can be grown. When the minerals are lost from these low organic matter soils, the farmer must move to a new area and start over by again cutting and burning the native plant community. This cycle of slash-and-burn agriculture is stable if there is sufficient time for the plant community to regenerate before it is again cut and burned. If the cycle is too short, as can occur with overpopulation, rapid and almost irreversible degradation of the soil can occur.

In many temperate region soils, in contrast, the decomposition rates are less than that of primary production, leading to litter accumulation. Deep root penetration in temperate grasslands results in the formation of fertile soils, which provide a valuable resource for the growth of crops in intensive agriculture (figure 30.4*b*).

The soils in many cooler coniferous forest environments suffer from an excessive accumulation of organic matter as plant litter (figure 30.4*c*). In winter, when moisture is available, the soils are cool, and this limits decomposition. In summer, when the soils are warm, water is not as available for decomposition. Organic acids are produced in the cool, moist litter layer, and they leach into the underlying soil. These acids solubilize soil components such as aluminum and iron, and a bleached zone may form. Litter continues to accumulate, and fire becomes the major means by which nutrient cycling is maintained. Controlled burns are becoming a more important part of environmental management in this type of plant-soil system.

Bog soils provide a unique set of conditions for microbial growth (figure 30.4*d*). In these soils the decomposition rate is slowed by the waterlogged, predominantly anoxic conditions, which lead to peat accumulation. When such areas are drained, they become more aerobic and the soil organic matter is degraded, resulting in soil subsidence. Under aerobic conditions the lignin-cellulose complexes of the accumulated organic matter are more susceptible to decomposition by the filamentous fungi.

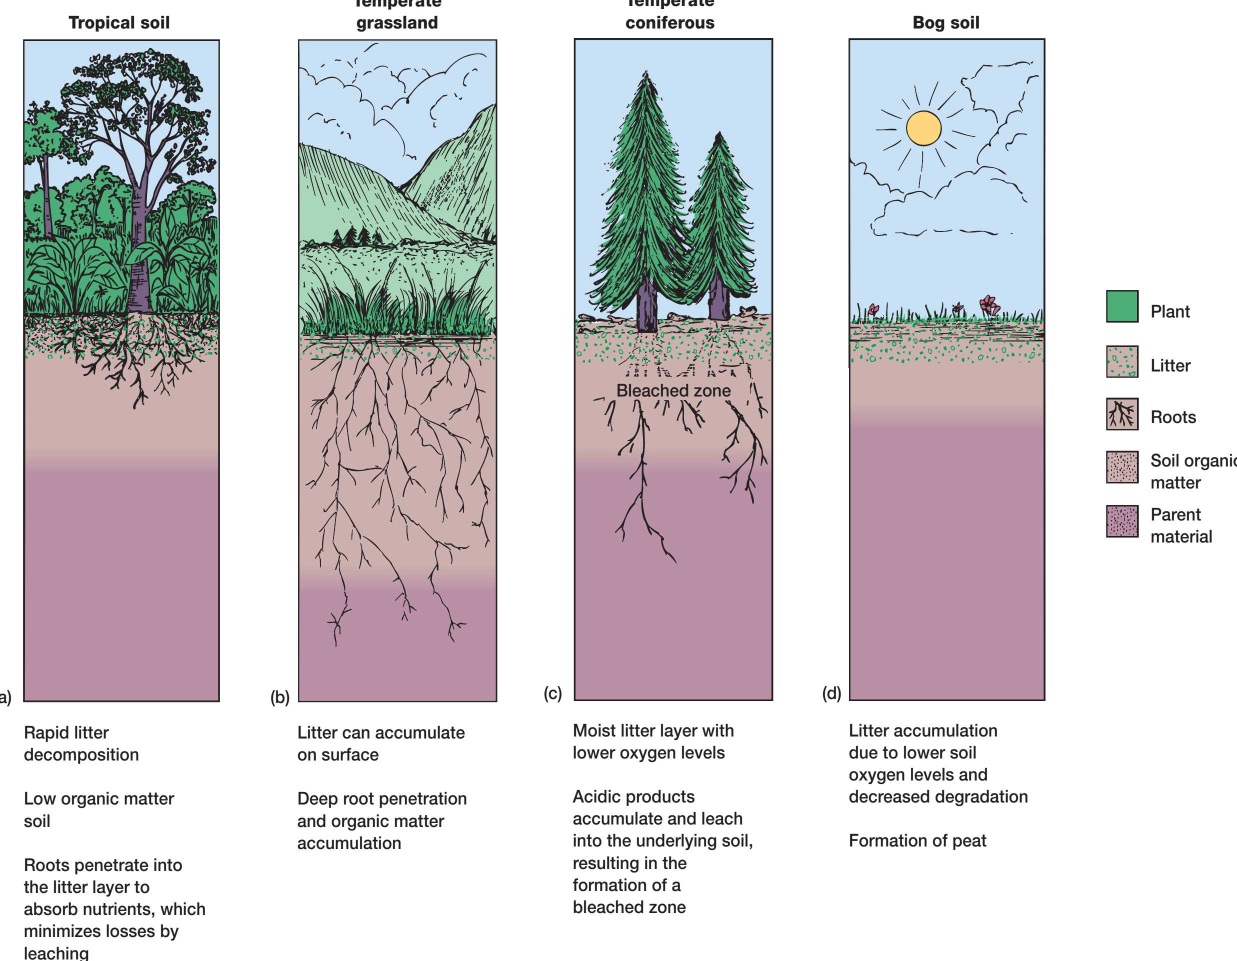

Figure 30.4 Examples of Tropical and Temperate Region Plant-Soil Systems. Climate, parent material, plants, topography, and microorganisms interact over time to form different plant-soil systems. In these figures the characteristics of (**a**) tropical, (**b**) temperate grassland, (**c**) temperate coniferous forest, and (**d**) bog soils are illustrated.

Cold Moist Area Soils

Soils in cold environments, whether in Arctic, Antarctic, or alpine regions, are of extreme interest because of their wide distribution and impacts on global-level processes. The colder mean soil temperatures at these sites decrease the rates of both decomposition and plant growth. In these cases soil organic matter accumulates, and plant growth can become limited due to the immobilization of nutrients in soil organic matter. Often, below the plant growth zone, these soils are permanently frozen. These permafrost soils hold 11% of the Earth's soil carbon and 95% of its organically bound nutrients. These soils are very sensitive to physical disturbance and pollution, and the widespread exploration of such areas for oil and minerals can have long-term effects on their structure and function. When plants are covered by snow, plant diseases are caused by **snow molds,** which can grow and attack plants at −5°C. These fungi produce special antifreeze proteins (AFP) that enable them to function under these harsh conditions.

In water-saturated bog areas, bacteria are more important than fungi in decomposition processes, and there is decreased degradation of lignified materials. As in other soils, the nutrient cycling processes of nitrification, denitrification, nitrogen fixation, and methane synthesis and utilization, although occurring at slower rates, can have major impacts on global gaseous cycles. Lignin degradation (pp. 613–14)

Desert Soils

Soils of hot and cold arid and semiarid deserts are dependent on periodic and infrequent rainfall. When these rainfalls occur, water can puddle in low areas and be retained on the soil surface by microbial communities called **desert crusts.** These consist of

Figure 30.5 A Desert Crust as Observed with the Scanning Electron Microscope. The crust has been disturbed to show the extracellular sheaths and filaments of the cyanobacterium *Microcoleus vaginatus.* The sand grains are linked by these filamentous growths, creating a unique ecological structure.

cyanobacteria and associated commensalistic microbes, including *Anabaena, Microcoleus, Nostoc,* and *Scytonema.* The depth of the photosynthetic layer is perhaps 1 mm, and the cyanobacterial filaments and slimes link the sand particles (**figure 30.5**), which change the surface soil albedo, water infiltration rate, and susceptibility to erosion. These crusts are quite fragile, and vehicle damage can be evident for decades. After a rainfall, nitrogen fixation will begin within approximately 25 to 30 hours, and when the rain has evaporated or drained into the soil, the crust will dry up and nitrogen will be released for use by other microorganisms and the plant community.

Geologically Heated Hyperthermal Soils

Geologically heated soils are found in such areas as Iceland and the Kamchatka peninsula in eastern Russia, and such heated soils also occur at many mining waste sites. An important microorganism found in heated mining wastes is *Thermoplasma.* These soils are populated by bacterial and archaeal procaryotes, many of which are chemolithoautotrophs. A wide variety of chemoorganotrophic genera also are found in these environments; these include the aerobes *Thermomicrobium, Thermoleophilum,* and also the anaerobes *Thermosipho* and *Thermotoga.* Such geothermal soils have been of great interest as a source of new microbes to use in biotechnology (*see p. 626*), and the search for new, unique microorganisms in these areas is intensifying all over the world. Thermoplasma (p. 463)

1. Characterize each major soil type discussed in this section in terms of the balance between primary production and organic matter decomposition.
2. What is unique about bogs in terms of organic matter degradation?
3. Why can nutrients become limiting for plants and microorganisms in tundra soils?
4. Describe desert crusts. What types of microorganisms function in these unique environments?
5. What is slash-and-burn agriculture? Describe the roles of microorganisms in this process.
6. What unique microbial genera are found in geothermally heated soils?

30.4 Soil Microorganism Associations with Vascular Plants

Plants—the major source of organic matter on which most soil microorganisms are dependent—are heavily colonized with microorganisms. Microorganisms of various kinds are associated with the leaves, stems, flowers, seeds, and roots. The microbial community influences plants in many direct and indirect ways. The community includes microorganisms that grow on the plant surface, between cells on the surface of the plant, and within plant cells.

Microorganisms on the Outside of Plants

Plants are covered by microorganisms, on both the above- and belowground surfaces. These microbes usually are simple commensals; in some cases they can become parasitic or pathogenic, especially when the plant surface has been damaged.

Phyllosphere Microorganisms

A wide variety of microorganisms are found on and in the aerial surfaces of plants, called the **phyllosphere.** These include microorganisms that have complex interactions with the plant at various stages of development. The plant leaves and stems release organic compounds, and this can lead to massive development of microbes. The genera present on plant leaves and stems include *Sphingomonas,* which is especially equipped to survive with the high levels of UV irradiation occurring on these plant surfaces. This bacterium, also common in soils and waters, can occur at 10^8 cells per gram of plant tissue. *Sphingomonas* often represents a majority of the culturable species. Phyllosphere microorganisms play important roles in protection and possibly harm to the plant.

Rhizosphere and Rhizoplane Microorganisms

Plant roots release a wide variety of materials to their surrounding soil, including various alcohols, ethylene, sugars, amino and organic acids, vitamins, nucleotides, polysaccharides, and enzymes as shown in **table 30.3.** These materials create unique en-

Table 30.3 Compounds Excreted by Microorganism-Free Wheat Roots

Ethylene		

From J. W. Woldendorp, "The Rhizosphere as Part of the Plant-Soil System" in *Structure and Functioning of Plant Populations* (Amsterdam, Holland: Proceedings, Royal Dutch Academy of Sciences, Natural Sciences Section: 2d Series, 1978) 70:243.

vironments for the soil microorganisms. These environments include the **rhizosphere,** first described by Lorenz Hiltner in 1904, the volume of soil around the root influenced by the materials released from the root. The plant root surface, termed the **rhizoplane,** also provides a unique environment for microorganisms, as these gaseous, soluble, and particulate materials move from the plant to the soil. The rhizosphere and rhizoplane microorganisms not only increase their numbers when these newly available substrates become available, but their composition and function also change. Rhizosphere and rhizoplane microorganisms, as they respond to these released materials, also serve as labile sources of nutrients for other organisms, thus creating a soil microbial loop in addition to playing critical roles in organic matter synthesis and degradation. Microbial loop (chapter 29)

A wide range of bacteria in the rhizosphere can promote plant growth, orchestrated by rhizosphere bacteria that communicate with the plant using complex chemical signals. These chemical signal compounds, including auxins, gibberellins, glycolipids, and cytokinins, are only now beginning to be fully appreciated in terms of their biotechnological potential. Plant growth/promoting rhizobacteria include the genera *Pseudomonas* and *Achromobacter.* These can be added to the plant, even in the seed stage, if the bacteria have the required attachment surface proteins. The genes that control the expression of these attachment proteins are still being identified.

A critical process that occurs on the surface of the plant, and particularly in the root zone, is **associative nitrogen fixation,** in which the nitrogen-fixing microorganism is on the surface of the plant root, the rhizoplane (**figure 30.6**), as well as in the rhizosphere. This process is carried out by representatives of the genera *Azotobacter, Azospirillum* and *Acetobacter.* These bacteria contribute to nitrogen accumulation by tropical grasses. Recent evidence suggests that their major contribution may not be in nitrogen fixation but in production of growth-promoting hormones that increase root hair development and thus greater ability of the plant to take up nutrients. This is an area of research that is particularly important in tropical agricultural areas.

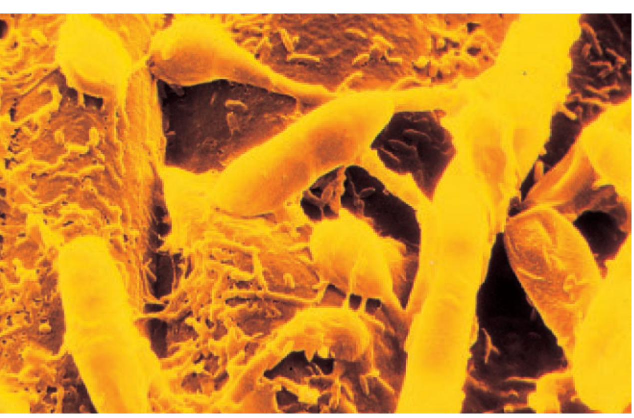

Figure 30.6 Root Surface Microorganisms. Plant roots release nutrients that allow intensive development of bacteria and fungi on and near the plant root surface, the rhizoplane. A scanning electron micrograph shows bacteria and fungi growing on a root surface.

1. Define the following terms: rhizosphere, rhizoplane, and associative nitrogen fixation.
2. What important genera are involved in associative nitrogen fixation?
3. What unique stresses face a microorganism on a leaf but not a microorganism in the soil?
4. What microbial genera are considered as plant growth–promoting rhizobacteria?

Microorganism Growth within Plants

In addition to the microorganisms growing on the surface of a plant, many interesting and important microbes grow within plants. These associations are dependent upon complex chemical signals, which indicates that these relationships are very ancient. It is important to emphasize that the mechanisms by which many of these plant-microbe interactions occur are also found in microorganism-animal interactions (*see chapter 31*).

Rhizobium

Several microbial genera are able to form nitrogen-fixing nodules with legumes. These include *Allorhizobium, Azorhizobium, Bradyrhizobium, Mesorhizobium, Sinorhizobium,* and *Rhizobium.* The mechanism of this interaction will be illustrated by work with *Rhizobium.*

The genus *Rhizobium* (*see p. 492*) is a prominent member of the rhizosphere community. This bacterium also can establish a symbiotic association with legumes and fix nitrogen for use by the plant. *Rhizobium* infects and nodulates specific legume hosts. The bacterium contains a large plasmid that encodes information that is not used when it grows as a free-living organism in the soil, but is vital for infection and nodulation of the susceptible host

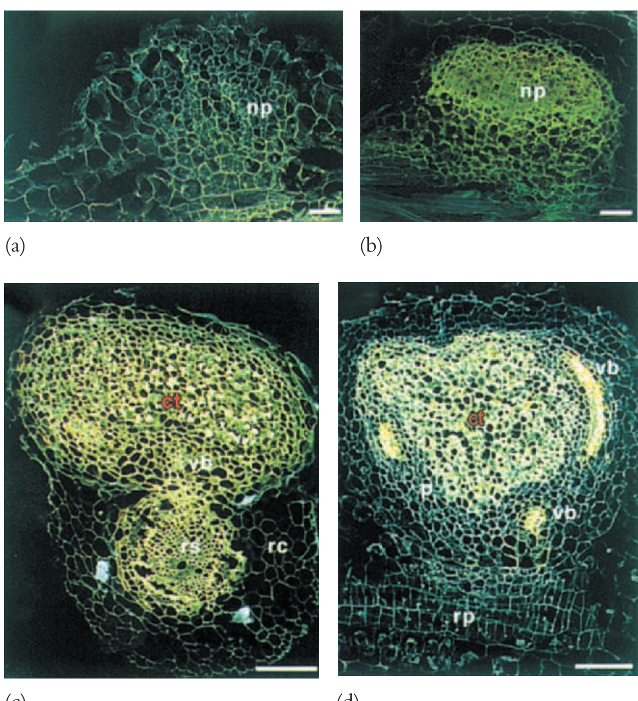

Figure 30.7 Controlled Initial Development of Legume Root Nodules Incited by *Rhizobium*. Expression of nodule inception (*nin*) activity is a critical step in infection thread formation and initiation of primordia: (**a**) early stage of primordial cell development with low levels of *nin* activity, (**b**) later higher-level expression of *nin* activity, (**c**) transverse nodule section showing extended *nin* expression, (**d**) fully differentiated nitrogen-fixing nodule with *nin* activity in central tissue area. In situ hybridization with probes used to detect activity. Abbreviations used: np, nodule primordium; ct, central tissue; rc, root cortex; rs, root stele; vb, vascular bundle. Bar = 100 μm.

plant. Plasmid-encoded genes also influence the range of host plants that *Rhizobium* can nodulate.

The *Rhizobium*-legume symbiosis is based on complex molecular interactions much like successive locks and doors that control this process. The *Rhizobium* infection process is controlled by the *bacA* gene that is required to establish the nodule. *Brucella abortus* has a similar *bacA* gene that is required to produce a chronic infection in animal hosts. Another similarity with pathogens is the *Lon* protease, which is important in *Rhizobium* and also influences capsule production in *E. coli, Klebsiella,* and *Erwinia.* Symbiotic development in legumes is controlled by a plant regulator protein that dedifferentiates root cortical cells and restarts cell division to establish nodule primordia within the invaded root. The primordia are invaded by *Rhizobium* using infection threads created by the plant. The establishment of the nodules involves a newly discovered plant gene called *nin.* Expression of this gene during nodule development has been detected by the use of in situ probes in legume root tissue (**figure 30.7**).

This complex infection process (**figure 30.8**), presented here in a simplified form, appears to involve a series of molecules produced by the host plant that lead to the exchange of recognition signals. Flavonoid inducers produced by the plant play a major role in this process by stimulating the *Rhizobium* to synthesize specific **Nod factors** that activate the host symbiotic processes necessary for root hair infection and nodule development (figure 30.8*a–d*). After bacterial attachment, the root hairs curl and the bacteria induce the plant to form an **infection thread** that grows down the root hair.

The *Rhizobium* then spreads within the infection thread into the underlying root cells as noted in figure 30.8*e.* At no time does the *Rhizobium* actually enter the plant cytoplasm while it is in the infection thread! When the bacteria are released from the infection thread into the host cell (figure 30.8*g*) the *Rhizobium* is enclosed by a plant-derived membrane, called the peribacteroid membrane, to form a **bacteroid** (figure 30.8*h*). Further growth and differentiation lead to the development of a nitrogen-fixing form, a structure called a **symbiosome** (figure 30.8*h*). At this point, specific nodule components such as leghemoglobin, which protect the nitrogen fixation enzymes from oxygen, are produced to complete the nodulation process (figure 30.8*i*). The final **root nodules** are shown in figure 30.8*j.*

The symbiosomes within mature root nodules are the site of nitrogen fixation. Within these nodules, the differentiated bacteroids reduce atmospheric N_2 and form ammonia (the primary product) and alanine; these compounds are released into the host plant cell, assimilated into various other nitrogen-containing organic compounds, and distributed throughout the plant. Because reduced nitrogen is the nutrient most commonly limiting plant growth, biological nitrogen fixation, as exemplified by the *Rhizobium*-legume symbiosis, is of major importance to agricultural productivity and the biogeochemical nitrogen cycle needed to sustain life on Earth.

After the *Rhizobium* cells have developed into the final differentiated bacteria, they no longer can revert back to bacteria capable of reproduction and have been lost to the "gene pool." The fittest members of the bacterial community, which have achieved nodulation, thus have sacrificed their own reproduction! This "altruism in the rhizosphere," a concept suggested by I. Olivieri and S. A. Frank, actually may promote increased root exudation and the maintenance of higher numbers of *Rhizobium* in the plant-root environment. The molecular biology of nitrogen fixation by *Rhizobium,* with the complex chemical communications involved, continues to be a subject of intense study around the world.

A major goal of biotechnology is to introduce nitrogen fixation genes into plants that do not normally form such associations. Recently it has been possible to produce modified lateral roots on nonlegumes such as rice, wheat, and oilseed rape; the roots are invaded by nitrogen-fixing bacteria. It appears that the infection begins with bacterial attachment to the root tips. Although these modified root structures have not yet been found to fix useful amounts of nitrogen, they do enhance rice production and intense work is expected to continue in this area. (Plant biotechnology, pp. 335–36, 337, 339–41)

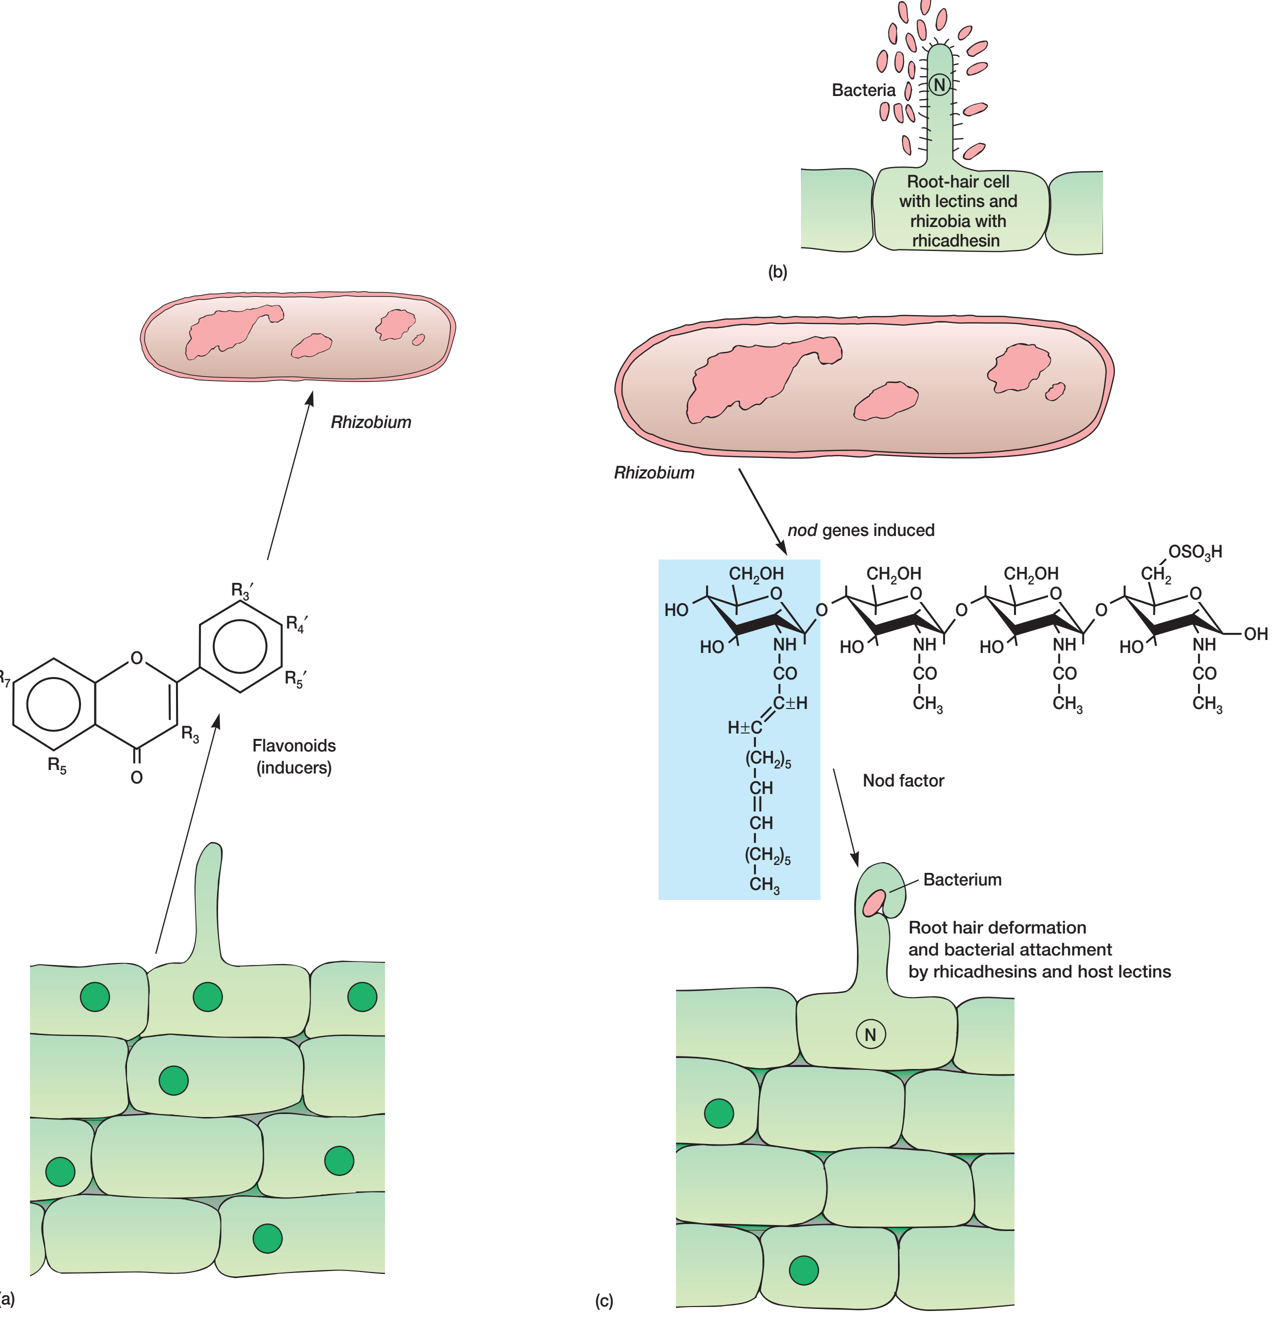

Figure 30.8 Root Nodule Formation by *Rhizobium*. Root nodule formation on legumes by *Rhizobium* is a complex process that produces the nitrogen-fixing symbiosis. (**a**) The plant root releases flavonoids that stimulate the production of various Nod metabolites by *Rhizobium.* There are many different Nod factors that control infection specificity. (**b**) Attachment of *Rhizobium* to root hairs involves specific bacterial proteins called rhicadhesins and host plant lectins that affect the pattern of attachment and *nod* gene expression. (**c**) Structure of a typical Nod factor that promotes root hair curling and plant cortical cell division. The bioactive portion (nonreducing *N*-fatty acyl glucosamine) is highlighted. These Nod factors enter root hairs and migrate to their nuclei. (**d**) A plant root hair covered with *Rhizobium* and undergoing curling. (**e**) Initiation of bacterial penetration into the root hair cell and infection thread growth coordinated by the plant nucleus "N." (**f**) A branched infection thread shown in an electron micrograph. (**g**) Cell-to-cell spread of *Rhizobium* through transcellular infection threads followed by release of rhizobia and infection of host cells. (**h**) Formation of bacteroids surrounded by plant-derived peribacteroid membranes and differentiation of bacteroids into nitrogen-fixing symbiosomes. The bacteria change morphologically and enlarge around 7 to 10 times in volume. The symbiosome contains the nitrogen-fixing bacteroid, a peribacteroid space, and the peribacteroid membrane. (**i**) Light micrograph of two nodules that develop by cell division (×5). This section is oriented to show the nodules in longitudinal axis and the root in cross section. Figure 30.9 Fungal Endophytes. Fungi can invade the upper parts of some plants. A fungal endophyte growing inside the leaf sheath of a grass, tall fescue, is shown.

Figure 30.10 Parasitic Castration of Plants by Endophytic Fungi. Stroma of the fungus *Atkinsonella hypoxylon* infecting *Danthonia compressa* and causing abortion of the terminal spikelets.

Fungal and Bacterial Endophytes of Plants

Specialized fungi and bacteria can live within some plants as **endophytes** and may be beneficial. Specialized clavicipitaceous fungi form systemic fungal infections in which the endophyte grows between the plant's cortex cells (**figure 30.9**). Plants infected with these endophytes may be less susceptible to attack by various chewing insects due to the production of alkaloids, a form of "chemical defense." *Rhizobium leguminosarum* bv *trifolii* can form a natural endophytic association with rice roots. This interaction, first observed in the Nile Delta, is supported by the rotation of clover with the rice. The association promotes rice root and shoot growth, resulting in increased rice grain yield at maturity. The rice/*Rhizobium*/clover association provides approximately one-quarter of the nitrogen needed by the rice crop.

Not all such relationships are mutualistic (beneficial to both partners). Some are parasitic. Parasitic fungal endophytes can actually reduce the genetic variability of the plant by sterilizing their host (**figure 30.10**). This "parasitic castration of plants" by systemic fungi, which promotes increased fungal spread in a less variable plant community, is suggested to be of major importance in the co-evolution of plants and fungi.

Endophytic bacteria have been discovered in sugar cane, cotton, pears, and potatoes. Some are plant pathogens that can survive for extended periods in a quiescent state. The majority have no known positive or deleterious effect on plant growth or development. The use of these bacteria as microbial delivery systems in agriculture is a current topic in agricultural biotechnology. It also has been possible to establish *Azorhizobium,* a root and stem nodulating bacterium for *Sesbana rostrata,* in the lateral roots of wheat plants, leading to a possible increased plant dry weight and nitrogen content.

1. Define and relate primordia and infection thread in terms of nodule formation.
2. What are possible effects of endophytic fungi on plants?
3. Give examples of genes that operate in microbe-plant and also in microbe-animal associations.
4. Describe the *nin* gene and its role in *Rhizobium* infection.
5. What are the basic steps in establishing the *Rhizobium*-legume root symbiosis?

Mycorrhizae

Mycorrhizae are fungus-root associations, first discovered by Albert Bernhard Frank in 1885 (**Box 30.1**). The term "mycorrhizae" comes from the Greek words meaning fungus and roots. These microorganisms contribute to plant functioning in natural environments, agriculture, and reclamation. The roots of about 95% of all kinds of vascular plants are normally involved in symbiotic associations with mycorrhizae.

Five mycorrhizal associations have been described (**figure 30.11**). These include both nonseptate and septate fungi. As noted in figure 30.11, there are endophytic arbuscular mycorrhizae (AM) that form arbuscules and sometimes vesicles (figure 30.11*a*), septate types associated with orchids (figure 30.11*b*), and those that form endomycorrhizal relationships with ericoid plants such as blueberries (figure 30.11*c*). In the endophytic mycorrhizae shown in figure 30.11*a–c,* the fungus penetrates the plant cells where it forms characteristic structures, including arbuscules and coils. Vesicles are not consistently observed. In addition, ectendomycorrhizae (figure 30.11*d*) are formed by basidiomycetes (*see p. 561*). These have sheaths and intracellular coils.

Box 30.1

Mycorrhizae and the Evolution of Vascular Plants

Fossil evidence shows that endomycorrhizal symbioses were as frequent in vascular plants during the Devonian period, some 387 to 408 million years ago, as they are today. As a result some botanists have suggested that the evolution of this type of association may have been a critical step in allowing colonization of the land by plants. During this period soils were poorly developed, and as a result mycorrhizal fungi were probably significant in aiding the uptake of phosphorus and other nutrients. Even during current times those plants that start to colonize extremely nutrient-poor soils survive much better if they have endomycorrhizae. Thus it may have been a symbiotic association of plants and fungi that initially colonized the land and led to our modern vascular plants.

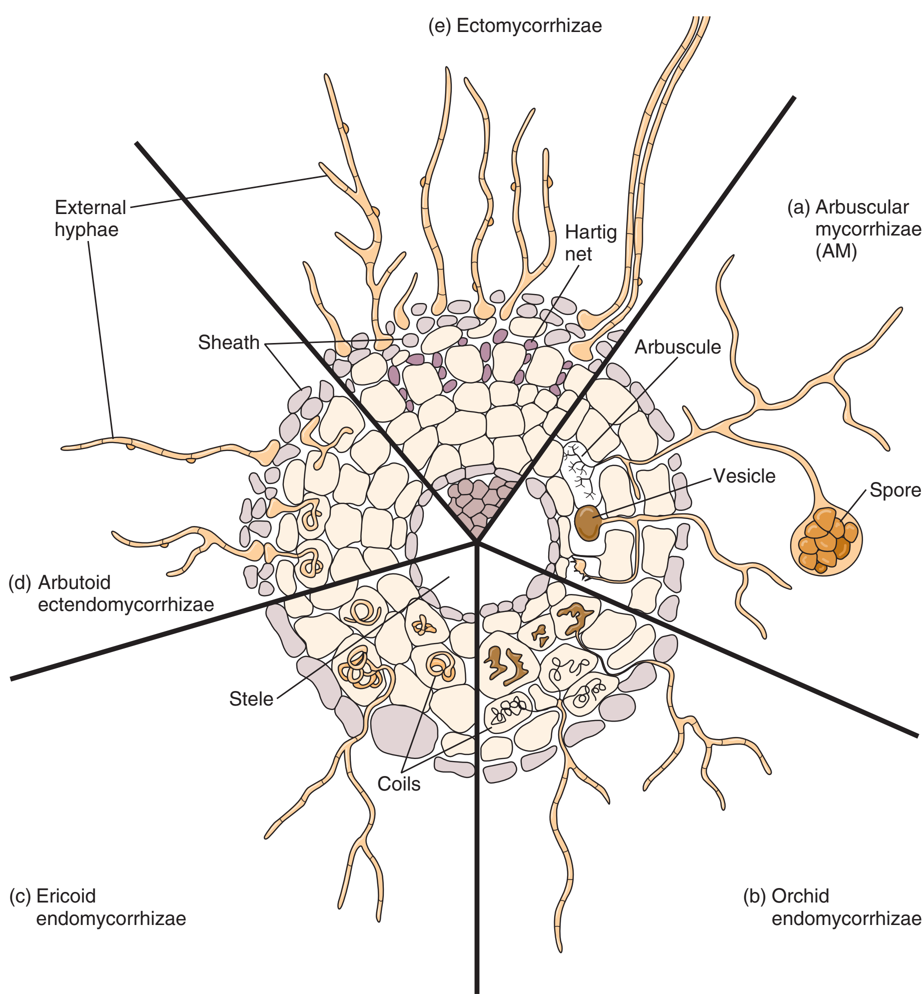

Figure 30.11 Mycorrhizae. Fungi can establish mutually beneficial relationships with plant roots, called mycorrhizae. Root cross sections illustrate different mycorrhizal relationships. See text for details.

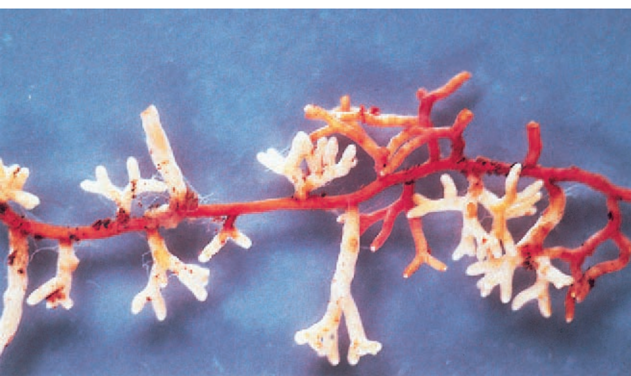

Figure 30.12 Ectomycorrhizae as Found on Roots of a Pine Tree. Typical irregular branching of the white, smooth mycorrhizae is evident.

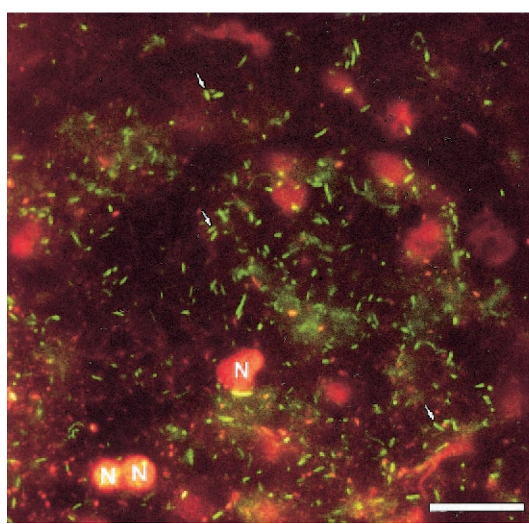

Figure 30.13 Mycorrhization Helper Bacteria. Stained bacterial endosymbionts in unfixed spores of the AM fungus *Gigaspora margarita.* Living bacteria fluoresce bright yellow-green; lipids and fungal nuclei (N) appear as diffuse masses. Bar = 7 μm.

Finally, the **ectomycorrhizae** (figure 30.11*e*) form a sheath, and the fungus grows between the plant cells, producing the "Hartig net." Such ectomycorrhizae, including *Cennococcum, Pisolithus* and *Amanita,* form irregular structures that are easy to recognize (**figure 30.12**).

Bacteria also have relations with the mycorrhizal fungi. As the external hyphal network radiates out into the soil, a **mycorrhizosphere** is formed due to the flow of carbon from the plant into the mycorrhizal hyphal network and then into the surrounding soil. In addition, "mycorrhization helper bacteria" (MHB) can play a role in the development of the mycorrhizal relationships with the ectomycorrhizal fungus. Bacterial symbionts also are found in the cytoplasm of AM fungi, as shown in **figure 30.13.** By using PCR, such bacterialike organisms (BLOs) appear to be related to *Burkholderia cepacia.* What is the possible function of these symbionts? It has been suggested that these "trapped" bacteria contribute to the nitrogen metabolism of the plant-fungal complex by assisting with the synthesis of essential amino acids.

More than 5,000 species of fungi, predominantly basidiomycetes, are involved in ectomycorrhizal symbiotic relationships. Their extensive mycelia extend far out into the soil and greatly aid the transfer of nutrients to the plant. One of the more important ectomycorrhizal fungi is *Pisolithus tinctorius.* This fungus can be grown in mass culture, with small Styrofoam beads acting as a physical support. The fungal inoculum is then mixed with rooting soil, resulting in improved plant establishment and growth.

Endomycorrhizae (**figure 30.14**) are of particular interest, as it has not been possible to grow these fungi, usually members of the zygomycetes, without the plant. In this association the fungal hyphae penetrate the outer cortical cells of the plant root, where they grow intracellularly and form coils, swellings, or minute branches. Endotrophic mycorrhizae are found in wheat, corn, beans, tomatoes, apples, oranges, and many other commercial crops, as well as most pasture and rangeland grasses. A characteristic intracellular structure is the **arbuscule,** and thus endomycorrhizae often are called **arbuscular mycorrhizal** or **AM fungi.** Recent studies show that plant flavonoids may stimulate spore germination, and this could lead to the development of plant-free cultures of these mycorrhizae.

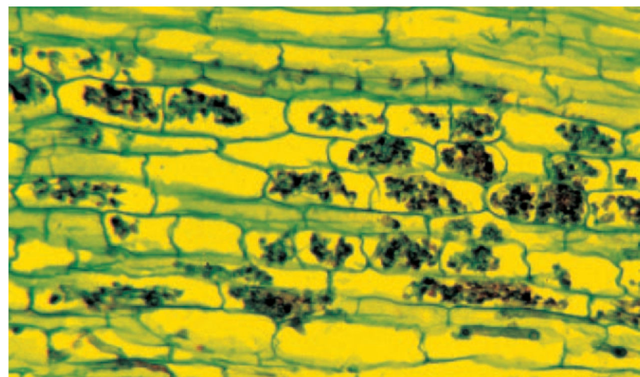

Figure 30.14 Endomycorrhizae. Endomycorrhizae, or arbuscular mycorrhizae, form characteristic structures within roots. These can be observed with a microscope after the roots are cleared and stained. The arbuscules of *Gigaspora margarita* can be seen inside the root cortex cells of cotton.

Depending on the environment of the plant, mycorrhizae can increase a plant's competitiveness. In wet environments they increase the availability of nutrients, especially phosphorus. In arid environments, where nutrients do not limit plant functioning to the same degree, the mycorrhizae aid in water uptake, allowing increased transpiration rates in comparison with nonmycorrhizal plants. These benefits have distinct energy costs for the plant in the form of photosynthate required to support the plant's "mycorrhizal habit." Under certain conditions the plant is apparently willing to trade photosynthate—produced with the increased water acquisition—for water.

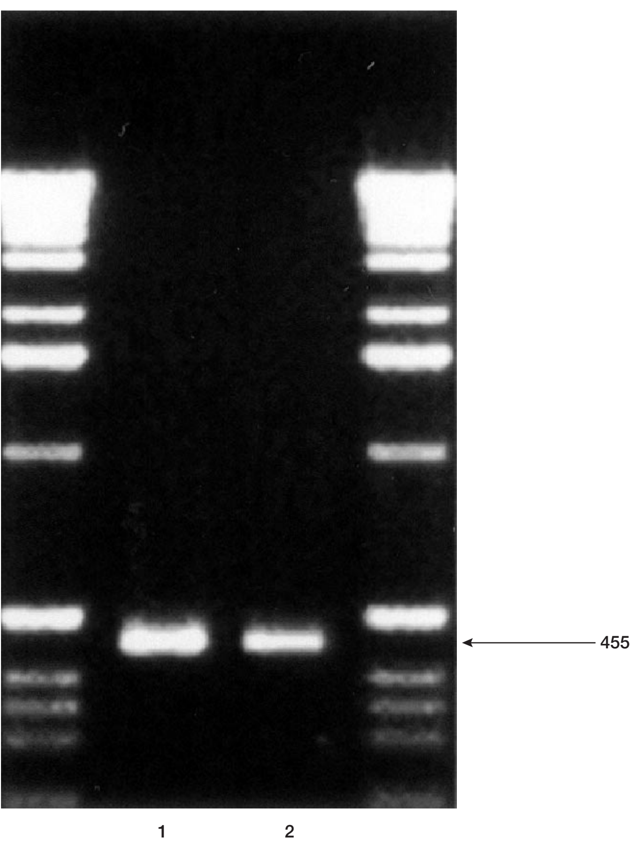

Figure 30.15 Use of the Polymerase Chain Reaction (PCR) to Detect a Mycorrhizal Fungus. Use of PCR to detect *Glomus intraradices* as spores (1) and after growth of the fungus in a root (2). In this example, a nested PCR was used. The second amplification is illustrated with the mycorrhizal fungal PCR product having a 455 base pair size. Molecular size markers are noted in the outer lanes.

Figure 30.16 Actinorhizae. *Frankia*-induced actinorhizal nodules in *Ceanothus* (Buckbrush).

Mycorrhizal and endophytic fungal communities have been found to influence the development of plant communities. The mycorrhizal fungi also can make it possible to share resources such as carbon minerals and water between different plants.

When studying mycorrhizal and endophytic relationships, molecular techniques are now used to identify spores and also mycorrhizal fungi within plant roots, as shown in **figure 30.15.** By the use of PCR (*see pp. 326–27*) with specific primers, it is possible to identify the presence of specific mycorrhizal fungi in association with a given plant after extraction of the rDNA from the root!

Actinorhizae

Actinomycete associations with plant roots, called **actinorhizae** or actinorhizal relationships, also occur (**figure 30.16**). These are formed by the association of *Frankia* strains (*see pp. 548–49*) with eight nonleguminous plant families (**table 30.4**). They fix nitrogen and are important, particularly in trees and shrubs. As examples, these associations occur in areas where Douglas fir forests have been clear-cut, and in bog and heath environments where bayberries and alders are dominant. The nodules of some actinorhizae are marble sized (**figure 30.17**). Not impressed? Some plants (*Alnus, Ceanothus*) have nodules as large as baseballs. The nodules of *Casuarina* approach soccer ball size!

Members of the genus *Frankia* are slow-growing, and, until 1978, it was impossible to culture the organisms apart from the plant. Since then, this actinomycete has been grown on specialized media supplemented with metabolic intermediates such as pyruvate. Major advances in understanding the physiology, genetics, and molecular biology of these microorganisms are now taking place.

As in all plant-microbe associations, the actinorhizal relationship costs the plant energy. However, the plant does benefit and is better able to compete in nature. This association provides a unique opportunity for microbial management to improve plant growth processes.

Other associations of nitrogen-fixing microorganisms with plants also occur. A particularly interesting association is caused by **stem-nodulating rhizobia,** found primarily in tropical legumes (**figure 30.18**). These nodules form at the base of adventitious roots branching out of the stem just above the soil surface and, because they contain oxygen-producing photosynthetic tissues, they have unique mechanisms to protect the oxygen-sensitive nitrogen fixation enzymes. Another microorganism that forms such root and stem nodules is *Azorhizobium caulinodans,* which forms nodules on the tropical legume *Sesbania rostrata.*

Nitrogen fixation: biochemical aspects (pp. 212–14); Nitrogen cycle (pp. 615–16)

Recently, it has been shown that some of these stem-nodulating rhizobia are photosynthetic. Thus they can obtain their energy not only from the plant organic compounds, but also from the light!

Figure 30.19 **Agrobacterium.** *Agrobacterium*-caused tumor on a *Kalanchoe* sp. plant.

1. Describe the major contributions of mycorrhizae and actinorhizae to plant functioning.
2. Discuss the major differences between endomycorrhizae and ectomycorrhizae.
3. What is the major contribution of *Frankia* to plant functioning? Which types of plants are infected?
4. What are stem-nodulating rhizobia?

Agrobacterium

Another exciting plant-soil microorganism interaction is the *Agrobacterium* infection that produces tumorlike growths on plants (**figure 30.19**; *see also Box 14.2.*). Gall formation involves *Agrobacterium* strains that contain the **Ti** (tumor-inducing) or **Ri plasmid.** Tumorigenesis is a natural form of genetic engineering, in which a portion of the Ti plasmid is excised, transferred from the bacterium to the plant host, and ligated into the host nuclear chromosome. The tumor is produced by an imbalance of phytohormones controlled by enzymes encoded by the introduced bacterial Ti DNA. Biotechnologists have modified this plasmid to allow the transfer of genetic characteristics such as herbicide resistance and bioluminescence to plants. With the ability to modify plant DNA using *Agrobacterium*-borne plasmids, rapid advances are being made in plant molecular biology. Agrobacterium (pp. 339–40, 492–93)

Tumor production involves binding of the bacterium to a plant, usually at a wound site, after plant phenolics are detected by the bacterium, which then expresses a tumor-inducing two-component system (**figure 30.20**). This oncogenic interaction is initiated by the transfer of tumor-DNA fragments (T-DNA) from the tumor-inducing (Ti) bacterial plasmid to the plant cell nucleus. One component controls the excision of the T-DNA, leading to the initiation of the tumor. The second component stimulates opine synthesis by the plant. The opine is used as a nutrient by the infecting *Agrobacterium,* but not as efficiently by other competing microorganisms. Thus plant metabolism is switched to produce substances that stimulate growth of the bacterium responsible for initiation of the tumor! This is a delicate interaction which has a genetic basis.

Fungi and Bacteria as Plant Pathogens

It should be noted that fungi can be devastating plant pathogens. Examples are the fungus *Puccinia graminis,* which causes wheat rust, and the fungus *Phytophthora infestans,* which was responsible for the Irish potato famine.

A wide variety of bacteria, including *Agrobacterium,* attack plants. Bacteria cause a bewildering array of spots, blights, wilts, rots, cankers, and galls, as shown in **table 30.5.** In addition, wall-less phytoplasmas are important pathogens of vegetable crops such as sweet potatoes.

Viruses

A wide range of viruses infect plants, as described in section 18.6, and are of worldwide importance in terms of plant disease and economic losses. These include TMV, the first virus to be characterized in 1892. A virus of particular interest in terms of plant-pathogen interactions is a hyphovirus that infects the fungus *Cryphanectria parasitica,* the cause of chestnut blight. Workers in Connecticut and West Virginia noted that if they infected the fungus with the hyphovirus, the rate and occurrence of infection was decreased. They are hoping to be able to treat trees with the less lethal virus strains and eventually transform the indigenous lethal strains of *Cryphanectria* into more benign fungi.

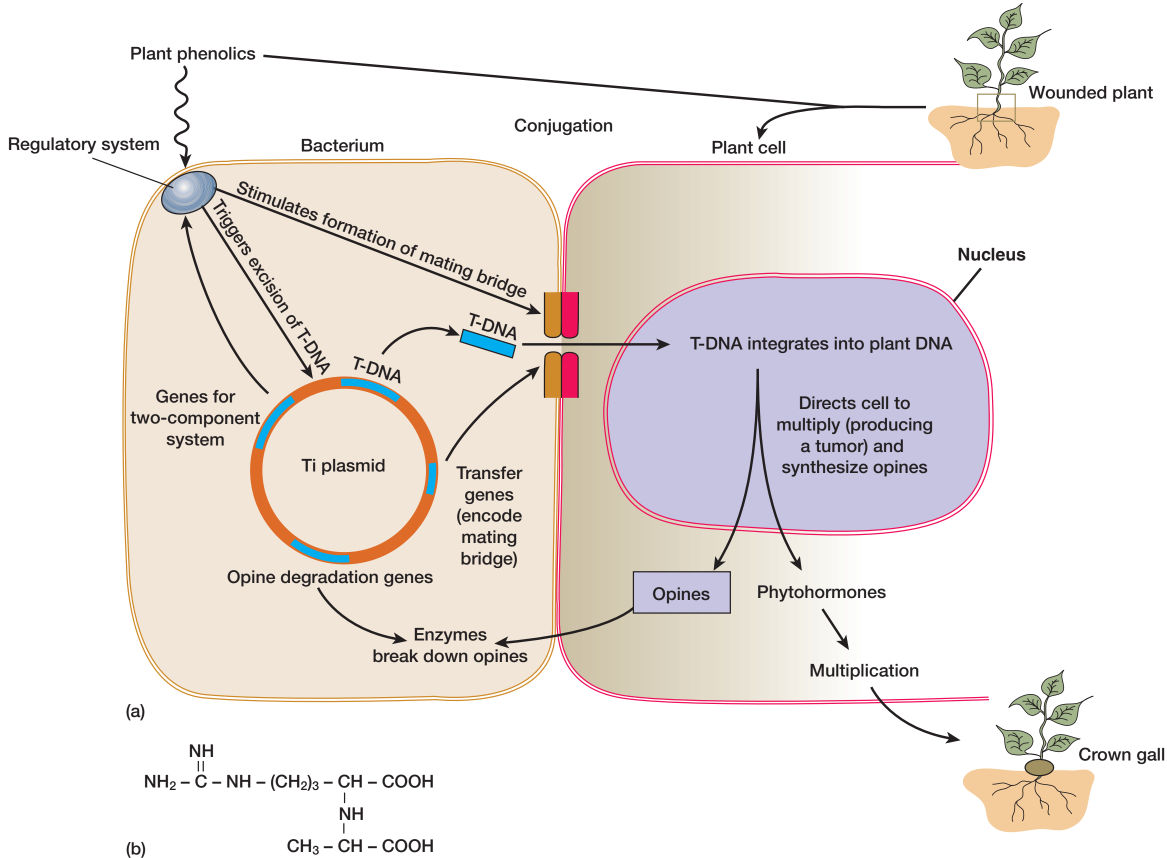

Figure 30.20 Functions of Genes Carried on the *Agrobacterium* Ti Plasmid. (**a**) Genes carried on the Ti plasmid of *Agrobacterium* control tumor formation by a two-component regulatory system that stimulates formation of the mating bridge and excision of the T-DNA. The T-DNA is moved by transfer genes, which lead to integration of the T-DNA into the plant nucleus. T-DNA encodes plant hormones that cause the plant cells to divide, producing the tumor. The tumor cells produce opines (shown in **b**) that can serve as a carbon source for the infecting *Agrobacterium.* This results in the formation of a crown gall on the stem of the wounded plant above the soil surface.

Tripartite and Tetrapartite Associations

An additional set of interactions occurs when the same plant develops relationships with two or three different types of microorganisms. These more complex interactions are important to a variety of plant types in both temperate and tropical agricultural systems. First described in 1896, these symbiotic associations involve the interaction of the plant-associated microorganisms with each other and the host plant. Several **tripartite associations** are known to occur: the plant plus (1) endomycorrhizae plus rhizobia, including *Rhizobium* and *Bradyrhizobium;* (2) endomycorrhizae and actinorhizae; and (3) ectomycorrhizae and actinorhizae. Nodulated and mycorrhizal plants are better suited for coping with nutrient-deficient environments. **Tetrapartite associations** also occur. These consist of endomycorrhizae, ectomycorrhizae, *Frankia,* and the host plant. These complex associations, in spite of their additional energy costs, provide important benefits for the plant.

1. Discuss the nature and importance of the Ti plasmid.
2. What are the functions of the members of the two-component system in infection of a plant by *Agrobacterium?* What are the roles of phenolics and opines in this infection process?
3. Give some important fungal and bacterial plant pathogens.
4. How are plant pathologists attempting to control chestnut blight?
5. What are tripartite and tetrapartite associations?

[a]pv., pathover, a variety of microorganisms with phytopathogenic properties.

30.5 Soils, Plants, and Nutrients

Soil organic matter helps retain nutrients, maintain soil structure, and hold water for plant use. This important resource is subject to gains and losses, depending on changes in environmental conditions and agricultural management practices. Plowing and other similar disturbances expose the soil organic matter to more oxygen, leading to extensive microbiological degradation of organic matter. Irrigation causes periodic wetting and drying, which can also lead to increased degradation of soil organic matter, especially at higher temperatures.

Several approaches have been developed to overcome management practices that stimulate soil microorganisms and lead to increased degradation of soil organic matter. These approaches include "no till" or "minimum till" agriculture, in which surface soil is minimally disturbed and chemicals are used to control weed growth.

Composting is another, much older but still effective approach to maintaining and augmenting the organic matter content of a soil. In this process plant materials are allowed to decompose under moist, aerobic conditions, in which the readily usable plant fractions are rapidly decomposed. If the compost is too moist or too dry, the desired decomposition process will not occur. The compost pile reaches higher temperatures, allowing thermophilic microorganisms to participate actively in these processes. When the composting is completed, the residual lignin and other more resistant plant materials will have been partially transformed to humus. Such biologically stabilized compost, when added to soil, increases the soil organic matter content and does not stimulate the soil microorganisms. Thermophile characteristics (pp. 125–26)

Throughout the world, soils are increasingly being impacted by mineral nitrogen releases resulting from human activities. This nitrogen is derived from two major sources: (1) agricultural fertilizers containing chemically synthesized nitrogen, and (2) fossil fuel combustion. It is interesting to compare the global distribution of releases from these two sources across the world (**figure 30.21**). North America, Europe, India, and eastern China are major sources of nitrogen from agriculture, whereas fossil fuel–based releases occur especially in eastern North America, Europe, eastern China, and Japan.

These nitrogen releases have had a wide variety of effects. Soils have a limited ability to tie up added nitrogen compounds in organic matter; they are limited by the amount of carbon that can be incorporated into microbial biomass and can reach the **nitrogen saturation point.** Beyond this point, added nitrogen will not be incorporated into organic matter and remains in a mobile form. The major types of nitrogen fertilizers used in agriculture are liquid ammonia and ammonium nitrate. Ammonium ion usually is added because it will be attracted to the negatively charged clays in a soil and be retained on the negative clay surfaces until used

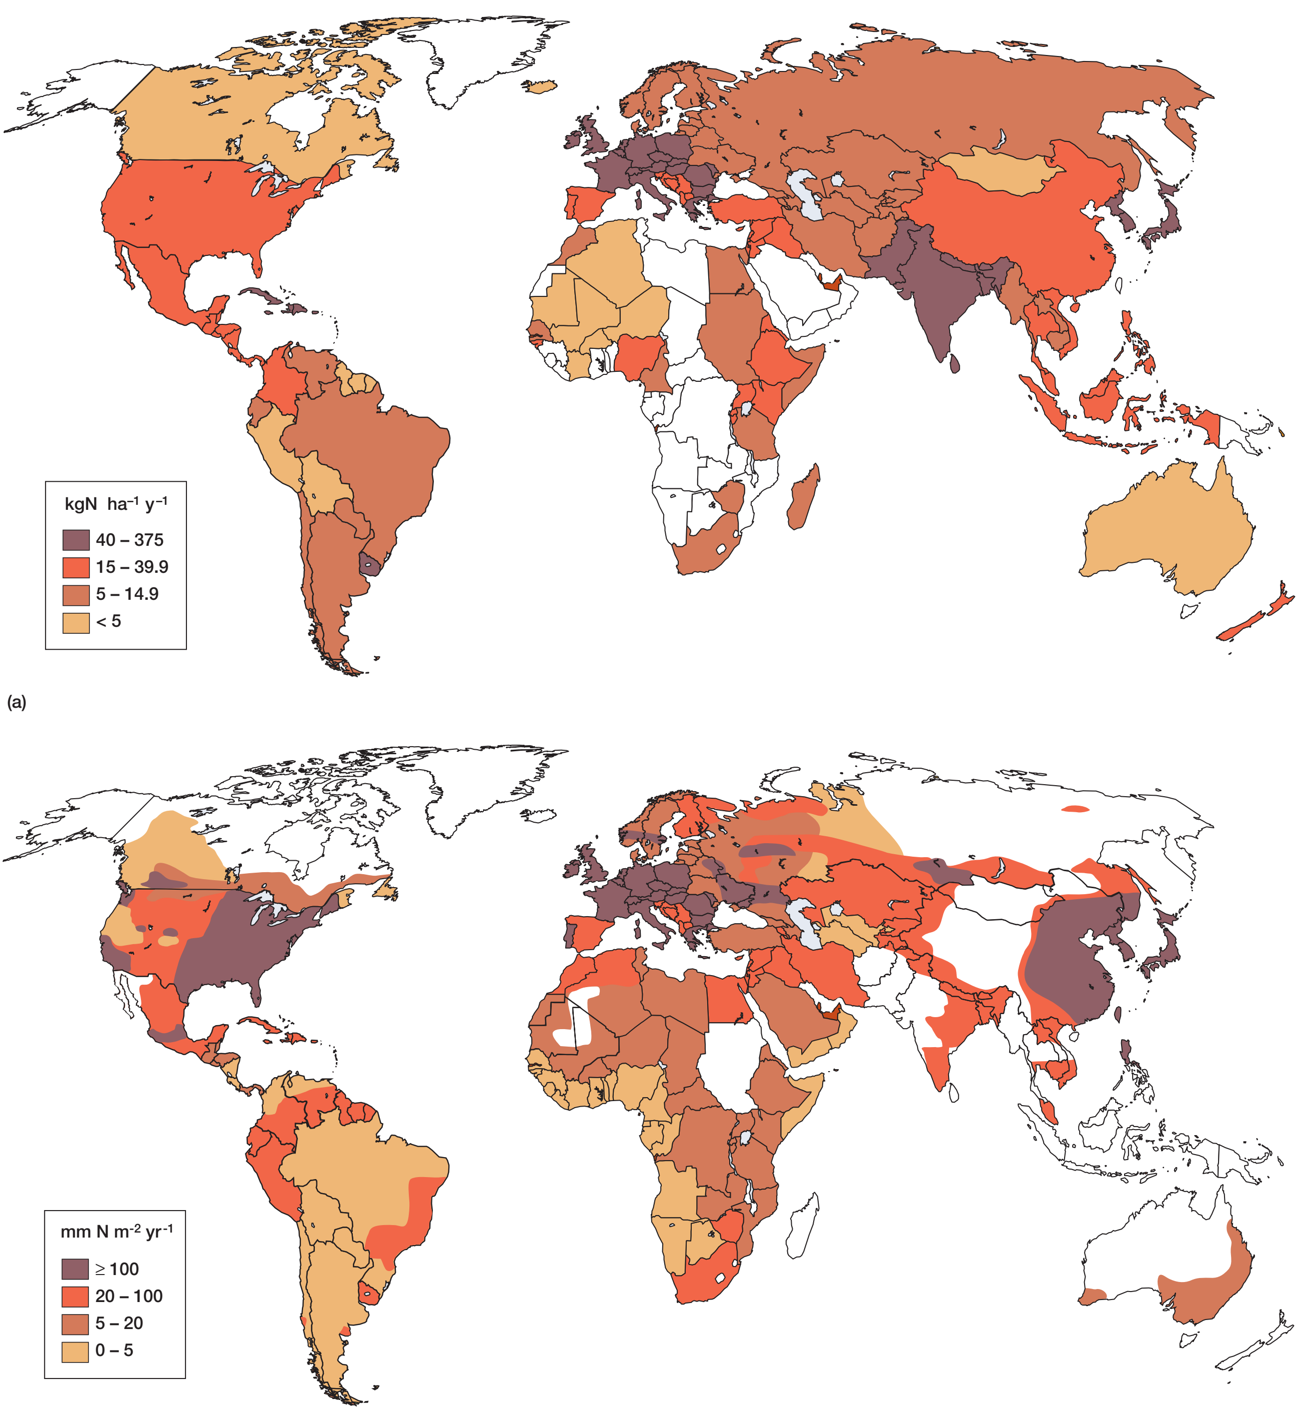

Figure 30.21 Global Releases of Nitrogen to the Environment from Agriculture and Fossil Fuels. Releases of nitrogen to the environment from agriculture and animal/human wastes for 1987 to 1990 have a somewhat different global distribution than the releases from fossil fuel burning. (**a**) Releases of agricultural and animal wastes from the Caribbean, Europe, India/Pakistan, and Japan/Korea are intense. (**b**) In contrast, fossil fuel combustion releases, expressed as mmoles N $m^{-2}yr^{-1}$, are primarily from developed/developing areas of the world with high population densities. *Adapted from: Nixon, S. W. 1995. Coastal marine eutrophication: a definition, social causes, and future concerns. Ophelia 41:199–219.*

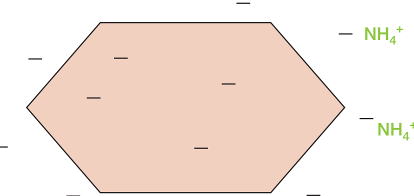
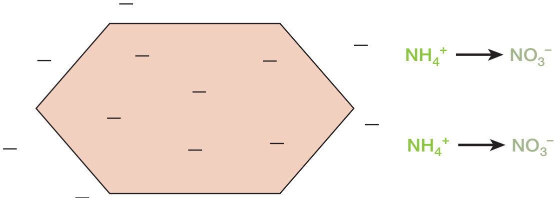
(a) Fertilizer-derived ammonium ions enter the soil and are attracted to negatively charged clays in the plant root zone.



(b) Nitrification occurs in aerobic zones, transforming ammonium ions to the anionic nitrate.



(c) Nitrate, repelled from the negatively charged clays, moves with the soil water out of the plant root zone.

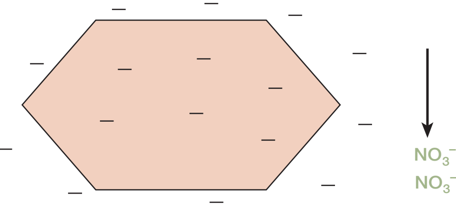


Figure 30.22 Fertilizer Mobility and Soil Clays. The role of negatively charged clays in (**a**) retaining ammonium ion-containing fertilizer in a soil, and (**b**) the release of nitrate, formed by nitrification of the ammonium ions, to the soil water and the environment. (**c**) Nitrate, being anionic or negatively charged, is not retained by the negatively charged soil clays.

as a nutrient by the plants (**figure 30.22**). However, the nitrifier populations in a soil (*see pp. 615–16*) can oxidize the ammonium ion to nitrite and nitrate, and these anions can be leached from the plant environment and enter surface waters and groundwaters.

When nitrogen fertilizers are used, an inevitable consequence has been higher nitrate levels in waters, which can contribute to infant respiratory problems, and possibly to the production of nitrites and the formation of nitrosamine carcinogens. In addition, plants grown in high nitrate-concentration soils may accumulate nitrate to a level that is harmful for animals. Cereal grains, many weeds, and grass hay contain high nitrate levels when grown in such soils.

Nitrogen fertilizers also can affect the microbial community structure and function. The use of nitrogen fertilizers has led to decreases in filamentous fungal development in a wide variety of soils. The loss of fungi affects the soil structure because fungi link soil particles to stabilize the soil peds. With a weakened and decreased fungal community, mycorrhizal-dependent plants become more susceptible to stresses such as drought and toxic metals.

As a final note, excessive fertilizer use can have global-level impacts when nitrogen enters coastal and marine waters (*see chapter 29*). The chemical synthesis of mineral fertilizers, a heritage of the Haber Process developed early in the twentieth century, has had many unexpected global-level effects.

Phosphorus in fertilizers also is critical. The binding of this anionic fertilizer component to soils is dependent on the cation exchange capacity (CEC) and soil pH. As the soil phosphorus sorption capacity is reached, the excess, together with phosphorus that moves to waters with soil erosion can stimulate the growth of freshwater organisms, particularly cyanobacteria, in the process of eutrophication. The cyanobacteria are then able to fix more nitrogen, because in most freshwater systems, phosphorus is the critical limiting element.

1. What soil management processes can lead to increases in degradation of soil organic matter?
2. Why might composted materials have different effects on soil microorganisms and organic matter than additions of fresh plant materials?
3. What are possible effects of nitrogen-containing fertilizers on microbial communities?
4. Most nitrogen fertilizer is added as ammonium ion. Why is this preferred over nitrate?
5. Why is nitrate of concern when it reaches rivers, lakes, and groundwaters?
6. Why might enrichment of fresh waters with phosphorus be even more critical than nitrogen enrichment?

30.6 Soils, Plants, and the Atmosphere

Soil microorganisms have interesting interactions with the atmosphere, another critical part of aerobiology. Ice-nucleating bacteria from decomposing litter can increase precipitation. Specific strains of *Pseudomonas syringae* synthesize proteins that can serve as nucleation centers for snow formation in cloud chambers. Such ice-nucleating soil microorganisms may significantly influence weather on a global scale. “Ice-minus” strains of *P. syringae,* developed by recombinant technology, can be sprayed on frost-sensitive crops such as strawberries. In the presence of the “ice-minus” bacteria, water will not freeze on the leaves as readily, making it possible to save frost-sensitive crops from destruction. The release of such genetically modified microorganisms (GEMs) to the environment is of continuing concern (*see pp. 341–42*).

Soil microorganisms also influence the atmosphere by degrading airborne pollutants such as methane, hydrogen, CO, benzene, trichloroethylene (TCE), and formaldehyde. They can substantially improve the air in closed buildings (**Box 30.2**). Although soil microorganisms cannot completely eliminate airborne pollutants, they can decrease these to equilibrium levels of approximately 1 to 2 ppm.

Soil microorganisms, through their activities in biogeochemical cycling (*see section 28.3*), also can have major effects on

Box 30.2

Keeping Inside Air Fresh with Soil Microorganisms

A major problem in the development of more energy-efficient homes and office buildings is the potential effect of such closed environments on human health. With many people spending much of their lives in such enclosed environments, the "sick building syndrome" is an increasing concern. While saving energy, these "sick buildings" have higher levels of many volatile compounds, including benzene, trichloroethylene (TCE), formaldehyde, phenolics, and solvents. These are released from rugs, furniture, plastic flooring, paints, and office machines such as photocopiers and printers. An important but still largely unappreciated means of improving the air in such "sick buildings" is through plants and their associated soil microorganisms. Plants not only produce oxygen, but the soil microorganisms degrade many airborne pollutants. It is recommended that one plant be used per 100 square feet of living area. As noted by B. C. Wolverton, "The ultimate solution to the indoor air pollution problem must involve plants, the plant soils and their associated microorganisms." Soil microorganisms, especially in association with plants, can help keep air in closed environments fresher and more healthful (plants are also nice to look at).

global fluxes of a variety of gases. These gases can be considered as those that are "relatively stable" and those that are "reactive gases." Relatively stable gases that are influenced by microbial activities include carbon dioxide, nitrous oxide, nitric oxide, and methane. Microorganisms also contribute to the flow of reactive gases such as ammonia, hydrogen sulfide, and dimethylsulfide, as major examples. These reactive gases tend to be produced in more waterlogged environments.

Addition of nitrogen-containing fertilizers also affects atmospheric gas exchange processes in a soil. Nitrogen additions stimulate the production of the nitrification intermediates NO and N_2O, which are critical as **greenhouse gases.** NO also appears to be required for *Nitrosomonas eutropha* to carry out nitrification. The oxidation of NH_4^+ involves the formation of hydroxylamine (NH_2OH) and NO as intermediates. This NO reacts with oxygen to give NO_2, which then can repeat the process in the following reaction:

$$NH_4^+ + NO_2 \rightarrow NH_2OH + NO$$

$$2NO + O_2 \rightarrow NO_2 \text{ (nitrogen dioxide)}$$

In this sequence molecular oxygen does not react with NH_4^+ but with NO. If NO is absent the reaction will not proceed. Nitrification (p. 193)

Atmospheric gases such as carbon dioxide, nitrous oxide, nitric oxide, and methane, that decrease the loss of radiation from the earth and may produce atmospheric warming, are called greenhouse gases. The production and consumption of these greenhouse gases can be influenced by a range of human activity-related factors. These include plant fertilization and automobile use, conversion of soils to agricultural use, and the use of landfills, all of which can cause increases in mineral nitrogen levels.

Methane is a greenhouse gas of increasing concern that can be derived from a variety of sources. These include ruminants, rice paddies, and landfills. Landfills, especially, can release methane to the atmosphere over longer terms (decades, centuries). Another interesting source of atmospheric methane is microorganisms that inhabit the gut of wood-eating termites. As noted in **Box 30.3,** with increased deforestation and the accumulation of plant residues, populations of termites (and termite gut-inhabiting methanogenic microorganisms) are increasing.

Methane levels are influenced by microorganisms and their functioning in the environment. Well-drained, aerobic soils are capable of methane oxidation by **methanotrophs** (*see pp. 502–3*), whereas in water-saturated sites of soils and in bogs and wetlands, methane may be produced faster than it can be used by methanotrophs. Based on analyses of gas bubbles in glacier ice cores, the levels of methane in the atmosphere remained essentially constant until about 400 years ago. Since then the methane level has increased 2.5-fold to the present level of 1.7 parts per million (ppm) by volume. Considering these trends, there is a worldwide interest in understanding the factors that control methane synthesis and use by microorganisms.

The processes of methane synthesis and use occur on a variety of scales in upland soils and in wetlands, as shown in **figure 30.23.** In nominally aerobic upland soils, there may be anaerobic hot spots (water-saturated local areas) where methane is produced. If these areas are surrounded by aerobic soils, methanotrophs degrade most of the methane before it can be released to the atmosphere. In more waterlogged areas such as lowland soils, methanogenesis can proceed and there is less opportunity for methanotrophs to function. In spite of this, most of the methane will be degraded. Aquatic plants transport oxygen to their rhizospheres and thus encourage methane oxidation in these localized aerobic hot spots. Methane oxidation also is sensitive to nitrogen-containing fertilizers and increases in atmospheric CO_2 levels. The balance between methane synthesis and degradation is very important. It is estimated that soils of all types provide 60% of the total atmospheric methane; wet areas, water-saturated hot spots, and rice paddies are particularly significant contributors.

1. What is a greenhouse gas? Give examples and discuss their possible importance.
2. Discuss the possible role of termites in the production of greenhouse gases.
3. What microbial processes occur in soils to both produce and degrade methane?
4. Describe factors that might lead to the formation of localized hot spots for the production and consumption of greenhouse gases.

Box 30.3

Soils, Termites, and Intestinal Microorganisms: Understanding Atmospheric Methane Changes

Termites are important components of tropical ecosystems, where their use of cellulose plant materials allows rapid—sometimes too rapid—recycling of plant materials. Termites harbor significant populations of archaea that use products of cellulose digestion, including CO_2 and hydrogen, to produce methane.

Termites occur on 2/3 of the Earth's land surface, and, based on laboratory studies, 0.77% of the carbon ingested by termites can be released as methane. In tropical wet savannas and cultivated areas, termite populations are increasing rapidly. This increase is being accelerated by the destruction of tropical forests, which results in the accumulation of dead plant materials on the soil surface. This provides an ideal environment for the growth of termites. Termites are estimated to be contributing annually at least 1.5×10^{14} grams of methane, together with hydrogen and CO_2, to the atmosphere. This is believed to be contributing to measurable increases in the atmospheric methane level. Thus unseen termites and their associated gut microorganisms may be affecting global warming.

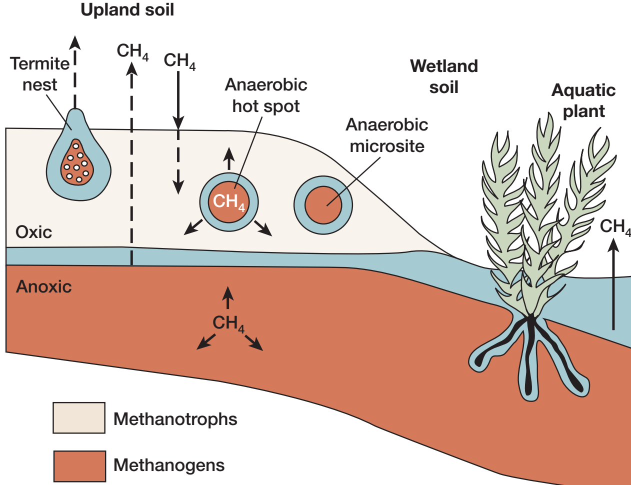

Figure 30.23 Methane Production and Use in Soils. Methane production and degradation can occur in closely located aerobic and anaerobic zones. In upland soils, methane synthesis can take place in localized anaerobic hot spots and termite nests. Much of this methane can be degraded in the surrounding aerobic soils. In wetland areas, methane production dominates in the waterlogged areas, and methane has a greater chance of being released to the atmosphere. If aquatic plants are present and translocate oxygen into anaerobic zones, these create localized aerobic hot spots in the rhizosphere for methane oxidation.

30.7 Microorganisms and Plant Decomposition

Plant growth is important in terrestrial ecosystems; equally important are plant death, decomposition, and recycling. Plants are constantly releasing leaves, branches, and other plant parts which enter the soil. These released soluble materials create a **residuesphere,** an area between decaying plant material and the soil. This has been described as a hotbed of microbial activity, which drives a wide range of microbiological processes. In anaerobic "hot spots" soluble plant materials support denitrification and possibly genetic exchange processes. After soluble materials have leached from the plant, the remaining starch, cellulose, and proteins are degraded both aerobically and anaerobically. Lignin, a random aromatic cyclic polymer that contains no nitrogen, is the one exception: its degradation requires oxygen. The basidiomycetes, which function best aerobically, are the major producers of laccases and the phenoloxidase enzymes required for lignin degradation. Lignin decomposition also is limited by the physical nature of the material: healthy woody plants are saturated with sap, creating an aerobic, low oxygen flux environment similar to that found in waters (*see chapter 29*). In addition, high ethylene and CO_2 levels, as well as the presence of phenolic and terpenoid compounds, retard the growth of lignin-degrading fungi. Thus the first step in lignin decomposition is physical rot, which involves cavitation or the creation of an "air embolism" in vascular tissue that begins when sap ceases flowing through the structure. This provides sufficient oxygen within the plant tissue to allow lignin biodegradation.

Unusual gases are produced, particularly by fungi, in this process of woody plant decomposition; these include chloromethanes and cyanide, compounds that we normally associate with industrial pollution. Large amounts of CH_3Cl, an important greenhouse gas, are produced by many fungi, including the basidiomycetes *Phellinus* and *Inonotus,* which are members of the wood-rotting *Hymenochaetaceae.* The global input of CH_3Cl to the atmosphere from plant decomposition is thought to be 160,000 tons, 75% of which is derived from tropical and subtropical soils. It is estimated that 15 to 20% of the chlorine-catalyzed ozone destruction is due to naturally-produced chlorohydrocarbons. Basidiomycetes (p. 561)

As noted in **table 30.6,** terrestrial environments, the oceans, and biomass burning are all important sources of atmospheric chloromethane. Large amounts also have been detected in some basidiomycetes. These include concentrations of 74 to 2,400 mg/kg in the basidia of some agarics and bracket fungi. It is of interest that the maximum permissible chlorophenol levels in soils

Table 30.6 Global Emissions of Chloromethane

Source	Inputs to Atmosphere (10^5 tons/year)
Natural Sources	
Terrestrial processes	0–20
Ocean fluxes	3–20
Biomass burning	4–14
Anthropogenic Sources	0–3

[a]Estimated atmospheric inputs from natural and anthropogenic sources.

are only 1 to 10 mg/kg! Cyanide is another chemical of widespread concern produced by fungi, especially by basidiomycetes and ascomycetes. This cyanide may be derived from the S-methyl group of L- and D-methionine, or its production may be linked to methyl benzoate synthesis. The best studied cyanide-producing fungi are *Marasmius oreades* (the cause of fairy ring disease) and the snow mold basidiomycetes. Some bacteria also produce cyanide. Cyanide synthesis involves the oxidative decarboxylation of glycine, which is stimulated by methionine or other methyl-group donors in the following reaction:

$$NH_2CH_2COOH \rightarrow HCN + CO_2 + 4[H]$$

Cyanide can inhibit respiration. It also can serve as a carbon and nitrogen source for microorganisms, including cyanogenic fungi such as *Marasmius* and *Pholiota,* and some actinomycetes. This illustrates the adaptability of microorganisms in the use of a nominally toxic metabolic product.

1. Why are fungi critical for the degradation of woody plants? How does the plant defend itself against these fungi?
2. What is the residuesphere?
3. What critical products of fungal growth on wood are usually considered only to be industrial pollutants?
4. How do microorganisms contribute to the cycling of cyanide?

30.8 The Subsurface Biosphere

An important habitat for microbial growth is the **subsurface biosphere,** a source of many questions concerning the origin of life on the Earth. The subsurface biosphere has been studied by examining outcrops, surface excavations, petroleum hydrocarbons, well corings, and materials from deep mine sites. Drillers have reached a depth of 6,100 meters (20,000 feet) at the Inigok well, North Slope, Alaska, and 9,150 meters (30,000 feet) at the Becha Rogers well in the Anadarko Basin, located in northern Texas and Oklahoma. In a South African gold mine, rocks from deeper than 3,350 meters (11,000 feet) below the surface have

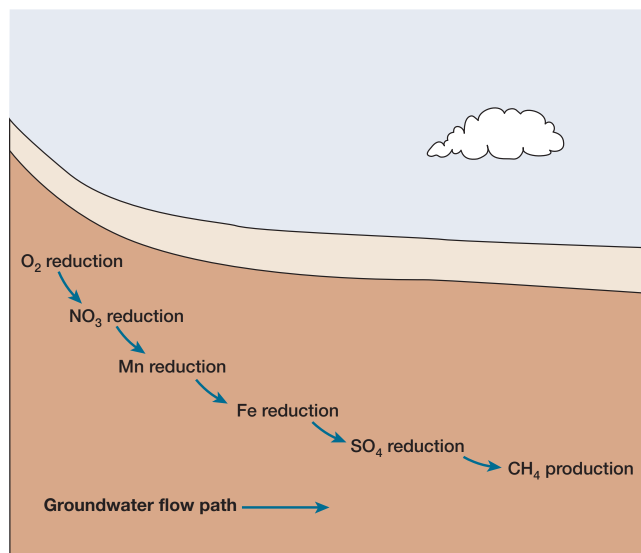

Figure 30.24 The Shallow Subsurface Biosphere. The shallow subsurface, as in a stable sediment, showing the distribution with depth of oxidants that can occur in an aerobic pristine aquifer. In aerobic sediments, the oxidants will be distributed with the most energetically favorable (oxygen) near the surface and the least energetically favorable at the lower zones of the geological structure. *Source: Lovley, D. K., 1991. Dissimilatory Fe (III) and Mn (IV) reduction. Microbiol. Rev. 55:259–287.*

been recovered by hand and examined in the search for new microorganisms. A long history of interest in the subsurface preceded these efforts, and there have been reports of microorganisms in rocks, particularly from rocks obtained in deep drilling programs. Much of this information has been discounted as being due to drilling contamination or water flows from surface areas. In recent years the use of improved techniques, including molecular approaches, has led to a greater acceptance of the idea of microorganisms occurring far below the Earth's surface, leading to a new field: deep subsurface microbiology.

Microbial processes take place in different subsurface regions, including (1) the shallow subsurface where water flowing from the surface moves below the plant root zone; (2) subsurface regions where organic matter, originating from the Earth's surface in times past, has been transformed by chemical and biological processes to yield coal (from land plants), kerogens (from marine and freshwater microorganisms), and oil and gas; and (3) zones where methane is being synthesized as a result of microbial activity.

In the shallow subsurface, surface waters often move through **aquifers,** porous geological structures below the plant root zone. As shown in **figure 30.24,** in a pristine system with an aerobic surface zone, the oxidants used in catabolism will be distributed from the most oxidized and energetically favorable (oxygen) near the surface to the least favorable (in which CO_2 is used in methanogenesis) in lower zones.

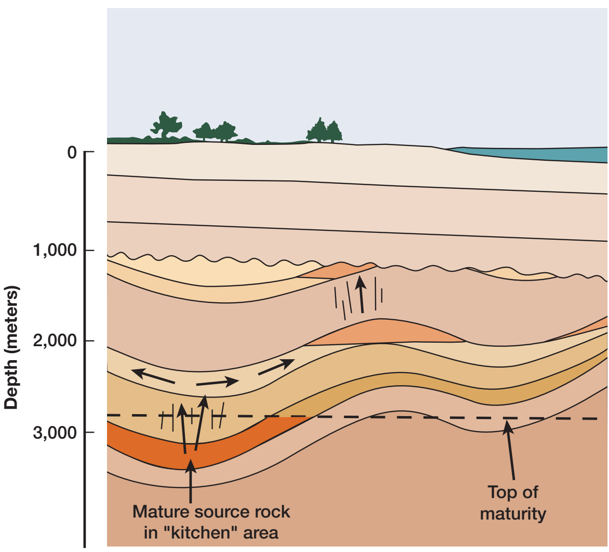

Figure 30.25 The Oil and Gas Region of the Subsurface. Organic matter, originating from the Earth's surface, is transformed to oil, gas and coal by chemical, thermal, and biological processes. Above the higher-temperature "kitchen" area, where chemical changes occur, microorganisms can contribute to the processing of these organic materials. Hydrocarbons migrate through porous strata and fractures, finally accumulating in porous, overlying geological structures. Lines indicate fractures, and arrows indicate hydrocarbon flows.

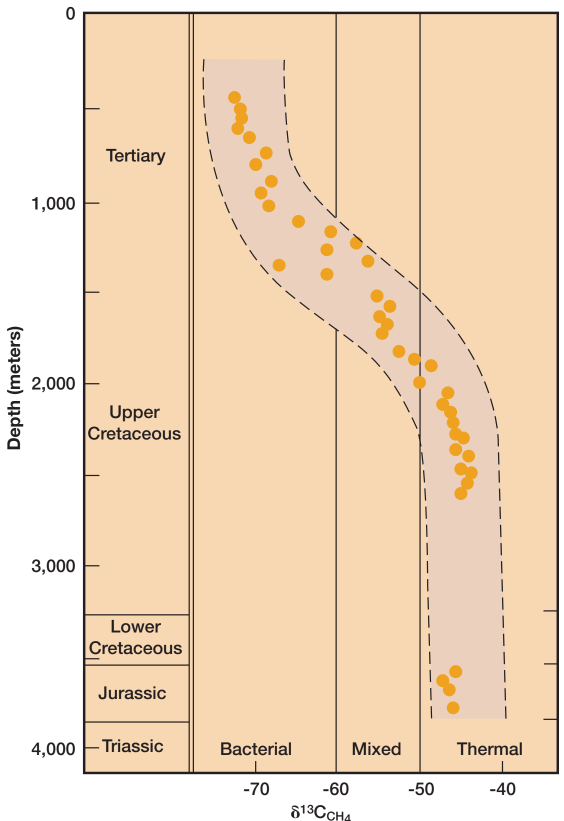

Figure 30.26 Methane Synthesis by Microorganisms in the Subsurface. The microbially mediated production of methane has been shown to occur in the subsurface by the use of stable isotope techniques. The decrease in the occurrence of the ^{13}C isotope of carbon indicates that the methane was produced by microorganisms down to a depth of 1,500 meters under the floor of the North Sea. Below a depth of 2,000 meters, the methane does not have a lower frequency of the ^{13}C isotope of carbon, indicating that it was formed by abiotic processes. The $\delta\ ^{13}C$ value gives an indication of the relative proportion of ^{13}C to ^{12}C in the sample. The more negative scale values signify a decreased presence of the heavier isotope in the upper zone at this location.

In subsurface regions where organic matter from the Earth's surface has been buried and processed by thermal and possibly biological processes, kerogen and coals break down to yield gas and oil, as noted in **figure 30.25.** After their generation, these mobile products, predominantly hydrocarbons, move upward into the more porous geological structures where microorganisms can be active. Chemical signature molecules from plant and microbial biomass are present in these petroleum hydrocarbons.

Below these zones lie vast regions where methane is present in geological structures (**figure 30.26**); this methane is continuously being released to the overlying strata. Based on studies of stable carbon isotopes, in the "biogenic" zone, methane has less ^{13}C isotope, indicating that it was derived from microorganisms using H_2 as an energy source and CO_2 as a carbon source and oxidant. Given a choice, microbes will tend to use the lighter of two isotopes—in this case ^{12}C over the ^{13}C isotope-containing CO_2. In the underlying hotter abiogenic zone, in comparison, the methane is not depleted of the heavier carbon isotope, indicating that this is of chemical and thermal origin.

Microorganisms also appear to be growing in intermediate depth oil-bearing structures. Recent studies indicate that active procaryotic assemblages are present in high-temperature (60 to 90°C) oil reservoirs, including such genera as *Thermotoga, Thermoanaerobacter,* and *Thermococcus.* The archaean genera are dominated by methanogens. Thus microbial activities may be occurring above or in the "deep hot biosphere," a term suggested by Thomas Gold to describe this poorly understood region.

1. What types of microbial activities have been observed in the deep subsurface?
2. What happens in terms of microbiological processes when organic matter leaches from the surface into the subsurface?
3. Why are stable isotope analyses so important in studies of microbe-geological interactions?
4. What microbial genera have been observed in oil field materials?

30.9 Soil Microorganisms and Human Health

As with waters, humans are in constant contact with soils. This occurs directly as when children or adults play in the "dirt," or even when leafy and root vegetables, covered with soil dust, are eaten. In most cases the contact with soil is harmless. However, soils do contain a wide variety of pathogenic organisms. What is needed is an entry point and favorable conditions within or on the human body. A wide variety of anaerobes, including *Clostridium,* are present in soils. Unless there is a deep puncture wound that will provide the anaerobic environment required for their growth, anaerobes are of little concern. However, puncture wounds, as occur in warfare and accidents, can lead to gangrene. This was an important cause of military fatalities prior to the advent of modern microbiology and antibiotics. Soils contain other pathogens. Organisms such as *Acanthamoeba,* which can be inhaled from dust, may cause primary amebic meningoencephalitis. When soils are used for surface disposal of human wastes without sewage treatment, the transmission of a wide variety of pathogens, including protozoa such as *Acanthamoeba* and *Cyclospora* can occur. The use of "night soil" as fertilizer has led to widespread contamination of fresh fruits and vegetables and has had international repercussions.

Soil and soil-related microorganisms also are of concern when they grow in buildings (**figure 30.27**). This increasingly common problem, often linked to the flooding of houses located in low-lying districts or to moisture accumulation in sink and bathroom areas (even in large and modern homes), has led to major health problems. This is particularly severe when water penetrates into house walls and insulation materials. The problem has reached the point that national newsmagazines have published articles, showing large new expensive homes, entitled "The Mold in Your Home May Be Deadly!" In a recent article it was noted that 50% of homes have mold problems, a major source of chronic sinus infections. These molds also have been related to increases in asthma rates. The major responsible fungi are *Stachybotrys chartarum, Eurotium herbariorum,* and *Aspergillus versicolor.* Fungal growth results in a black slime; when this fungal growth dries, a dry dusty layer remains and the spores can be dispersed into the air. These spores are particularly dangerous for infants, whose lungs are less developed. *Stachybotrys* infection can result in pulmonary hemosiderosis, which causes bleeding of the lungs and sometimes death. Rapid drying of water-damaged buildings is required to control this problem. Recently a bioassay for such "sick buildings" has been developed using boar spermatozoa! In this analysis the motility of the spermatozoa is inhibited by extracts from moist fungal-infested materials. Items of particular concern are moldy carpets as well as piles of old newspapers.

It has been reported that wallboards can contain baseline bioburdens of these organisms, which need only high humidity to trigger fungal growth. In addition, *Mycobacterium komossense* and gram-negative endotoxin-producing bacteria have been isolated. There are limited alternatives for controlling and removing such dangerous fungi; the most important are the removal/disinfection of moldy materials and keeping a house dry.

30.10 Understanding Microbial Diversity in the Soil

As noted in table 28.8, a wide variety of methods are available to attempt to learn more about the diversity of microorganisms that are present in a soil. As with other environments, such as waters, animal bodies, and insects, it is estimated that only 1 to 10% of the microscopically observable organisms can be cultured in the laboratory. With the availability of molecular techniques, as discussed in chapters 19 and 28, it is now becoming possible assess the range of microbial diversity in a

soil sample by extracting and analyzing the nucleic acids that are present. Ultimately, it will be necessary to grow the microorganisms and relate specific nucleic acids to known structures in a soil (*see section 28.5*). Without growth of microorganisms considered to contain these nucleic acids, it is not possible to do more than note that these specific sequences are present. This makes it doubly important to better understand the physiology and activities of the microorganisms that make up so much of our world.

1. How can the growth of fungi affect human health inside of a home?
2. What important fungal genera are involved in mold problems in homes?
3. Surface soil spreading of untreated human wastes is carried out in many parts of the world. What are some of the effects of this practice?
4. Why is the growth of microorganisms important for furthering our understanding of microbial diversity?

Summary

1. Terrestrial environments are dominated by the solid phase, consisting of organic and inorganic components.
2. In an ideal soil, microorganisms function in thin water films that have close contact with air (**figure 30.1**). If isolated water volumes are present within the soil volume, from a microbial viewpoint, these are miniaquatic environments.
3. Most microorganisms in these environments are associated with surfaces, and these surfaces influence microbial use of nutrients and interactions with plants and other living organisms (**figure 30.2**).
4. Soils form under a bewildering array of conditions (**figure 30.4**). In all cases organic matter accumulation occurs through the direct activities of primary producers or by the import of preformed organic materials. Soils can be formed in regions such as the antarctic where there are no vascular plants.
5. Bacteria and fungi in soils have different functional strategies. Fungi tend to develop on the surfaces of aggregates, whereas microcolonies of bacteria are commonly associated with smaller pores.
6. Insects and other soil animals are also important parts of the soil. These decomposer-reducers interact with the microorganisms to influence nutrient cycling and other processes.
7. Soils differ in the relationship between organic matter accumulation—primary production—and decomposition.
8. Plants develop associations with many types of microorganisms. These include important associations with rhizobia; actinomycetes, forming actinorhizae; and with endophytic fungi and bacteria. *Agrobacterium* forms tumors and is useful in molecular biology (**figure 30.20**).
9. The *Rhizobium*-legume symbiosis is one of the best-studied examples of plant-microorganism interactions. This interaction is mediated by complex chemicals that serve as communication signals (**figure 30.8**).
10. Mycorrhizal relationships (plant-fungal associations) are varied and complex. Five basic types are now known to exist (**figure 30.11**). The hyphal network of the mycobiont can lead to the formation of a mycorrhizosphere.
11. The mycorrhizal relationship often is established with the assistance of mycorrhization helper bacteria (MHB). In addition, bacteria may occur inside of the mycorrhizal fungus. These bacteria apparently contribute to the nitrogen cycling of the plant-fungus complex.
12. Some plants form tripartite and tetrapartite associations.
13. Composting is useful for maintaining and increasing soil fertility.
14. Soil microorganisms can interact with the atmosphere. Some can serve as nucleating agents, whereas others can degrade airborne pollutants.
15. Microorganisms can play major roles in the dynamics of greenhouse gases such as carbon dioxide, nitrous oxide, nitric oxide, and methane. Microorganisms can contribute to both the production and consumption of these gases.
16. Nitrogen fertilizers can affect soil microbial communities, and the nitrification of ammonium ion-containing fertilizers to nitrate allows the nitrogen to enter ground and surface waters.
17. Fungi play important roles in the decomposition of woody plants. The basidiomycetes are the major decomposers of lignin in woody plant materials. The functioning of these fungi requires the presence of oxygen.
18. Fungi, especially, can produce chemicals that are normally considered as anthropogenic pollutants. These include chloromethane and cyanide.
19. The subsurface includes at least three zones: the shallow subsurface; the zone where gas, oil, and coal have accumulated; and the deep subsurface, where methane synthesis occurs.
20. Microorganisms, particularly the fungi, can develop in moist areas in houses and cause major health problems for humans, including asthma. An important fungus involved in these problems is *Stachybotrys*.

Questions for Thought and Review

1. Considering the oxygen gradients, together with nutrient and waste-product gradients present in soils, is there a typical soil microenvironment? Explain.
2. Why might protozoa prefer to use laboratory-grown microorganisms as a nutrient source rather than normal soil microorganisms?
3. Tropical soils throughout the world are under intense pressure in terms of agricultural development. What land use and microbial approaches might be used to better maintain this valuable resource?
4. Microorganisms interact with plants in many ways. How might it be possible to improve these interactions through molecular biology?
5. Why might vascular plants have developed subtle relationships with so many types of microorganisms? What do these molecular-level interactions, which show so many similarities when microbe-plants and microbe-human interactions are considered, suggest concerning possible common evolutionary relationships?
6. Why might a plant assist in its parasitism by *Agrobacterium?*
7. What alternatives could be used to minimize the environmental effects of nitrogen-containing fertilizers on the environment?
8. If lignin-containing plant materials didn't decompose, what could happen?
9. How might you maintain organisms from the deep hot subsurface under their in situ conditions? Compare this problem with that of working with microorganisms from deep marine environments.
10. What are some of the potential strong and weak points of using stable isotope-based analyses of microbial processes?

Critical Thinking Questions

1. How might it be possible to minimize the production of pollutants by soil fungi? Is there any possible role for genetic engineering in solving this problem?
2. Soil bacteria such as *Streptomyces* produce the bulk of known antibiotics. Look up the competitors for *Streptomyces,* the types of antibiotics these bacteria produce, and how the compounds are effective against competitors (what are the physiological targets?). Would you expect aquatic/marine bacteria to be major producers of antibiotics? Why or why not?

Concepts

1. Gnotobiotic refers to a microbiologically monitored environment or animal in which the identities of all microorganisms present are known or to an environment or animal that is germfree.
2. Most microorganisms associated with the human body are bacteria; they normally colonize specific sites. There are both positive and negative aspects of these normal microorganisms. Sometimes they compete with pathogens; other times they are capable of producing opportunistic infections.
3. The host's ability to resist infection depends on a constant defense against microbial invasion. Resistance arises from both nonspecific and specific body defense mechanisms.
4. Nonspecific host defenses are those innate mechanisms with which a host is genetically endowed. Examples include physical and mechanical barriers: specifically, the skin, mucous membranes, the respiratory system, gastrointestinal tract, genitourinary tract, and the eye. Other nonspecific host defenses include chemical barriers such as bacteriocins, betalysin, and other polypeptides.
5. Inflammation, the alternative complement pathway, phagocytosis, cytokines, fever, and natural killer cells are other examples of nonspecific defenses that help protect the host against microorganisms and cancer.

Half the secret of resistance is cleanliness, the other half is dirtiness.

—Anonymous

As presented in chapter 28, many microorganisms live much of their lives in a special ecological relationship: an important part of their environment is a member of another species. Previously you learned about many different environments in chapters 28, 29, and 30; this chapter presents the normal microorganisms associated with the human body. Very little is known about the nature of these normal associations, but they are thought to be dynamic interactions rather than associations of mutual indifference. Each member of the symbiosis is thought to derive some benefit from the other, and the associations are for the most part mutualistic or commensalistic (*see section 28.2*). The survival of a host, such as a human, depends upon an elaborate network of defenses that keeps harmful microorganisms and other foreign material from infecting the body. Should they gain access, additional host defenses are summoned to prevent them from establishing another type of relationship, one of parasitism or **pathogenicity.** Pathogenicity is the ability to produce pathologic changes or disease. A **pathogen** [Greek *patho,* and *gennan,* to produce] is any disease-producing microorganism. Nonspecific host defenses involve general barriers, physical barriers, chemical barriers, and biological barriers such as inflammation and fever. This chapter introduces the normal human microbiota and the main lines of nonspecific host defenses against invasion by harmful microorganisms, cancer cells, and foreign proteins. We begin, however, with a look at the field of gnotobiotics in which it is possible to have an environment or an animal that is free of microorganisms.

31.1 Gnotobiotic Animals

Environments and animals with known microorganisms increasingly are used in research. For example, to determine the role of the normal microorganisms associated with a host, it is possible to deliver an animal by cesarean section and raise that animal in the absence of microorganisms—that is, germfree. These microorganism-free animals provide suitable experimental models for investigating the interactions of animals and their microorganisms. Comparing animals possessing normal microorganisms with germfree animals permits the elucidation of many of the complex relationships covered in chapters 28, 29, and 30 between microorganisms, hosts, and specific environments. Germfree experiments also extend the microbiologist's "pure culture concept" to in vivo research.

The term **gnotobiotic** [Greek *gnotos,* known, and *biota,* the flora and fauna of a region] has been defined in two ways. Some think of a gnotobiotic environment or animal as one in which all the microbiota are known; they distinguish it from one that is truly germfree. We shall use the term in a more inclusive sense. Gnotobiotic refers to a microbiologically monitored environment or animal that is germfree (axenic) or in which the identities of all microbiota are known.

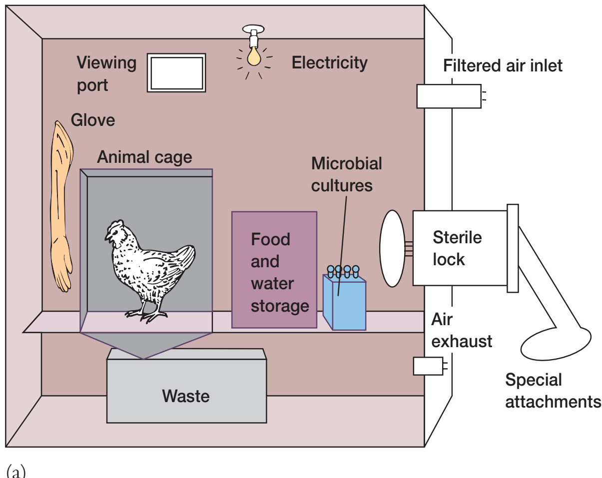
The human fetus in utero (as is the case in most mammals) is usually free from microorganisms. Within hours after birth, it begins to acquire a normal microbiota, which stabilizes during the first week or two of life. From then on, enormous numbers of microorganisms become associated with the human body. Under normal conditions the human lives in symbiosis with billions of microorganisms.

Louis Pasteur first suggested that animals could not live in the absence of microorganisms. Attempts between 1899 and 1908 to grow germfree chickens had limited success because the birds died within a month. Thus it was believed that intestinal bacteria were essential for the adequate nutrition and health of the chickens. It was not until 1912 that germfree chickens were shown to be as healthy as normal birds when they were fed an adequate diet. Since then, gnotobiotic animals and systems have become commonplace in research laboratories (**figure 31.1**).

Gnotobiotic animals and techniques provide good experimental systems to investigate the interactions of animals and specific microorganisms. The comparison of animals containing normal microbiota with gnotobiotic animals helps one better understand the many complex symbiotic associations that exist between the host and its microorganisms.

Establishing a germfree colony of rats, mice, hamsters, rabbits, guinea pigs, or monkeys begins with cesarean sections on pregnant females. The operation is performed under aseptic conditions in a sterile isolator. The newborn animals are then transferred to other germfree isolators in which all entering air, water, and food is sterile. Once the gnotobiotic animals become established, normal mating among themselves maintains the germfree colony.

Establishment of a germfree colony is much easier with chickens and other birds than with mammals. Fertile eggs from the birds are first sterilized with a germicide and then placed in



(a)

(b)

Figure 31.1 Raising Gnotobiotic Animals. (**a**) Schematic of a gnotobiotic isolator. The microbiological cultures monitor the sterile environment. If growth occurs on any of the cultures, gnotobiotic conditions do not exist. (**b**) Gnotobiotic isolators for rearing colonies of small mammals.

sterile isolators. When the chick hatches, it is sterile and able to feed by itself. To make sure that a colony is germfree, periodic bacteriologic examination of all exhaust air, waste material, and cages must be done. Microorganisms should not be found.

Germfree animals are not anatomically and physiologically normal. For example, they possess poorly developed lymphoid tissue, a thin intestinal wall, an enlarged cecum (where one is present), and a low antibody titer (*see section 32.3*). They require high amounts of vitamin K and the B complexes. Germfree animals also have reduced cardiac output and lower metabolic rates.

Germfree animals are usually more susceptible to pathogens. With the normal protective microbiota absent, foreign and pathogenic microorganisms establish themselves very easily. The number of microorganisms necessary to infect a germfree animal and produce a diseased state also is much smaller. Conversely, germfree animals are almost completely resistant to the intestinal protozoan *Entamoeba histolytica* that causes amebic dysentery. This resistance results from the absence of the bacteria that *E. histolytica* uses as a food source. Germfree animals also do not show any dental caries or plaque formation (*see section 39.6*). However, if they are inoculated with cariogenic (caries or cavity-causing) streptococci of the *Streptococcus mutans–Streptococcus gordonii* group and fed a high-sucrose diet, they will develop caries. (*S. gordonii* was formerly considered a subpopulation of *S. sanguis.*)

Entamoeba histolytica (pp. 950–51)

1. Define gnotobiotic.
2. How would you establish a germfree colony of mice? Of chickens?
3. Compare a germfree mouse to a normal one with regard to overall health. What benefits does an animal gain from its microbiota?

31.2 Normal Microbiota of the Human Body

In a healthy human the internal tissues (e.g., brain, blood, cerebrospinal fluid, muscles) are normally free of microorganisms. Conversely, the surface tissues (e.g., skin and mucous membranes) are constantly in contact with environmental microorganisms and become readily colonized by certain microbial species. The mixture of microorganisms regularly found at any anatomical site is referred to as the normal microbiota, the indigenous microbial population, the microflora, or the normal flora. For consistency, the term **normal microbiota** is used in this chapter. An overview of the microbiota native to different regions of the body (**figure 31.2**) and an introduction to the microorganisms one can expect to find on culture reports is presented next. Because bacteria make up most of the normal microbiota, they are emphasized over the fungi (mainly yeasts) and protozoa.

There are many reasons to acquire knowledge of the normal human microbiota. Four specific examples include:

1. An understanding of the different microorganisms at specific locations provides greater insight into the possible infections that might result from injury to these body sites.
2. A knowledge of the normal microbiota in an infected part of the body gives the physician-investigator a better perspective concerning the possible source and significance of microorganisms isolated from an infection site.
3. A knowledge of the normal microbiota helps the physician-investigator understand the causes and consequences of colonization and growth by microorganisms normally absent at a specific body site.
4. An increased awareness of the role that these normal microbiota play in stimulating the host immune response can be gained. This awareness is important because the immune system provides protection against potential pathogens.

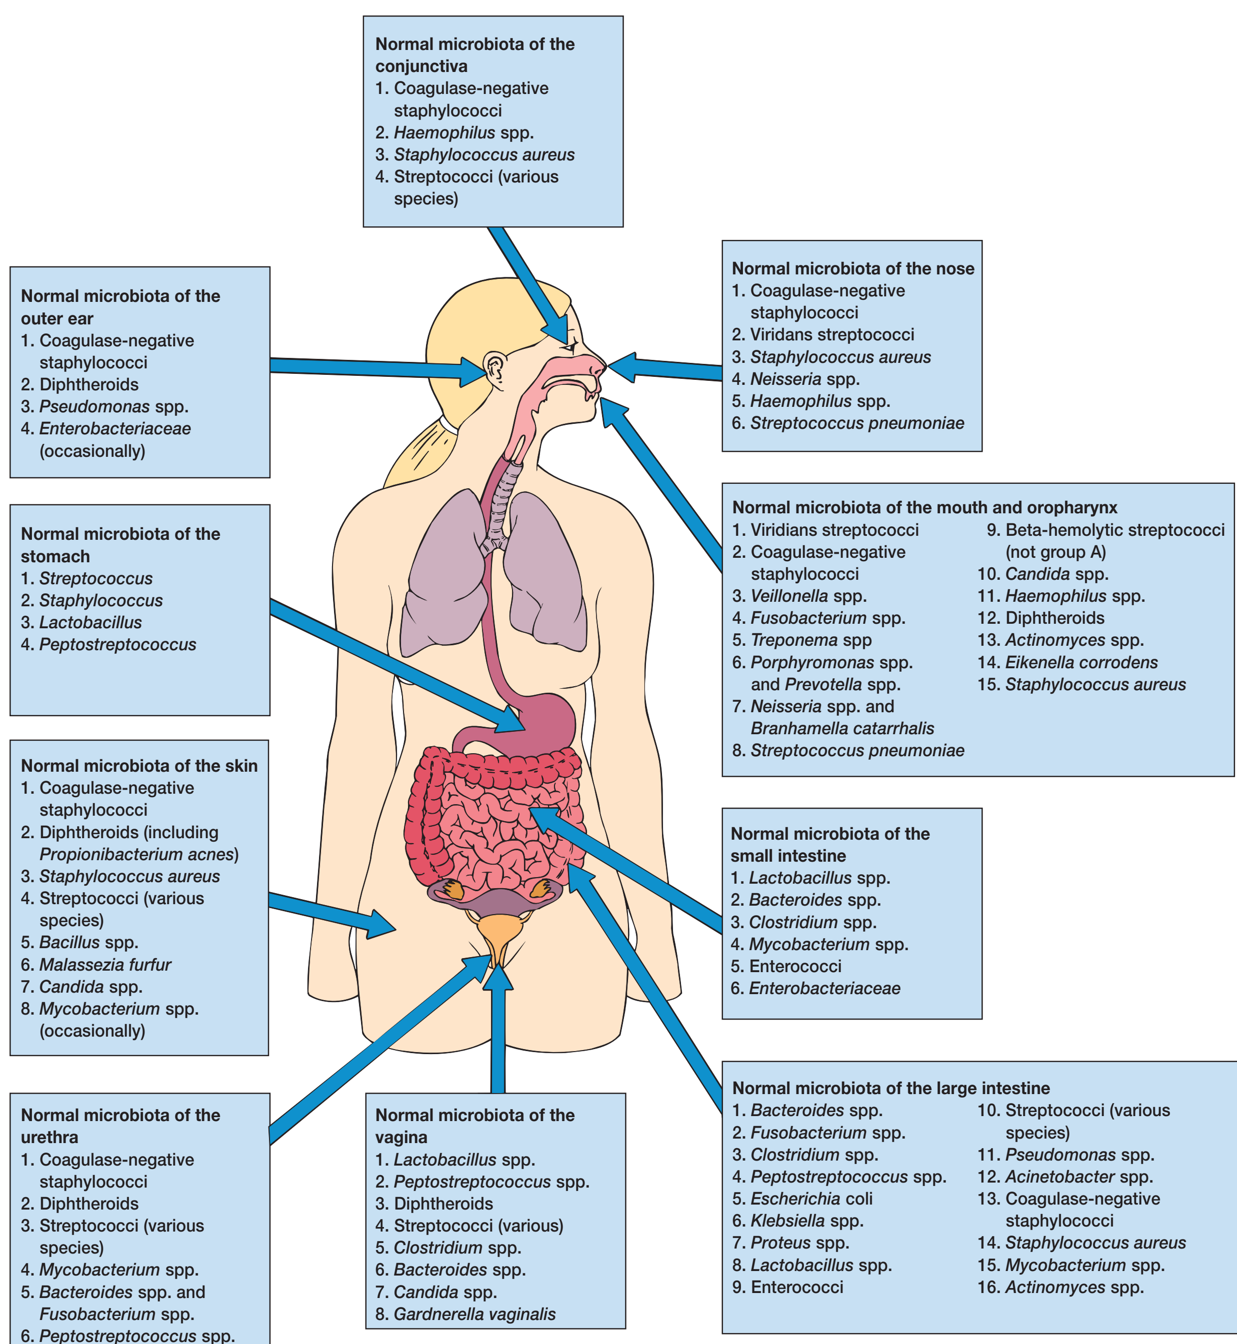


Figure 31.2 Normal Microbiota of a Human. A compilation of microorganisms that constitute normal microbiota encountered in various body sites.

Distribution of the Normal Microbiota

As noted in chapter 28, three of the most important types of symbiotic relationships are commensalism, mutualism, and parasitism. Within each category the association may be either ectosymbiotic or endosymbiotic. In **ectosymbiosis** one organism remains outside the other. In **endosymbiosis** one organism is present within the other. In the following subsections, examples will be presented of both ecto- and endosymbiotic relationships that exist with the human host. Both commensalistic and mutualistic relationships are considered. Parasitism and pathogenicity will be presented in chapter 34.

Skin

The adult human is covered with approximately 2 square meters of skin. It has been estimated that this surface area supports about 10^{12} bacteria. As noted in chapter 28, a commensal is an organism that participates in commensalism. Commensalism is a symbiotic relationship in which one species benefits and the other is unharmed. Commensal microorganisms living on or in the skin can be either resident (normal) or transient microbiota. Resident organisms normally grow on or in the skin. Their presence becomes fixed in well-defined distribution patterns. Those microorganisms that are temporarily present are transients. Transients usually do not become firmly entrenched; they are unable to multiply and normally die in a short time.

The anatomy and physiology of the skin vary from one part of the body to another, and the normal resident microbiota reflect these variations. The skin surface or epidermis is not a favorable environment for microbial colonization. Several factors are responsible for this hostile microenvironment. First, the skin is subject to periodic drying. Lack of moisture drives many resident microbiota into a dormant state. However, in certain parts of the body (scalp, ears, axillary areas, genitourinary and anal regions, perineum, palms), moisture is sufficiently high to support a resident microbiota. Second, the skin has a slightly acidic pH due to the organic acids produced by normal staphylococci and secretions from skin oil and sweat glands. The acidic pH (4 to 6) discourages colonization by many microorganisms. Third, sweat contains a high concentration of sodium chloride. This makes the skin surface hyperosmotic and osmotically stresses most microorganisms. Finally, certain inhibitory substances (bactericidal and/or bacteriostatic) on the skin help control colonization, overgrowth, and infection from microorganisms. For example, the sweat glands release lysozyme (muramidase), an enzyme that lyses *Staphylococcus epidermidis* and other gram-positive bacteria by hydrolyzing the β (1→4) glycosidic bond connecting *N*-acetylmuramic acid and *N*-acetylglucosamine in the bacterial cell wall peptidoglycan (figure 31.9). The oil glands secrete complex lipids that may be partially degraded by the enzymes from certain gram-positive bacteria (*Propionibacterium acnes*). These bacteria can change the secreted lipids to unsaturated fatty acids such as oleic acid that have strong antimicrobial activity against gram-negative bacteria and some fungi. Some of these fatty acids are volatile and may be associated with a strong odor. Therefore many body deodorants contain antibacterial substances that act selectively against gram-positive bacteria to reduce the production of volatile unsaturated fatty acids and body odor. However, deodorants can shift the normal microbiota to predominantly gram-negative bacteria and precipitate subsequent infections.

Most skin bacteria are found on the superficial cells, colonizing dead cells, or closely associated with the oil and sweat glands. Secretions from these glands provide the water, amino acids, urea, electrolytes, and specific fatty acids that serve as nutrients primarily for *Staphylococcus epidermidis* and aerobic corynebacteria. Gram-negative bacteria generally are found in the moister regions. The yeasts *Pityrosporum ovale* and *P. orbiculare* normally occur on the scalp. Some dermatophytic fungi may colonize the skin and produce athlete's foot and ringworm. Athlete's foot disease (p. 944)

The most prevalent bacterium in the skin glands is the gram-positive, anaerobic, lipophilic rod *Propionibacterium acnes.* This bacterium usually is harmless; however, it has been associated with the skin disease acne vulgaris. Acne commonly occurs during adolescence when the endocrine system is very active. Hormonal activity stimulates an overproduction of **sebum,** a fluid secreted by the oil glands. A large volume of sebum accumulates within the glands and provides an ideal microenvironment for *P. acnes.* In some individuals this accumulation triggers an inflammatory response that causes redness and swelling of the gland's duct and produces a **comedo** [pl., comedones], a plug of sebum and keratin in the duct. Inflammatory lesions (papules, pustules, nodules) commonly called "blackheads" or "pimples" can result. *P. acnes* produces lipases that hydrolyse the sebum triglycerides into free fatty acids. Free fatty acids are especially irritating because they can enter the dermis and promote inflammation. Because *P. acnes* is extremely sensitive to tetracycline, this antibiotic may aid acne sufferers. Accutane, a synthetic form of vitamin A, is also used.

Some pathogens found on or in the skin are residents that colonize the area around orifices. *Staphylococcus aureus* is the best example. It resides in the nostrils and perianal region but survives poorly elsewhere. In like manner *Clostridium perfringens* usually colonizes only the perineum and thighs, especially in those who suffer from diabetes.

1. What are four reasons why knowledge of the normal human microbiota is important?
2. Why is the skin not usually a favorable microenvironment for colonization by bacteria?
3. How do microorganisms contribute to body odor?
4. What physiological role does *Propionibacterium acnes* play in the establishment of acne vulgaris?

Nose and Nasopharynx

The normal microbiota of the nose is found just inside the nostrils. *Staphylococcus aureus* and *S. epidermidis* are the predominant bacteria present and are found in approximately the same numbers as on the skin of the face.

The nasopharynx, that part of the pharynx lying above the level of the soft palate, may contain small numbers of potentially pathogenic bacteria such as *Streptococcus pneumoniae, Neisseria meningitidis,* and *Haemophilus influenzae.* Diphtheroids, a large group of nonpathogenic gram-positive bacteria that resemble *Corynebacterium* (*see section 24.5*), are commonly found in both the nose and nasopharynx.

Oropharynx

The oropharynx is that division of the pharynx lying between the soft palate and the upper edge of the epiglottis. Like the nose, large numbers of *Staphylococcus aureus* and *S. epidermidis* inhabit this region. The most important bacteria found in the oropharynx are the various alpha-hemolytic streptococci (*S. oralis, S. milleri, S. gordonii, S. salivarius*); large numbers of diphtheroids; *Branhamella catarrhalis;* and small gram-negative cocci related to *Neisseria meningitidis.* It should be noted that the palatine and pharyngeal tonsils harbor a similar microbiota, except that within the tonsillar crypts, there is an increase in *Micrococcus* and the anaerobes *Porphyromonas, Prevotella,* and *Fusobacterium.* (*Porphyromonas* spp. and *Prevotella* spp. were formerly classified as *Bacteroides.*)

Respiratory Tract

The upper and lower respiratory tracts (trachea, bronchi, bronchioles, alveoli) do not have a normal microbiota. This is because microorganisms are removed by (1) the continuous stream of mucus generated by the ciliated epithelial cells and (2) the phagocytic action of the alveolar macrophages. In addition, a bactericidal effect is exerted by the enzyme lysozyme, present in nasal mucus. Mucociliary blanket (p. 711)

Mouth

The normal microbiota of the mouth or oral cavity contains organisms able to resist mechanical removal by adhering to surfaces like the gums and teeth. Those that cannot attach are removed by the mechanical flushing of the oral cavity contents to the stomach where they are destroyed by hydrochloric acid. The continuous desquamation (shedding) of epithelial cells also removes microorganisms. Those microorganisms able to colonize the mouth find a very comfortable environment due to the availability of water and nutrients, the suitability of pH and temperature, and the presence of many other growth factors. Biofilms (pp. 620–22)

The oral cavity is colonized by microorganisms from the surrounding environment within hours after a human is born. Initially the microbiota consists mostly of the genera *Streptococcus, Neisseria, Actinomyces, Veillonella,* and *Lactobacillus.* Some yeasts also are present. Most microorganisms that invade the oral cavity initially are aerobes and obligate anaerobes. When the first teeth erupt, the anaerobes (*Porphyromonas, Prevotella,* and *Fusobacterium*) become dominant due to the anaerobic nature of the space between the teeth and gums. As the teeth grow, *Streptococcus parasanguis* and *S. mutans* attach to their enamel surfaces; *S. salivarius* attaches to the buccal and gingival epithelial surfaces and colonizes the saliva. These streptococci produce a glycocalyx and various other adherence factors that enable them to attach to oral surfaces. The presence of these bacteria contributes to the eventual formation of dental plaque, caries, gingivitis, and periodontal disease. Periodontal disease (p. 936)

Eye

At birth and throughout human life, a small number of bacterial commensals are found on the conjunctiva of the eye. The predominant bacterium is *Staphylococcus epidermidis* followed by *S. aureus,* aerobic corynebacteria (diphtheroids), and *Streptococcus pneumoniae.* Cultures from the eyelids or conjunctiva also yield *Branhamella catarrhalis, Escherichia, Klebsiella, Proteus, Enterobacter, Neisseria,* and *Bacillus* species. Few anaerobic organisms are present.

External Ear

The norma microbiota of the external ear resemble those of the skin, with coagulase-negative staphylococci and *Corynebacterium* predominating. Less frequently found are *Bacillus, Micrococcus,* and *Neisseria* species. Gram-negative rods such as *Proteus, Escherichia,* and *Pseudomonas* are occasionally seen. Mycological studies show the following fungi to be normal microbiota: *Aspergillus, Alternaria, Penicillium, Candida,* and *Saccharomyces.*

Stomach

As noted earlier, many microorganisms are washed from the mouth into the stomach. Owing to the very acidic pH values (2 to 3) of the gastric contents, most microorganisms are killed. As a result the stomach usually contains less than 10 viable bacteria per milliliter of gastric fluid. These are mainly *Sarcina, Streptococcus, Staphylococcus, Lactobacillus, Peptostreptococcus,* and yeasts such as *Candida* spp. Microorganisms may survive if they pass rapidly through the stomach or if the organisms ingested with food are particularly resistant to gastric pH (mycobacteria). Normally the number of microorganisms increases after a meal but quickly falls as the acidic pH takes its toll. Changes in the gastric microbiota also occur if there is an increase in gastric pH following intestinal obstruction, which permits a reflux of alkaline duodenal secretions into the stomach. If the gastric pH increases, the microbiota of the stomach are likely to reflect that of the oropharynx and, in addition, contain both gram-negative aerobic and anaerobic bacteria.

Small Intestine

The small intestine is divided into three anatomical areas: the duodenum, jejunum, and ileum. The duodenum (the first 25 cm of the small intestine) contains few microorganisms because of the combined influence of the stomach's acidic juices and the inhibitory action of bile and pancreatic secretions. Of the bacteria present, gram-positive cocci and rods comprise most of the microbiota. *Enterococcus faecalis,* lactobacilli, diphtheroids, and the yeast *Candida albicans* are occasionally found in the je-

Box 31.1

Probiotics for Humans and Animals

The large intestine of humans and animals contains a very complex and balanced microbiota. These microorganisms normally prevent infection and have a positive effect on nutrition. Any abrupt change in diet, stress, or antibiotic therapy can upset this microbial balance, making the host susceptible to disease and decreasing the efficiency of food use. **Probiotics** [Greek *pro,* for, and *bios,* life], the oral administration of either living microorganisms or substances to promote health and growth, has the potential to reestablish the natural balance and return the host to normal health and nutrition.

Probiotic microorganisms are host specific; thus a strain selected as a probiotic in one animal may not be suitable in another species. Furthermore, microorganisms selected for probiotic use should exhibit the following characteristics:

1. Adhere to the intestinal mucosa of the host
2. Be easily cultured
3. Be nontoxic and nonpathogenic to the host
4. Exert a beneficial effect on the host
5. Produce useful enzymes or physiological end products that the host can use
6. Remain viable for a long time
7. Withstand HCl in the host's stomach and bile salts in the small intestine

There are several possible explanations of how probiotic microorganisms displace pathogens and enhance the development and stability of the microbial balance in the large intestine. These include:

1. Competition with pathogens for nutrients and adhesion sites
2. Inactivation of pathogenic bacterial toxins or metabolites
3. Production of substances that inhibit pathogen growth
4. Stimulation of nonspecific immunity

A wide variety of probiotic preparations have been patented for cattle, goats, horses, pigs, poultry, sheep, and domestic animals. Most of these preparations contain lactobacilli and/or streptococci; a few contain bifidobacteria.

Evidence has accumulated that certain probiotic microorganisms also offer considerable health benefits for humans. Potential benefits include:

1. Anticarcinogenic activity
2. Control of intestinal pathogens
3. Improvement of lactose use in individuals who have lactose intolerance
4. Reduction in the serum cholesterol concentration

Although the development of probiotics is still in its early stages, a better understanding of the normal microbiota in the large intestine of both animals and humans will be forthcoming as more microbiologists investigate probiotic activity. Food microbiology (chapter 41)

junum. In the distal portion of the small intestine (ileum), the microbiota begin to take on the characteristics of the colon microbiota. It is within the ileum that the pH becomes more alkaline. As a result anaerobic gram-negative bacteria and members of the family *Enterobacteriaceae* become established.

Large Intestine (Colon)

The large intestine or colon has the largest microbial community in the body. Microscopic counts of feces approach 10^{12} organisms per gram wet weight. Over 400 different species have been isolated from human feces. The colon can be viewed as a large fermentation vessel, and the microbiota consist primarily of anaerobic, gram-negative, nonsporing bacteria and gram-positive, spore-forming, and nonsporing rods. Not only are the vast majority of microorganisms anaerobic, but many different species are present in large numbers. Several studies have shown that the ratio of anaerobic to facultative anaerobic bacteria is approximately 300 to 1. Even the most abundant of the latter, *Escherichia coli,* is only about 0.1% of the total population.

Besides the many bacteria in the large intestine, the yeast *Candida albicans* and certain protozoa may occur as harmless commensals. *Trichomonas hominis, Entamoeba hartmanni, Endolimax nana,* and *Iodamoeba butschlii* are common inhabitants. Protozoan diseases (pp. 950–58)

Various physiological processes move the microbiota through the colon so an adult eliminates about 3×10^{13} microorganisms daily. These processes include peristalsis and desquamation of the surface epithelial cells to which microorganisms are attached, and continuous flow of mucus that carries adhering microorganisms with it. To maintain homeostasis of the microbiota, the body must continually replace those lost microorganisms. The bacterial population in the human colon usually doubles once or twice a day. Under normal conditions the resident microbial community is self-regulating. Competition and mutualism between different microorganisms and between the microorganisms and their host serve to maintain a status quo. However, if the intestinal environment is disturbed, the normal microbiota may change greatly. Disruptive factors include stress, altitude changes, starvation, parasitic organisms, diarrhea, and use of antibiotics or probiotics (**Box 31.1**). Finally, it should be emphasized that the actual proportions of the individual bacterial populations within the indigenous microbiota depend largely on a person's diet.

The initial residents of the colon of breast-fed infants are members of the gram-positive *Bifidobacterium* genus, because human milk contains a disaccharide amino sugar that *Bifidobacterium* species require as a growth factor. In formula-fed infants, gram-positive *Lactobacillus* species predominate because formula lacks the required growth factor. With the ingestion of solid food, these initial colonizers of the colon are eventually displaced

by a typical gram-negative microbiota. Ultimately the composition of the adult's microbiota is established.

Genitourinary Tract

The upper genitourinary tract (kidneys, ureters, and urinary bladder) is usually free of microorganisms. In both the male and female, a few bacteria (*Staphylococcus epidermidis, Enterococcus faecalis,* and *Corynebacterium* spp.) usually are present in the distal portion of the urethra. *Neisseria* and some members of the *Enterobacteriaceae* are occasionally found.

In contrast, the adult female genital tract, because of its large surface area and mucous secretions, has a complex microbiota that constantly changes with the female's menstrual cycle. The major microorganisms are the acid-tolerant lactobacilli, primarily *Lactobacillus acidophilus,* often called Döderlein's bacilli. They ferment the glycogen produced by the vaginal epithelium, forming lactic acid. As a result the pH of the vagina and cervix is maintained between 4.4 and 4.6.

1. What are the most common microorganisms found in the nose? The oropharynx? The nasopharynx? The tonsillar crypts? The lower respiratory tract? The mouth? The eye? The external ear? The stomach? The small intestine? The colon? The genitourinary tract?
2. Why is the colon considered a large fermentation vessel?
3. What physiological processes move the microbiota through the gastrointestinal tract?
4. How do the initial microbial colonizers of breast-fed infants differ from those of bottle-fed infants?
5. Describe the microbiota of the upper and lower female genitourinary tract.

The Relationship between Normal Microbiota and the Host

The interaction between a host and a microorganism is a dynamic process in which each protagonist acts to maximize its survival. In some instances, after a microorganism enters or contacts a host, a positive mutually beneficial relationship occurs that becomes integral to the health of the host. These microorganisms become the normal microbiota. In other instances, the microorganism produces or induces deleterious effects on in the host; the end result may be disease or even death of the host (*see chapter 34*).

Our environment is teeming with microorganisms and we come in contact with many of them every day. Some of these microorganisms are pathogenic—that is, they cause disease. Yet these pathogens are at times prevented from causing disease by the competition provided by the normal microbiota. In general, the normal microbiota use space, resources, nutrients, and may produce chemicals that repel invading pathogens. These normal microbiota prevent colonization of pathogens and possible disease through "bacterial interference." For instance, the lactobacilli in the female genital tract maintain a low pH and inhibit colonization by pathogenic bacteria, and the corynebacteria on the skin produce fatty acids that inhibit colonization by pathogenic bacteria. This is an excellent example of amensalism (*see p. 609*).

Although normal microbiota offer some protection from invading pathogens, they may themselves become pathogenic and produce disease under certain circumstances, and then are termed **opportunistic microorganisms** or **pathogens.** These opportunistic microorganisms are adapted to the noninvasive mode of life defined by the limitations of the environment in which they are living. If removed from these environmental restrictions and introduced into the bloodstream or tissues, disease can result. For example, streptococci of the viridans group are the most common resident bacteria of the upper respiratory tract. If large numbers of them are introduced into the bloodstream (e.g., following tooth extraction or a tonsillectomy), they may settle on deformed or prosthetic heart valves and cause endocarditis.

Opportunistic microorganisms often cause disease in compromised hosts. A **compromised host** is seriously debilitated and has a lowered resistance to infection. There are many causes of this condition including malnutrition, alcoholism, cancer, diabetes, leukemia, another infectious disease, trauma from surgery or an injury, an altered normal microbiota from the prolonged use of antibiotics, and immunosuppression by various factors (e.g., drugs, viruses [HIV], hormones, and genetic deficiencies). For example, *Bacteroides* species are the most common residents in the large intestine (figure 31.2) and are quite harmless in that location. If introduced into the peritoneal cavity or into the pelvic tissue as a result of trauma, they cause suppuration (the formation of pus) and bacteremia (the presence of bacteria in the blood). Many other examples of opportunistic infections will be presented in chapters 38, 39, and 40. The important point here is that the normal microbiota are harmless and may be beneficial in their normal location in the host and in the absence of coincident abnormalities. However, they can produce disease if introduced into foreign locations or compromised hosts.

1. Give one example of the normal microbiota benefitting a host.
2. Provide two examples of how the normal host microbiota prevent the establishment of a pathogen.
3. How would you define an opportunistic microorganism or pathogen? A compromised host?

31.3 Overview of Host Resistance

To establish an infection, the pathogenic microorganism must first overcome many surface barriers, such as enzymes and mucus, that are either directly antimicrobial or inhibit attachment of the microorganism to the host (section 31.5). Because neither the surface of the skin nor the mucus-lined body cavities are ideal environments for many microorganisms, some pathogens must breach these barriers and get to underlying tissues. Any microorganism that penetrates these barriers encounters the two levels of resistance: other nonspecific resistance mechanisms and the specific immune response.

Vertebrates (including humans) are continuously exposed to microorganisms and their metabolic products that can cause disease. Fortunately these animals are equipped with an immune sys-

tem that protects them against adverse consequences of this exposure. The **immune system** is composed of widely distributed cells, tissues, and organs that recognize foreign substances and microorganisms and act to neutralize or destroy them. **Immunity** [Latin *immunis,* free of burden] refers to the general ability of a host to resist a particular infection or disease. **Immunology** is the science that is concerned with immune responses to the foreign challenge and how these responses are used to resist infection. It includes the distinction between "self" and "nonself" and all the biological, chemical, and physical aspects of the immune response.

There are two fundamentally different types of immune responses to invading microorganisms and foreign material. The **nonspecific immune response** is also known as **nonspecific resistance** and **innate** or **natural immunity;** it offers resistance to any microorganism or foreign material encountered by the vertebrate host. It includes general mechanisms inherited as part of the innate structure and function of each animal, and acts as a first line of defense. The nonspecific immune response lacks immunological memory—that is, nonspecific responses occur to the same extent each time a microorganism or foreign body is encountered.

In contrast, the **specific immune responses** also known as **acquired** or **specific immunity** resist a particular foreign agent; moreover, specific immune responses improve on repeated exposure to foreign agents such as viruses, bacteria, and toxins. Substances that are recognized as foreign and provoke immune responses are called antigens. The antigens cause specific cells to produce proteins called antibodies. Antibodies bind to and inactivate a specific antigen. Other cells destroy virus-infected cells. The nonspecific and specific responses usually work together to eliminate pathogenic microorganisms and other foreign agents.

Section 31.4 provides an overview of the participants in the immune system, and section 31.5 describes the nonspecific immune responses. The specific immune response will be covered in chapter 32.

1. Define each of the following terms: immune system, immunity, immunology, antigen, antibody.
2. Briefly describe the nonspecific immune response. What are some of its characteristics?
3. Briefly describe the specific immune response. What are some of its characteristics?

31.4 Cells, Tissues, and Organs of the Immune System

The immune system is an organization of cells, tissues, organs, and molecules with specialized roles in defending against viruses, microorganisms, cancer cells, and nonself proteins (e.g., organ transplants). Immune system cells and tissue will now be considered.

Cells of the Immune System

The cells responsible for both nonspecific and specific immunity are the white blood cells called **leukocytes**. [Greek *leukos,* white, and *kytos,* cell]. All of the leukocytes originate from pluripotent stem cells in the fetal liver and in the bone marrow of the animal host (**figure 31.3**), from which they migrate to other body sites, undergo further development, and perform their various functions. These cells of the immune system are present throughout the host's body. Some become residents within tissues, where they respond to local trauma and sound the alarm; others circulate in body fluids and are recruited to the sites of infection. In defending the host against pathogenic microorganisms, leukocytes cooperate with each other first to recognize the pathogen as an invader and then to destroy it. These different leukocytes are now briefly examined.

Lymphoid Cells

Lymphocytes [Latin *lympha,* water, and *cyte,* cell] are the major cells of the specific immune system. Lymphocytes can be divided into three populations: T cells, B cells, and natural killer cells. **B cells** or **B lymphocytes** reach maturity within the bone marrow, circulate in the blood, and also settle in various lymphoid organs. **T cells** or **T lymphocytes** mature in the thymus gland; they can remain in the thymus, circulate in the blood, or reside in lymphoid organs such as the lymph nodes and spleen. B cells and T cells will be discussed further in chapter 32 along with their roles in specific immunity. Natural killer cells are important in killing cells infected with either viruses or intracellular bacteria and destroying cancer cells (section 31.10).

Mononuclear Cells

There are two types of mononuclear (i.e., a single large nucleus) cells—monocytes and macrophages. Both types are highly phagocytic and make up the **monocyte-macrophage system** (**figure 31.4**). Recall (*see figure 4.10*) that during phagocytosis large particles and even other microorganisms are engulfed and enclosed in a phagocytic vacuole or phagosome.

Monocytes [Greek *monos,* single, and *cyte,* cell] are mononuclear phagocytic leukocytes with an ovoid or kidney-shaped nucleus and granules in the cytoplasm that stain gray-blue (figure 31.3). They are produced in the bone marrow and enter the blood, circulate for about eight hours, enlarge, migrate to the tissues, and mature into macrophages.

As just noted, **macrophages** [Greek *macros,* large, and *phagein,* to eat] are derived from monocytes and are also classified as mononuclear phagocytic leukocytes. However, they may be larger than monocytes, contain more organelles (especially lysosomes and phagolysosomes), and have a plasma membrane covered with ruffles or microvilli (**figure 31.5**). Macrophages have receptors for antibodies and complement; these can coat microorganisms or foreign material and enhance phagocytosis. This enhancement is termed opsonization. Macrophages spread throughout the animal body and take up residence in specific tissues where they are given special names (figure 31.4). Since macrophages are highly phagocytic, their function in nonspecific resistance will be discussed in more detail in the context of phagocytosis.

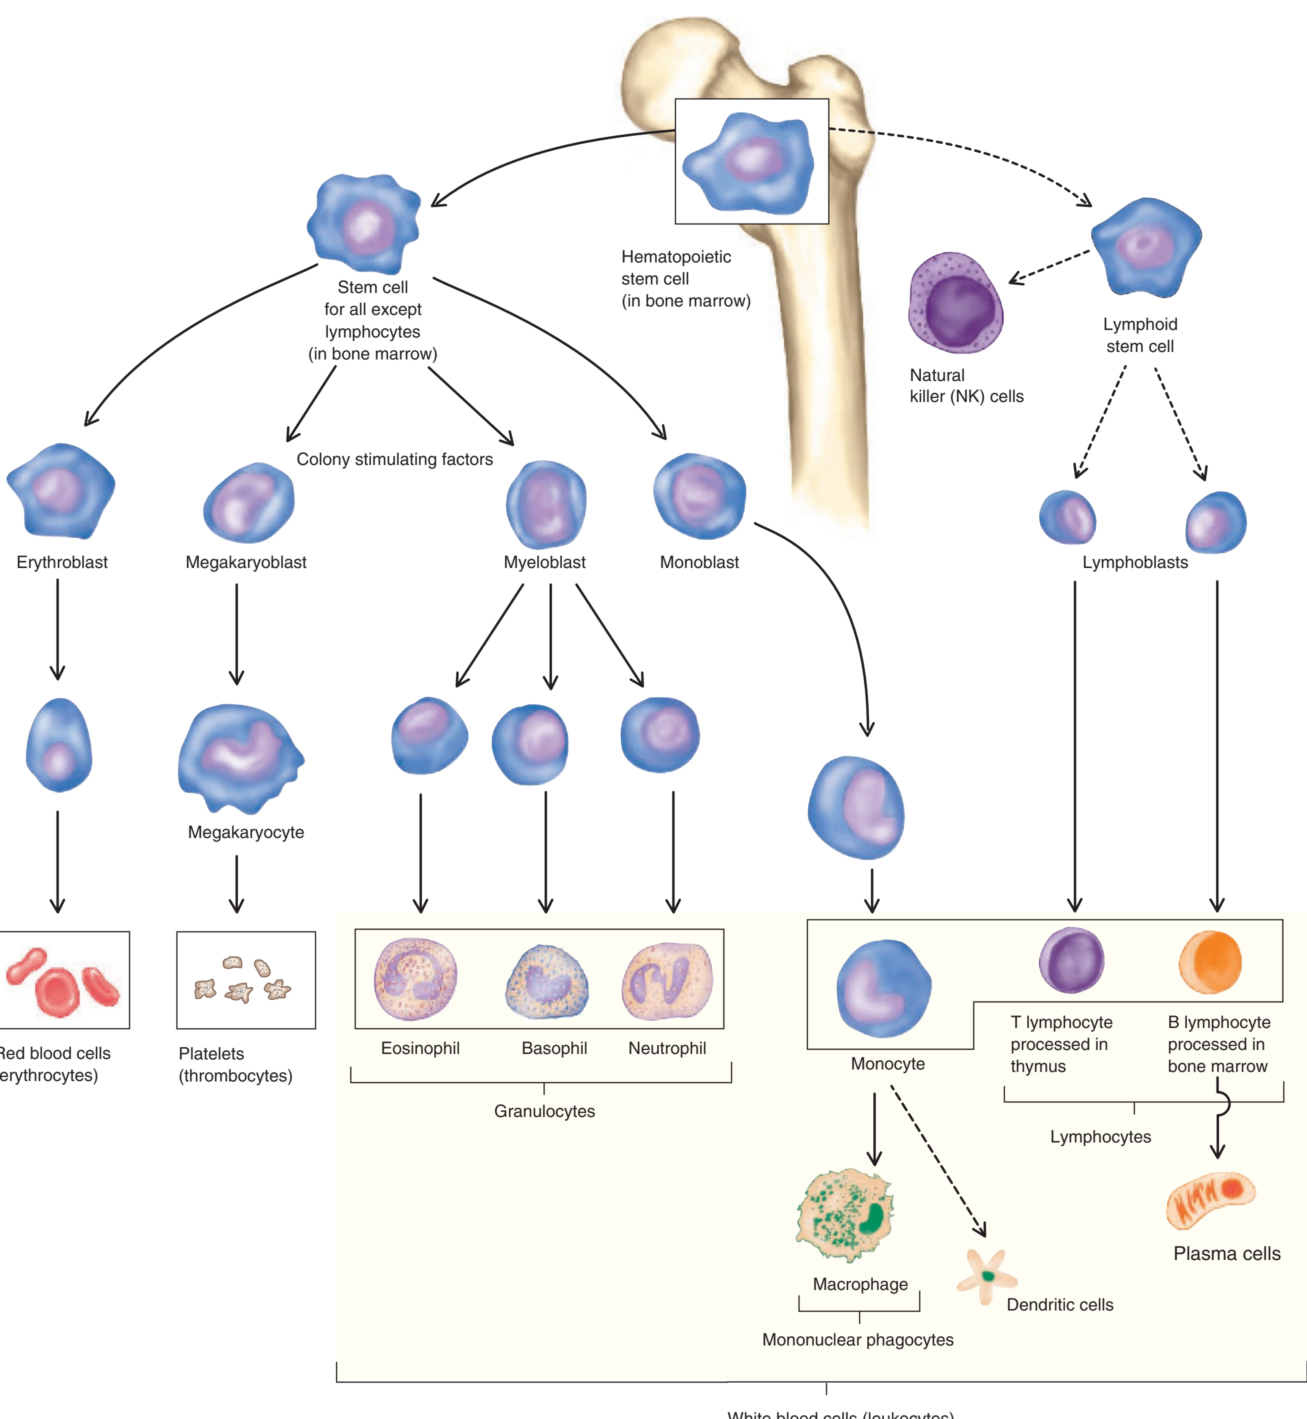

Figure 31.3 The Different Types of Human Blood Cells. Pluripotent stem cells in the bone marrow divide to form two lineages: (1) the lymphoid stem cell gives rise to B cells that become antibody-secreting plasma cells, T cells that become activated T cells, and natural killer cells. (2) The common myeloid progenitor cell gives rise to the granulocytes (neutrophils, eosinophils, basophils), monocytes that give rise to macrophages and dendritic cells, an unknown precursor that gives rise to mast cells, megakaryocytes that produce platelets, and the erythroblast that produces erythrocytes (red blood cells). The dashed lines indicate steps that have not been very well studied.

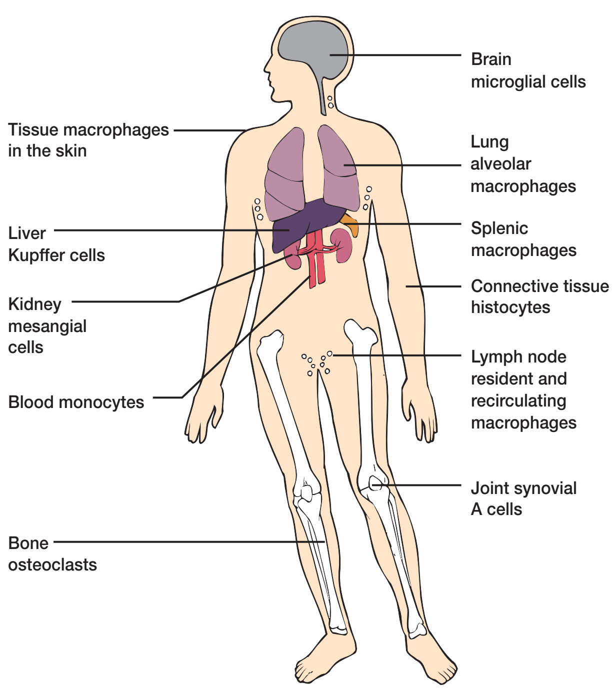

Figure 31.4 **The Monocyte-Macrophage System.** This system consists of tissue (such as found within the liver, spleen, and lymph nodes) containing "fixed" or immobile phagocytes that have specific names depending on their location.

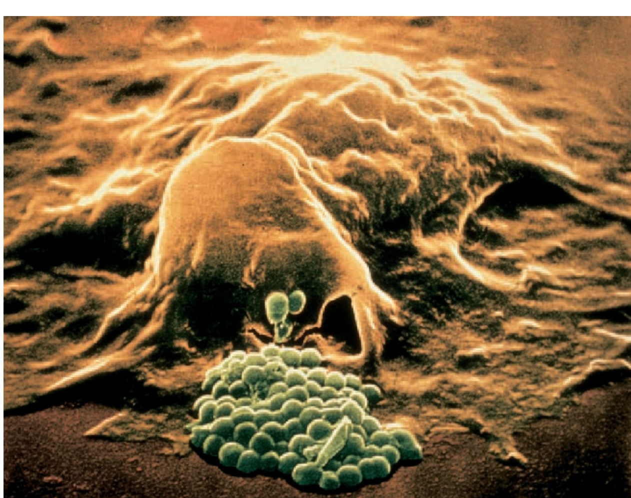

Figure 31.5. **Phagocytosis by a Macrophage.** One type of nonspecific host resistance involves white blood cells called macrophages and the process of phagocytosis. This scanning electron micrograph (×3,000) shows a macrophage devouring a colony of bacteria. Phagocytosis is but one of many nonspecific defenses humans and other animals have to combat microbial pathogens.

Granulocytes

Granulocytes have irregular-shaped nuclei with two to five lobes, and the cytoplasmic matrix has granules (figure 31.3) that contain reactive substances that kill microorganisms and enhance inflammation. Because of the irregular-shaped nuclei, granulocytes are also called **polymorphonuclear leukocytes** or **PMNs.** Three types of granulocytes exist: basophils, eosinophils, and neutrophils.

Basophils [Greek *basis,* base, and *philein,* to love] have an irregular-shaped nucleus with two lobes, and the granules stain bluish-black with basic dyes. Basophils are nonphagocytic cells that function by releasing histamine, prostaglandins, serotonin, and leukotrienes from their granules upon appropriate stimulation. Because these physiological mediators influence the tone and diameter of blood vessels, they are termed vasoactive agents. Basophils (and mast cells) possess high-affinity receptors for an immunoglobulin (IgE; *see figure 32.14*) and thereby become coated with IgE antibodies. Once coated, antigens can trigger the cell to secrete vasoactive mediators. These inflammatory mediators play a major role in certain allergic responses such as eczema, hay fever, and asthma.

Eosinophils [Greek *eos,* dawn, and *philien*] have a two-lobed nucleus connected by a slender thread of chromatin, and the granules stain red with acidic dyes. Unlike basophils, eosinophils are mobile cells that can migrate from the bloodstream into tissue spaces. Their role is important only in the defense against protozoan and helminth parasites, mainly by releasing cationic proteins and reactive oxygen metabolites into the extracellular fluid to damage the parasite's plasma membranes.

Neutrophils [Latin *neuter,* neither, and *philien*] stain readily at a neutral pH, have a nucleus with three to five lobes connected by slender threads of chromatin, and contain fine primary and secondary inconspicuous granules. Like macrophages, neutrophils have receptors for antibodies and complement proteins and are highly phagocytic cells. However, unlike the macrophage, neutrophils do not reside in healthy tissue but rapidly migrate to the site of tissue damage and infection where they are the principal phagocytic and microbicidal cells. The lytic enzymes and bactericidal substances in neutrophils are contained within large primary and smaller secondary granules. Primary granules contain peroxidase, lysozyme, and various hydrolytic enzymes, whereas secondary granules have collagenase, lactoferrin, and lysozyme. Both of these granules help accomplish intracellular digestion. Neutrophils also use oxygen-dependent and oxygen-independent pathways that generate antimicrobial substances and defensins to kill ingested microorganisms (section 31.8). Neutrophils are described in more detail in the contexts of the inflammatory response and phagocytosis.

Mast Cells

Mast cells are bone marrow–derived cells found in connective tissue. They contain granules with histamine and other pharmacologically active substances that contribute to the inflammatory

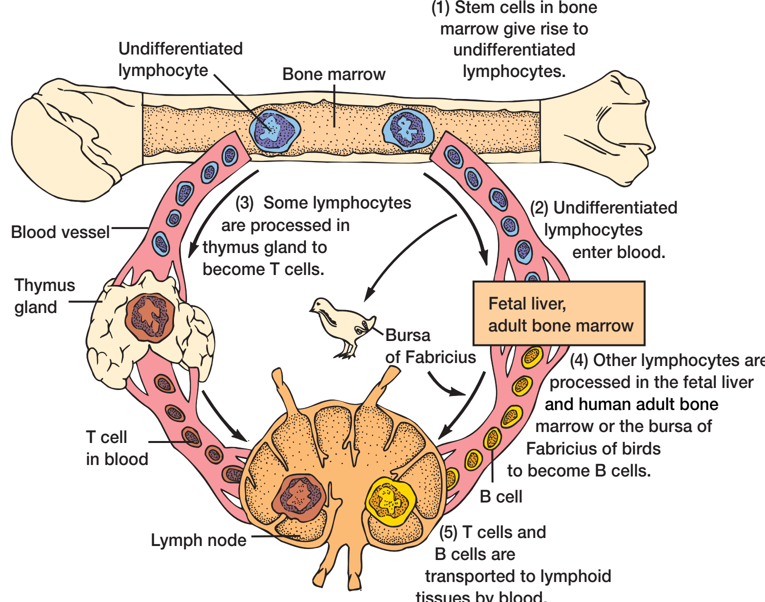

Figure 31.6 Schematic Representation of Lymphocyte Development. Bone marrow releases undifferentiated lymphocytes, which, after processing, become T and B cells.

response. Mast cells, along with basophils, play an important role in the development of allergies and hypersensitivities (*see section 33.2*).

Dendritic Cells

Dendritic cells (chapter opener figure, p. 697) can recognize specific pathogen-associated molecular patterns on microorganisms and play an important role in nonspecific resistance. They can differentiate between potentially harmful microorganisms and "self" molecules. After the pathogen is recognized, it binds to the dendritic cell's pattern recognition receptors and then is phagocytosed. These cells are also stimulated by endogenous activators such as interferon-α, heat-shock proteins, and tumor necrosis factor that are released in response to microbial infection. After stimulation, dendritic cells migrate to the bloodstream or lymphatic system and present antigens to T cells. Thus dendritic cells also play an important role in the specific immune response.

Organs and Tissues of the Immune System

Based on function, the organs and tissues of the immune system can be divided into primary or secondary lymphoid organs or tissues. The primary organs or tissues are where immature lymphocytes mature and differentiate into antigen-sensitive mature B and T cells. The thymus is the primary lymphoid organ and bone marrow is the primary lymphoid tissue. The secondary organs and tissues serve as areas where lymphocytes may encounter and bind antigen, whereupon they proliferate and differentiate into fully mature, antigen-specific effector cells. The spleen is a secondary lymphoid organ and the lymph nodes and mucosal-associated tissues (GALT, gut-associated lymphoid tissue and SALT, skin-associated lymphoid tissues) are the secondary lymphoid tissues. The thymus, bone marrow, lymph nodes, and spleen will now be discussed in more detail. GALT and SALT are described in section 31.5 under physical and mechanical barriers.

Primary Lymphoid Organs and Tissues

Immature undifferentiated lymphocytes are generated in the bone marrow, and mature and become committed to a particular antigenic specificity within the primary lymphoid organ/tissues. The two most important of these in mammals are the thymus and bone marrow.

The **thymus** is a lymphoid organ located above the heart. Precursor cells from the bone marrow migrate into the thymus to the outer cortex where they proliferate. As they mature and acquire T-cell surface markers, they move to the inner cortex where approximately 90% die, possibly as part of the acquisition of immune tolerance (*see section 32.8*). The other 10% move into the medulla, become mature T cells, and enter the bloodstream (**figure 31.6**).

In birds, undifferentiated lymphocytes move from the bone marrow to the **bursa of Fabricius** where B cells mature. In mammals, the bone marrow is the site of B-cell maturation. Like thymic selection during T-cell maturation, a selection process within the bone marrow eliminates B cells with self-reactive antibody receptors (the acquisition of tolerance).

Secondary Lymphoid Organ/Tissue

The spleen is the most highly organized secondary lymphoid organ and the lymph nodes the most highly organized tissue.

The **spleen** is the large secondary lymphoid organ located in the abdominal cavity. Whereas lymph nodes are specialized for trapping microorganisms and antigens from local tissues, the spleen specializes in filtering the blood and trapping blood-borne microorganisms

and antigens. Once trapped by macrophages and dendritic cells, the pathogen is phagocytosed and antigens are presented to B and T cells, which become activated to carry out their immune functions.

Lymph nodes lie at the junctions of lymphatic vessels where they filter out harmful microorganisms and antigens from the lymph; pathogens and antigens are trapped by phagocytic and dendritic cells. Fixed macrophages then phagocytose the foreign material. It is within the lymph nodes that B cells proliferate into antibody-secreting **plasma cells.** Dendritic and T cells are also found here; dendritic cells serve as antigen-presenting cells and T helper cells promote the B-cell immune response.

1. Describe the structure and function of each of the following blood cells: monocytes, macrophages, basophils, eosinophils, neutrophils, mast cells, and dendritic cells.
2. Briefly describe each of the primary lymphoid organs and tissues.
3. What is the function of the spleen? A lymph node? The thymus?

31.5 Physical and Chemical Barriers in Nonspecific Resistance

With few exceptions a potential microbial pathogen invading a human host immediately confronts a vast array of nonspecific defense mechanisms (**figure 31.7**). Although the effectiveness of some mechanisms is not great, collectively their defense is formidable.

Many direct factors (nutrition, physiology, fever, age, genetics) and equally as many indirect factors (personal hygiene, socioeconomic status, living conditions) influence all host-microbe relationships. At times they favor the establishment of the microorganism; at other times they provide some measure of defense to the host. For example, when the host is either very young or very old, susceptibility to infection increases. Babies are at a particular risk after their maternal immunity has disappeared and before their own immune system has matured. In very old persons there is a decline in the immune system and in the homeostatic functioning of many organs that reduces host defenses. In addition to these direct and indirect factors, a vertebrate host has some very specific physical and mechanical barriers.

Physical and Mechanical Barriers

Physical or mechanical barriers, along with the host's secretions (flushing mechanisms), are the first line of defense against microorganisms. Protection of the most important body surfaces by these mechanisms is discussed next.

Skin

The intact skin contributes greatly to nonspecific host resistance. It forms a very effective mechanical barrier to microbial invasion. There are several reasons for this:

1. Few microorganisms can penetrate the skin because its outer layer consists of thick, closely packed cells called **keratinocytes.** These cells produce keratins. Keratins are scleroproteins comprising the main components of hair, nails, and outer skin cells that microorganisms cannot enzymatically attack. Keratinocytes also secrete a number of specialized proteins that produce inflammation.
2. Continuous shedding of the outer epithelial cells removes many of those microorganisms that do manage to adhere.
3. Relative dryness of the skin slows microbial growth.
4. Mild acidity (pH 5 to 6, due to the breakdown of lipids into fatty acids by means of the normal skin microbiota [figure 31.2]) inhibits the growth of many microorganisms.
5. The normal skin microbiota acts antagonistically against many pathogens; it also occupies attachment sites and competes for nutrients.
6. Sebum liberated from the oil (sebaceous) glands forms a protective film over the surface of the skin.
7. Normal washing by humans continually removes microorganisms.

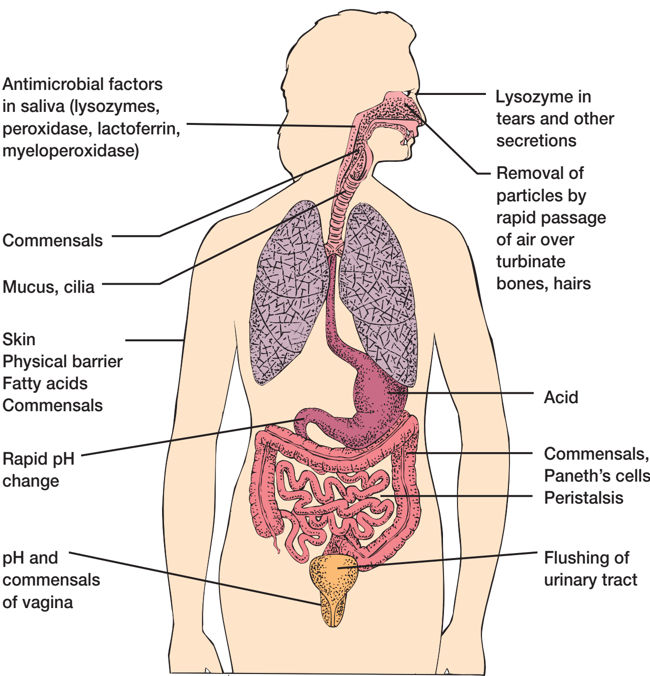

Figure 31.7 Host Defenses. Some nonspecific host defense mechanisms that help prevent entry of microorganisms into the host's tissues.

Despite these defenses, at times some pathogenic microorganisms gain access to the tissue under the skin. Here they encounter a specialized set of cells called the ***s*kin-*a*ssociated *l*ymphoid *t*issue (SALT).** The major function of SALT is to confine microbial invaders to the area immediately underlying the skin and to prevent them from gaining access to the bloodstream.

One type of SALT cell is the **Langerhans cell,** a specialized dendritic cell that can phagocytose antigens. Once the Langerhans

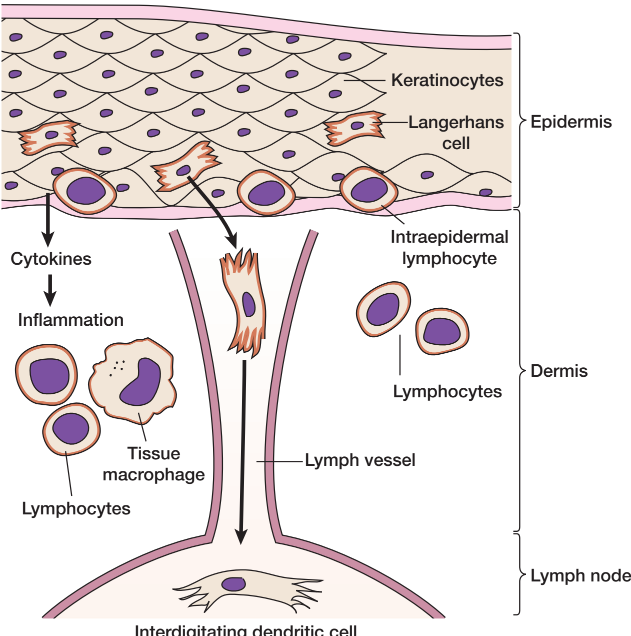

Figure 31.8 Skin-Associated Lymphoid Tissue. Keratinocytes make up 90% of the epidermis. They are capable of secreting cytokines that cause an inflammatory response to invading pathogens. Langerhans cells internalize antigen and move it to a lymph node where they differentiate into interdigitating dendritic cells that present antigen to helper T cells. The intraepidermal lymphocytes can function as T cells.

cell has internalized the antigen, it migrates from the epidermis to nearby lymph nodes where the cell differentiates into a specialized cell called the **interdigitating dendritic cell.** This cell can present the antigen on its surface and activate nearby T cells that destroy the antigen (**figure 31.8**).

The epidermis also contains another type of SALT cell called the **intraepidermal lymphocyte** (figure 31.8). These cells are strategically located in the skin so that they can intercept any antigens that breach the first line of defense. These specialized SALT cells function as T cells to destroy the antigen. A large number of tissue macrophages (figure 31.4) are also located in the dermal layer of the skin and phagocytose (figure 31.5) most microorganisms they encounter.

Mucous Membranes

The mucous membranes of the eye (conjunctiva), respiratory, digestive, and urogenital systems withstand microbial invasion because the intact stratified squamous epithelium and mucous secretions form a protective covering that resists penetration and traps many microorganisms. This mechanism contributes to nonspecific immunity. Furthermore, many mucosal surfaces are bathed in specific antimicrobial secretions. For example, cervical mucus, prostatic fluid, and tears are toxic to many bacteria. One antibacterial substance is **lysozyme** (muramidase), an enzyme that lyses bacteria by hydrolyzing the β(1→4) bond connecting *N*-acetylmuramic acid and *N*-acetylglucosamine in the bacterial cell wall peptidoglycan (*see figures 3.16–3.19*)—especially in gram-positive bacteria (**figure 31.9**). These mucous secretions also contain specific immune proteins that help prevent the attachment of microorganisms and significant amounts of iron-binding lactoferrin. **Lactoferrin** is released by activated macrophages and PMNs. It sequesters iron from the plasma. This sequestration reduces the amount of iron available to invading microbial pathogens and limits their ability to multiply. Finally, mucous membranes produce lactoperoxidase, an enzyme that produces superoxide radicals (*see p. 128*), a reactive form of oxygen that is toxic to many microorganisms.

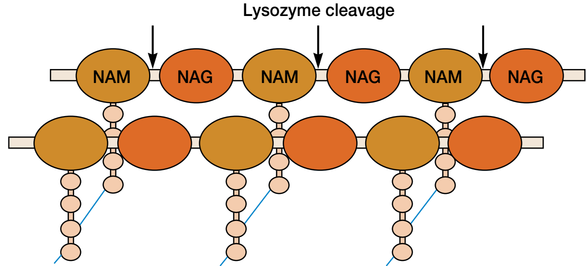

Figure 31.9 Action of Lysozyme on the Cell Wall of Gram-Positive Bacteria. In the structure of the cell wall peptidoglycan backbone, the β (1→4) bonds connect alternating *N*-acetylglucosamine (NAG) and N-acetylmuramic acid (NAM) residues. The chains are cross-linked through the tetrapeptide side chains. Lysozyme splits the molecule at the places indicated by the arrows.

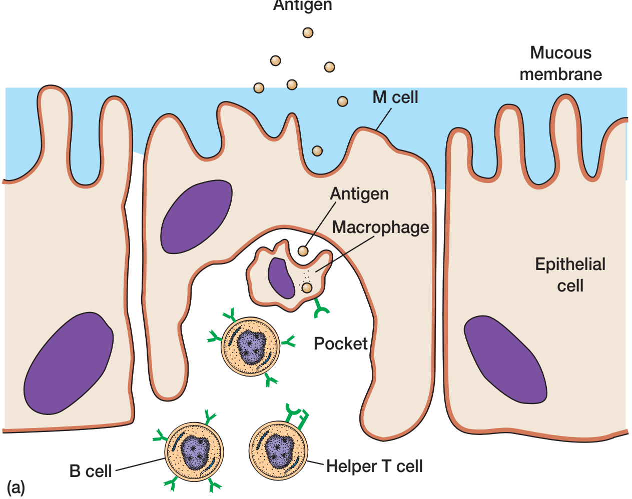
Like the skin, mucous membranes also have a specialized immune barrier called ***m*ucosal-*a*ssociated *l*ymphoid *t*issue (MALT).** There are several types of MALT. The system most studied is the **gut-*a*ssociated *l*ymphoid *t*issue (GALT).** GALT includes the tonsils, adenoids, and Peyer's patches in the intestine. Less well-organized mucosal-associated lymphoid tissue also occurs in the respiratory system and is called ***b*ronchial-*a*ssociated *l*ymphoid *t*issue (BALT);** the diffuse MALT in the urogenital system does not have a specific name.

MALT can operate by two basic mechanisms. First, when an antigen arrives at the mucosal surface, it contacts a type of cell called the **M cell** (**figure 31.10*a***). The M cell does not have the brush border or microvilli found on adjacent columnar epithelial cells but does have a large pocket containing B cells, T cells, and macrophages. When an antigen contacts the M cell, it is phagocytosed and released into the pocket. Macrophages engulf the antigen or pathogen and try to destroy it. An M cell also can phagocytose an antigen and transport it to a cluster of cells called an organized lymphoid follicle (figure 31.10*b*). The B cells within this follicle recognize the antigen and mature into plasma cells. The plasma cells leave the follicle and secrete a class of antibody called secretory IgA. sIgA is then transported into the lumen of the gut where it interacts with the antigen that caused its production.



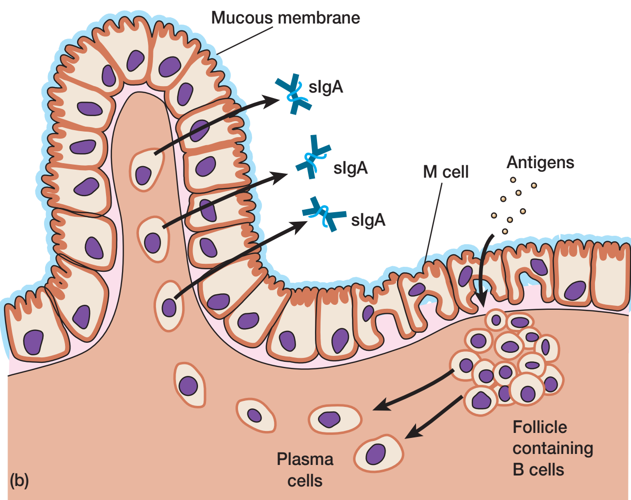


Figure 31.10 Function of M Cells in Mucosal-Associated Immunity. (**a**) Structure of an M cell located between two epithelial cells in a mucous membrane. The M cell endocytoses the pathogen and releases it into the pocket containing helper T cells, B cells, and macrophages. It is within the pocket that the pathogen often is destroyed (**b**) The antigen is transported by the M cell to the organized lymphoid follicle containing B cells. The activated B cells mature into plasma cells, which produce secretory IgA and release it into the lumen where it reacts with the antigen that caused its production.

1. Why is the skin such a good first line of defense against pathogenic microorganisms?
2. How do intact mucous membranes resist microbial invasion of the host?
3. How do M cells function in MALT?
4. Describe SALT function in the immune response.

Respiratory System

The mammalian respiratory system has formidable defense mechanisms. The average person inhales at least eight microorganisms a minute, or 10,000 each day. Once inhaled, a microorganism must first survive and penetrate the air filtration system of the upper and lower respiratory tracts. Because the airflow in these tracts is very turbulent, microorganisms are deposited on the moist, sticky mucosal surfaces. The cilia in the nasal cavity beat toward the pharynx, so that mucus with its trapped microorganisms is moved toward the mouth and expelled. Humidification of the air within the nasal cavity causes many hygroscopic microorganisms to swell and aids the phagocytic process.

The **mucociliary blanket** of the respiratory epithelium traps microorganisms less than 10 μm in diameter that are deposited on the mucosal surface and transports them by ciliary action away from the lungs. Microorganisms larger than 10 μm usually are trapped by hairs and cilia lining the nasal cavity. Coughing and sneezing reflexes clear the respiratory system of microorganisms by expelling air forcefully from the lungs through the mouth and nose, respectively. Salivation also washes microorganisms from the mouth and nasopharyngeal areas into the stomach. Microorganisms that succeed in reaching the alveoli of the lungs encounter a population of fixed phagocytic cells called **alveolar macrophages** (figure 31.4). These cells can ingest and kill most bacteria by phagocytosis.

Gastrointestinal Tract

Once microorganisms reach the stomach, many are killed by its gastric juice (a mixture of hydrochloric acid, proteolytic enzymes, and mucus). The very high acidity of gastric juice (pH 2 to 3) is usually sufficient to destroy most organisms and their toxins, although exceptions exist (protozoan cysts, *Clostridium* and *Staphylococcus* toxins). However, many organisms are protected by food particles and reach the small intestine.

Once in the small intestine, microorganisms often are damaged by various pancreatic enzymes, bile, enzymes in intestinal secretions, and the GALT system. **Peristalsis** [Greek *peri,* around, and *stalsis,* contraction] and the normal loss of columnar epithelial cells act in concert to purge intestinal microorganisms. In addition, the normal microbiota of the large intestine (figure 31.2) is extremely important in preventing the establishment of pathogenic organisms. For example, many normal commensals in the intestinal tract produce metabolic products, such as fatty acids, that prevent “unwanted” microorganisms from becoming established. Other normal microbiota take up attachment sites and compete for nutrients.

The mucous membranes of the intestinal tract contain cells called **Paneth cells.** These cells produce lysozyme (figure 31.9) and a set of peptides called **cryptins.** Cryptins are toxic for some bacteria, although their mode of action is not known.

Genitourinary Tract

Under normal circumstances the kidneys, ureters, and urinary bladder of mammals are sterile. Urine within the urinary bladder also is sterile. However, in both the male and female, a few bacteria are usually present in the distal portion of the urethra (figure 31.2).

The factors responsible for this sterility are complex. For example, urine kills some bacteria due to its low pH and the presence of urea and other metabolic end products (uric acid, hippuric acid, indican, fatty acids, mucin, enzymes). The kidney medulla is so hypertonic that few organisms can survive. The lower urinary tract is flushed with urine and some mucus 4 to 10 times each day, eliminating potential pathogens. In males the anatomical length of the urethra (20 cm) provides a distance barrier that excludes microorganisms from the urinary bladder. Conversely the short urethra (5 cm) in females is more readily traversed by microorganisms; this explains why general urinary tract infections are 14 times more common in females than in males.

The vagina has another unique defense. Under the influence of estrogens, the vaginal epithelium produces increased amounts of glycogen that acid-tolerant *Lactobacillus acidophilus* bacteria called Döderlein's bacilli degrade to form lactic acid. Normal vaginal secretions contain up to 10^8 Döderlein's bacilli per ml. Thus an acidic environment (pH 3 to 5) unfavorable to most organisms is established. Cervical mucus also has some antibacterial activity.

The Eye

The conjunctiva is a specialized mucus-secreting epithelial membrane that lines the interior surface of each eyelid and the exposed surface of the eyeball. It is kept moist by the continuous flushing action of tears (lacrimal fluid) from the lacrimal glands. Tears contain large amounts of lysozyme, lactoferrin, and sIgA (*see p. 738*) and thus provide chemical as well as physical protection.

1. Describe the different antimicrobial defense mechanisms that operate within the respiratory system of mammals.
2. What factors operate within the gastrointestinal system that help prevent the establishment of pathogenic microorganisms?
3. Except for the anterior portion of the urethra, why is the genitourinary tract a sterile environment?

Chemical Barriers

Mammalian hosts have a chemical arsenal with which to combat the continuous onslaught of microorganisms. Some of these chemicals (gastric juices, salivary glycoproteins, lysozyme, oleic acid on the skin, urea) have already been discussed with respect to the specific body site(s) they protect. In addition, blood, lymph, and other body fluids contain a potpourri of defensive chemicals such as bacteriocins, beta-lysin, and other polypeptides.

Bacteriocins

As previously noted, the first line of defense against microorganisms is the host's anatomical barrier, consisting of the skin and mucous membranes. These surfaces are colonized by normal microbiota, which by themselves provide a biological barrier against uncontrolled proliferation of foreign microorganisms. Many of these normal bacteria synthesize and release plasmid-encoded toxic proteins (e.g., colicin, staphylococcin) called **bacteriocins** that are lethal to related species. Bacteriocins may give their producers an adaptive advantage against other bacteria. Sometimes they may increase bacterial virulence by damaging host cells such as mononuclear phagocytes.

Most bacteriocins that have been identified are peptides or proteins and are produced by gram-negative bacteria. (However, recently it has been discovered that some gram-positive bacteria produce bacteriocin-like peptides). For example, *E. coli* synthesizes bacteriocins called **colicins,** which are coded for by several different plasmids (ColB, ColE1, ColE2, ColI, and ColV). Some colicins bind to specific receptors on the cell envelope of sensitive target bacteria and cause cell lysis, attack specific intracellular sites such as ribosomes, or disrupt energy production. It is now widely recognized that these antimicrobial peptides act as defensive effector molecules in the large intestine.

Beta-Lysin and Other Polypeptides

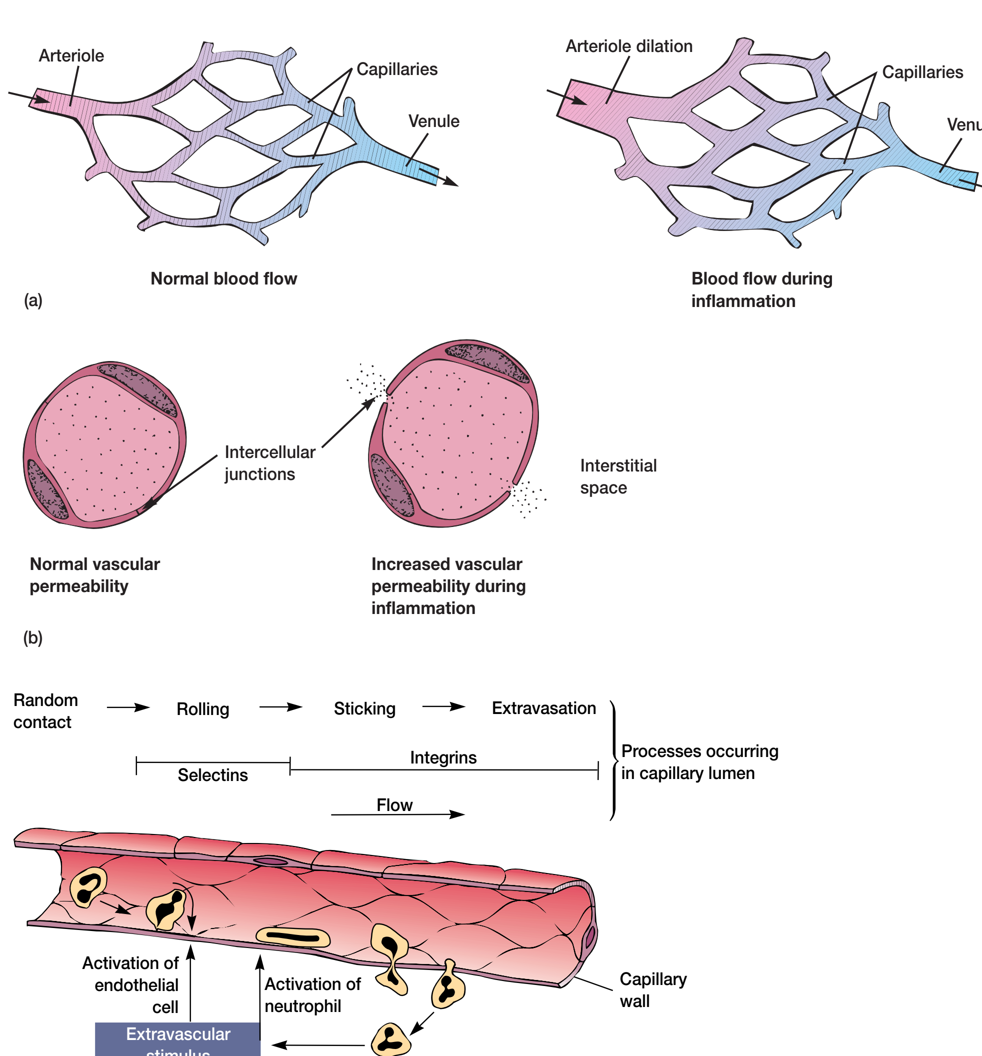
Beta-lysin is a cationic polypeptide released from blood platelets; it can kill some gram-positive bacteria by disrupting their plasma membranes. Other cationic polypeptides include leukins, plakins, cecropins, and phagocytin. A zinc-containing polypeptide, known as the prostatic antibacterial factor, is an important antimicrobial substance secreted by the prostate gland in males.

1. How does beta-lysin function against gram-positive bacteria?
2. How do bacteriocins function?

31.6 Inflammation

Inflammation [Latin, *inflammatio,* to set on fire] is an important nonspecific defense reaction to tissue injury, such as that caused by a pathogen or wound. Acute inflammation is the immediate response of the body to injury or cell death. The gross features were described over 2,000 years ago and are still known as the cardinal signs of inflammation. These signs include redness (*rubor*), warmth (*calor)*, pain (*dolor*), swelling (*tumor*), and altered function (*functio laesa*).

The acute inflammatory response begins when injured tissue cells release chemical signals (inflammatory mediators) that activate the inner lining (endothelium) of nearby capillaries (**figure 31.11**). Within the capillaries **selectins** (a family of cell adhesion molecules) are displayed on the activated endothelial cells—first P-selectin and then E-selectin. These adhesion molecules randomly attract and attach neutrophils to the endothelial cells, slow the neutrophils down, and cause them to roll along the endothelium. As the neutrophils (figure 31.3) roll along the endothelium, they encounter the inflammatory mediators that act as activating signals. These signals activate **integrins** (adhesion receptors) on the neutrophils. The neutrophil integrins then tightly attach to endothelial adhesion molecules such as the intracellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1). This causes the



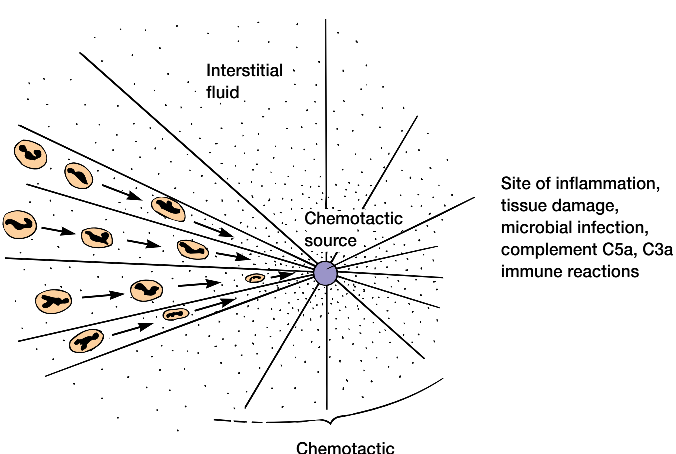


Figure 31.11 Physiological Events of the Acute Inflammatory Response. (**a**) The diameter of the arteriole controls the normal blood flow into a capillary bed. Inflammation causes arteriole dilation and increased blood flow (hyperemia) into the affected tissue. The capillary becomes distended and produces the gross red-purple discoloration of tissue due to an increased blood content. (**b**) The junctions between capillary endothelial cells are sufficiently tight to keep large molecules within the lumen. In inflammation, gaps are created that allow leakage of fluid and large molecules into the interstitial space. The fluid leakage produces swelling (edema). (**c**) Normally leukocytes (such as neutrophils) are carried in the lumen of a capillary. During inflammation selectins and integrins cause leukocytes to adhere to the capillary wall, insert pseudopods between the endothelial cells, and squeeze through (extravasation) by a process called diapedesis. (**d**) After leaving the capillary, the leukocytes are attracted (chemotaxis) to the source of the inflammation by various chemotactic or chemokinetic substances (extravascular stimulus). Once at the infection site, leukocytes phagocytose the microorganisms or dead tissue.

neutrophils to stick to the endothelium and stop rolling. The neutrophils now undergo dramatic shape changes, squeeze through the endothelial wall (extravasation) into the interstitial tissue fluid, migrate to the site of injury, and attack the pathogen or other cause of the tissue damage. Neutrophils and other leukocytes are attracted to the infection site by chemotactic factors or chemotaxins such as substances released by bacteria and mast cells, and tissue breakdown products. Depending on the severity and nature of tissue damage, other types of leukocytes (e.g., lymphocytes, monocytes, and macrophages) may follow the neutrophils.

The inflammatory mediators that are released by the injured tissue cells also raise the acidity in the surrounding extracellular fluid. This decrease in pH activates the extracellular enzyme kallikrein, which splits bradykinin from its long precursor chain. Bradykinin binds to receptors on the capillary wall, opening the junctions between cells and allowing fluid and infection-fighting leukocytes to leave the capillary and enter the infected tissue. Simultaneously bradykinin (**figure 31.12**) binds to mast cells in the connective tissue associated with most small blood vessels. This activates the mast cells by causing an influx of calcium ions, which leads to degranulation and release of preformed mediators such as histamine. If nerves in the infected area are damaged, they release substance P, which also binds to mast cells, boosting preformed-mediator release. Histamine in turn makes the intercellular junctions in the capillary wall wider so that more fluid, leukocytes, kallikrein, and bradykinin precursors move out, causing edema. Bradykinin then binds to nearby capillary cells and stimulates the production of prostaglandins (PGE_2 and $PGF_{2\alpha}$) to promote tissue swelling in the infected area. Prostaglandins also bind to free nerve endings, making them fire and start a pain impulse.

The change in mast cell plasma membrane permeability associated with activation allows phospholipase A2 to release arachidonic acid. Arachidonic acid is then metabolized by the cyclooxygenase or lipoxygenase pathways, depending on mast cell type. The newly synthesized mediators include prostaglandins E_2 and $F_{2\alpha}$, thromboxane A_2, slow-reacting substance (SRS), and leukotrienes ($LTC_4 + LTD_4$). All play various roles in the inflammatory response.

During acute inflammation, the offending pathogen is neutralized and eliminated by a series of events, the most important of which are the following:

1. The increase in blood flow and capillary dilation bring into the area more antimicrobial factors and leukocytes that destroy the pathogen. Dead cells also release antimicrobial factors.
2. The rise in temperature stimulates the inflammatory response and may inhibit microbial growth.
3. A fibrin clot often forms and may limit the spread of the invaders so that they remain localized.
4. Phagocytes collect in the inflamed area and phagocytose the pathogen. In addition, chemicals stimulate the bone marrow to release neutrophils and increase the rate of granulocyte production.

Chronic Inflammation

Chronic inflammation is a slow process characterized by the formation of new connective tissue, and it usually causes permanent tissue damage. Superficially, the difference between acute and chronic inflammation is one of duration. Regardless of the cause, chronic inflammation lasts two weeks or longer. Chronic inflammation can occur as a distinct process without much acute inflammation. The persistence of bacteria by a variety of mechanisms can stimulate chronic inflammation. For example, the mycobacteria have cell walls with a very high lipid and wax content, making them relatively insensitive to phagocytosis. The bacteria that cause tuberculosis, leprosy, and syphilis often survive within the macrophage. In addition, some bacteria produce toxins that stimulate tissue-damaging reactions even after bacterial death.

Chronic inflammation is characterized by a dense infiltration of lymphocytes and macrophages. If the macrophages are unable to protect the host from tissue damage, the body attempts to wall off and isolate the site by forming a **granuloma** [Latin, *granulum,* a small particle; Greek *oma,* to form]. Granulomas are formed when neutrophils and macrophages are unable to destroy the microorganism during inflammation. Infections caused by some bacteria (listeriosis, brucellosis), fungi (histoplasmosis, coccidiodomycosis), helminth parasites (leishmaniasis, schistosomiasis), and large antibody-antigen complexes (rheumatoid arthritis) result in granuloma formation and chronic inflammation.

1. What major events occur during an inflammatory reaction, and how do they contribute to pathogen destruction?
2. What causes degranulation of mast cells?
3. How does chronic inflammation differ from acute inflammation?

31.7 The Complement System

Complement was discovered many years ago as a heat-labile component of human blood plasma that augments opsonization (section 31.8) of bacteria by antibodies and helps other antibodies kill bacteria. This activity was said to "complement" the antibacterial activity of antibody; hence, the name complement. It is now known that the **complement system** is composed of a large number of serum proteins that play a major role in the animal's defensive immune response. For example, complement proteins can lyse antibody-coated eucaryotic cells and bacteria (cytolysis). Complement can mediate inflammation and attract and activate phagocytic cells. Generally, complement proteins amplify the effects of antibodies (e.g., lysis of cells).

The complement cascade is made up of at least 20 complement proteins designated C1 (which has three protein subcomponents) through C9 in addition to Factor B, Factor $\bar{D}$, Factor H, Factor I, C4b binding protein, C1 INH complex, S protein, and

© The McGraw–Hill Companies, 2002

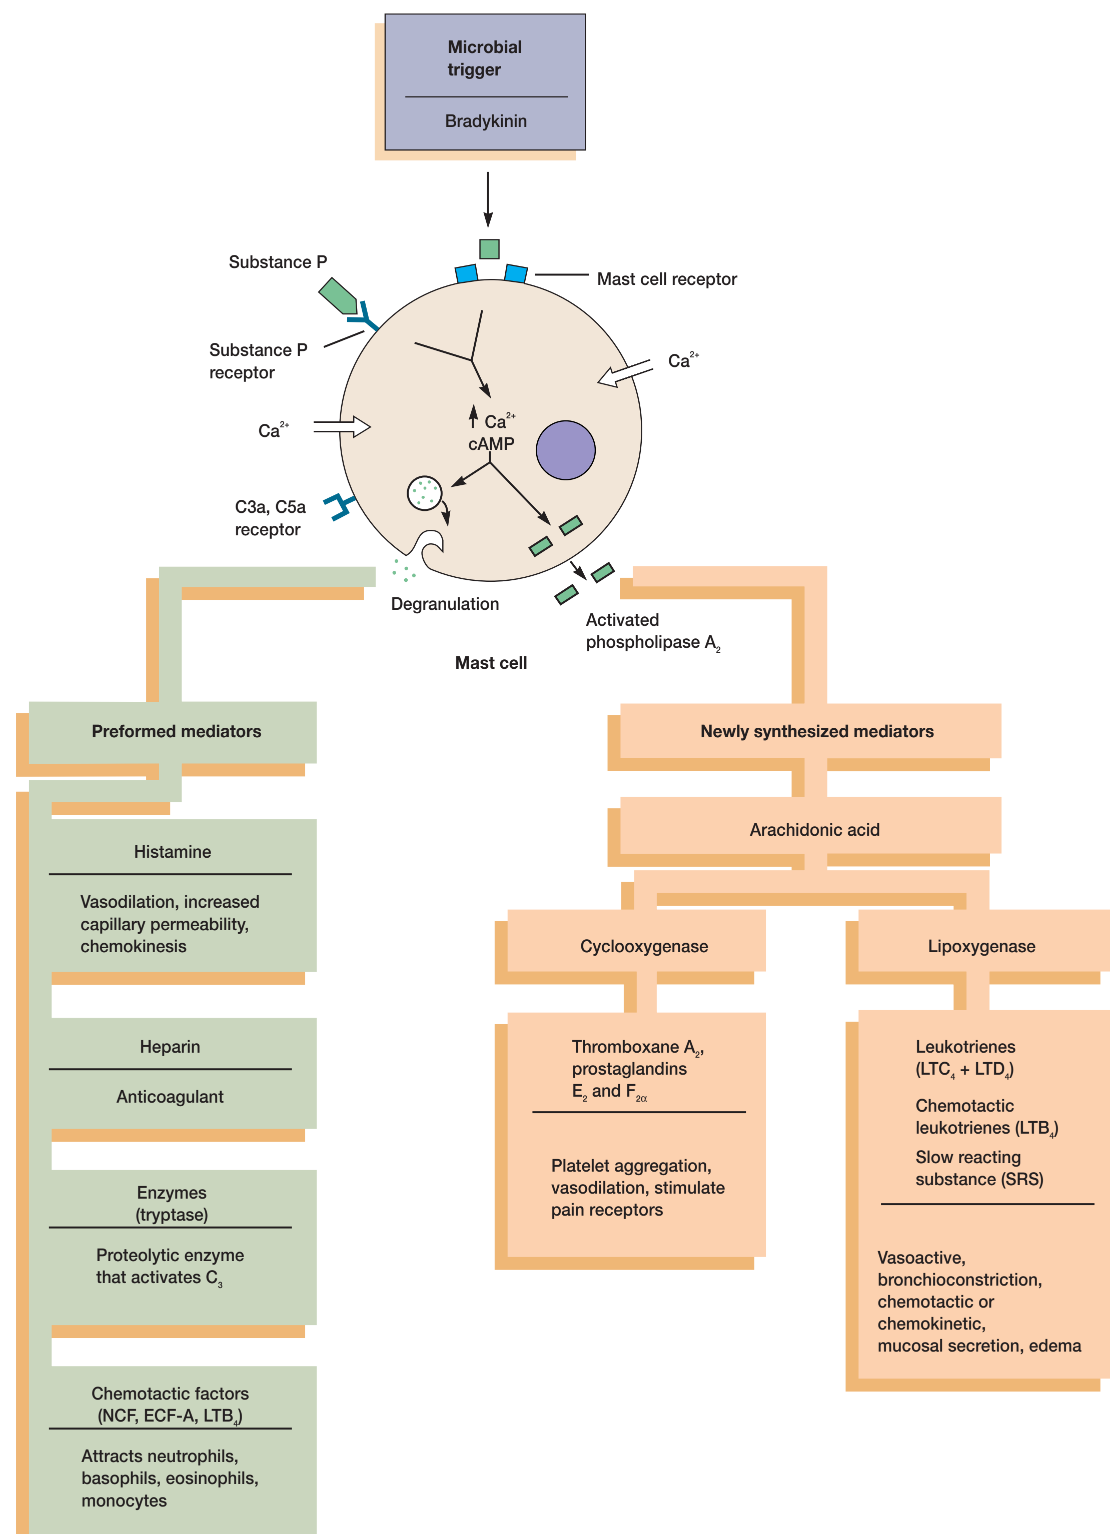

Figure 31.12 Biochemical Events of Inflammation. Mast cell activation and physiological effects of mast cell–derived performed and newly synthesized mediators that lead to the inflammatory response.

Table 31.1 Proteins of the Complement Cascade in Serum

Protein	Fragment	Function
Recognition Unit		
C1	q	Binds to the Fc portion of antigen-antibody complexes
	r	Subunit of C1; activates C1s
	s	Cleaves C4 and C2 due to its enzymatic activity
Activation Unit		
C2		Causes viral neutralization
C3	a	Anaphylatoxin, immunoregulatory
	b	Key component of the alternative pathway and major opsonin in serum
	e	Induces leukocytosis
C4	a	Anaphylatoxin
	b	Causes viral neutralization; opsonin
Membrane Attack Unit		
C5	a	Anaphylatoxin; principal chemotactic factor in serum; induces neutrophil attachment to blood vessel walls
	b	Initiates membrane attack
C6, C7, C8, C9		Participate with C5b in formation of the membrane attack complex that lyses targeted cells
Alternative Pathway		
Factor B		Causes macrophage spreading on surfaces; precursor of C3 convertase
Factor $\overline{D}$		Cleaves Factor B to form active C3Bb in alternative pathway
Properdin		Stabilizes alternative pathway C3 convertase
Regulatory Proteins		
Factor H		Promotes C3b breakdown and regulates alternative pathway
Factor I		Degrades C3b and regulates alternative pathway
C4b binding protein		Inhibits assembly and accelerates decay of C4bC2a
C1 INH complex		Binds to and dissociates C1r and C1s from C1
S protein		Binds fluid-phase C5b67; prevents membrane attachment

properdin (**table 31.1**). The complement system acts in a cascade fashion, the activation of one component resulting in the activation of the next. Collectively the complement proteins make up much of the globulin fraction of serum (*see section 32.3 and figure 32.6*). Within plasma and other body fluids, complement proteins are in an inactive state.

There are three pathways of complement activation: the classical, alternative, and lectin pathways. Although they employ similar mechanisms, specific proteins are unique to the first part of each pathway. Since the classical pathway involves an understanding of the specific immune response, it will be discussed in section 32.7.

The **alternative complement pathway (figure 31.13)** plays an important role in the innate, nonspecific immune defense against intravascular invasion by bacteria and some fungi. The alternative pathway begins with cleavage of C3 into fragments C3a and C3b by a blood enzyme. These fragments are produced at a slow rate and do not carry out the next step, the cleavage of C5, because free C3b is rapidly cleaved into inactive fragments. However, C3b becomes stable when it binds to the lipopolysaccharide (LPS) of gram-negative bacterial cell walls, to aggregates of IgA or IgE, or to some endotoxins. A protein in blood termed Factor B adsorbs to bound C3b and is cleaved into two fragments by Factor $\overline{D}$, leading to the formation of active enzyme $C\overline{3bBb}$ (this complex is sometimes called the C3 convertase because it cleaves more C3 to C3a and C3b). $C\overline{3bBb}$ is further stabilized by a second blood protein, properdin, and is changed into the C5 convertase ($C\overline{3bBb3b}$). The convertase then cleaves C5 to C5a and C5b. C6 and C7 rapidly bind to C5b, forming a $C\overline{5b67}$ complex that possesses an unstable membrane-binding site; once bound to a membrane, this complex is stable. C8 and C9 then bind, forming the **membrane attack complex** ($C\overline{5b6789}$) that creates a pore in the plasma membrane of the target cell (**figure 31.14**). It is believed that the actual pore is a doughnut-shaped polymer of C9. If the cell is eucaryotic, Na^+ and H_2O enter through the pore and the cell lyses osmotically. Lysozyme can pass through pores in the outer membrane of gram-negative cell walls and digest the peptidoglycan cell wall, thus weakening the wall and aiding lysis. In contrast, gram-positive bacteria resist the cytolytic action of the membrane attack complex because they lack an exposed outer membrane and have a thick peptidoglycan that prevents an attack on the plasma membrane. However, gram-positive bacteria are very susceptible to opsonization (figure 31.15) when coated with C3b.

The **lectin complement pathway** activates C3 convertase by using a lectin, a special protein that binds to specific carbohydrates. When macrophages ingest viruses, bacteria, and other foreign material, they release chemicals that stimulate liver cells to secrete mannose-binding protein (MBP). Because mannose is a major component of bacterial cell walls and of some virus envelopes and immune complexes, MBP binds to many pathogens and soluble immune complexes. MBP is an opsonin and directly enhances phagocytosis. The lectin also activates complement in two ways (figure 31.13). After binding to the surface, it can trigger the alternative pathway directly. In addition, if MBP is bound to the MBP-associated serine esterase (MASP), it activates the classical complement pathway. Thus although the lectin pathway activates the complement cascade just as the classical and alternative pathways do, it uses a mechanism that is independent of antibody-antigen interactions (the classical pathway) and the interaction of complement with pathogen surfaces (alternative pathway).

This overview of the alternative and lectin complement pathways provides a basis for consideration of the function of complement as an integrated system during an animal's defensive effort. Gram-negative bacteria arriving at a local tissue site will interact with components of the alternative pathway, resulting in the generation of biologically active fragments, opsonization of the bacteria, and initiation of the lytic sequence. If the bacteria

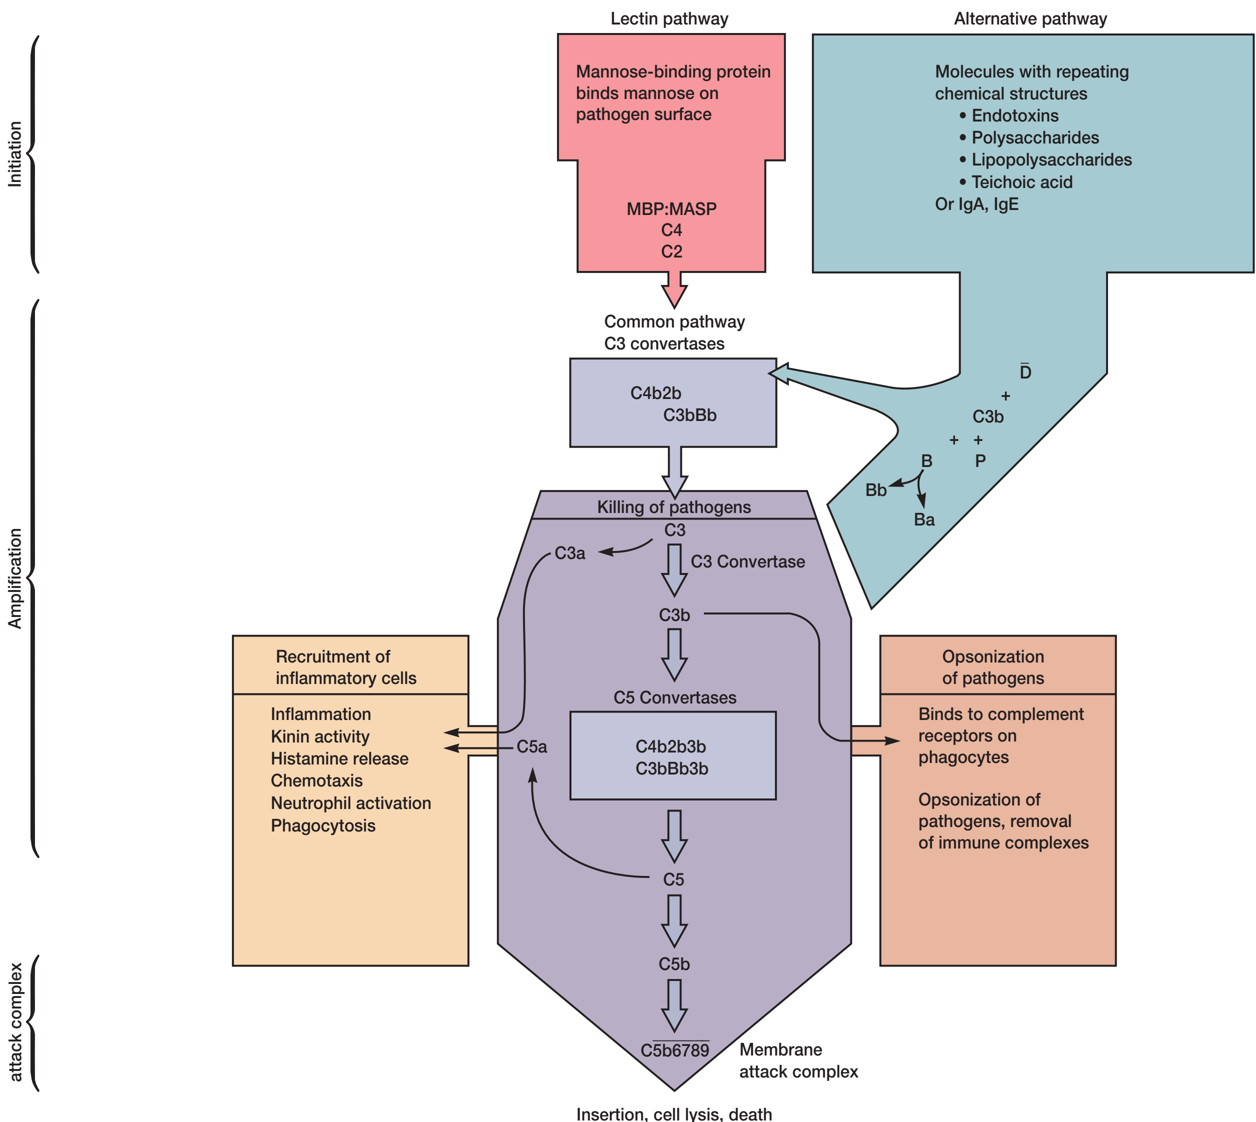

Figure 31.13 Alternative and Lectin Complement Pathways. Within each pathway the components are arranged in order of their activation and aligned opposite their functional and structural analogs in the opposite pathway. Two of the three pathways of complement activation are shown: (1) the lectin-mediated pathway (red), which is triggered by a serum protein that binds to mannose residues of bacteria; and (2) the alternative pathway (blue), which is triggered directly on pathogen surfaces. Both of these generate a crucial enzymatic activity (common pathway of C3 convertases) that in turn generates the effector activity of complement. The three main consequences of complement activation are recruitment of inflammatory cells (left box), direct killing of pathogens by the membrane attack complex (middle box), and opsonization of pathogens (right box).

persist or if they invade the animal a second time, antibody responses also will activate the classical pathway (*see section 32.7*).

The generation of complement fragments C3a and C5a leads to several important inflammatory effects. Mast cells release their contents, and the blood supply to the area increases markedly (hyperemia) as blood vessels dilate due to released histamine (figure 31.12). These fragments also cause the release of neutrophils from the bone marrow into the circulation. Neutrophils then make their way to the site of hyperemia where, in the presence of C5a, they attach to the endothelium and leave the blood. C5a induces a directed, chemotactic migration of neutrophils to the site of complement activation. Macrophages in the area can synthesize even

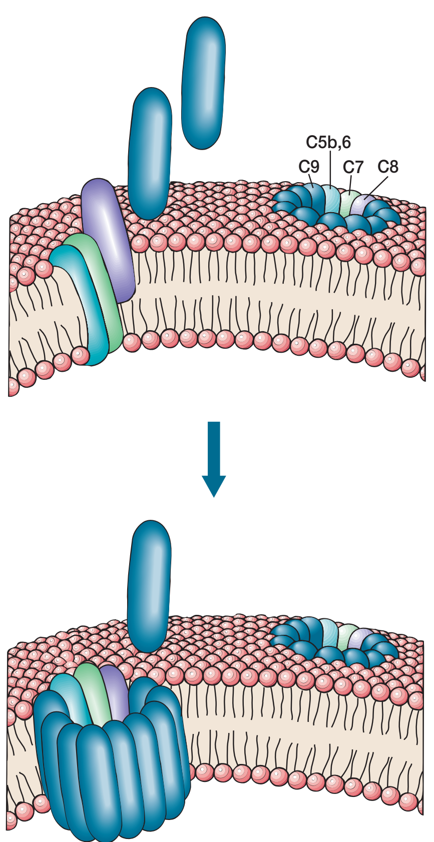

Figure 31.14 The Membrane Attack Complex. The membrane attack complex (MAC) is a tubular structure that forms a transmembrane pore in the target cell's plasma membrane. This representation is the subunit architecture of the membrane attack complex. The transmembrane channel is formed by a C5b678 complex and 10 to 16 polymerized molecules of C9.

more complement components to interact with the bacteria. All these defensive events promote the ingestion and ultimate destruction of the bacteria by the neutrophils and macrophages.

1. List the major functions of complement.
2. How is the alternative pathway activated? The lectin pathway?
3. What is the membrane attack complex, and how does its formation lead to cell lysis?
4. What role do complement fragments C3a and C5a play in an animal's defense against gram-negative bacteria?

31.8 Phagocytosis

During their lifetimes, humans and other vertebrates encounter many microbial species, but only a few of these species can grow and cause serious disease in otherwise healthy hosts. Phagocytic cells (monocytes, tissue macrophages, and neutrophils) are an important early defense against invading microorganisms. These phagocytic cells recognize, ingest, and kill many extracellular microbial species by the process called **phagocytosis** [Greek *phagein,* to eat, and *cyte,* cell, and *osis,* a process]. The concept of phagocytosis was briefly introduced in section 4.5 within the discussion of lysosomes and how certain cells obtain nutrients by endocytosis. Phagocytosis will now be considered in more detail in the context of nonspecific host resistance.

Phagocytic cells use two basic molecular mechanisms for the recognition of microorganisms: (1) opsonin-dependent (opsonic) and (2) opsonin-independent (nonopsonic) recognition. The phagocytic process can be greatly enhanced by opsonization. **Opsonization** [Greek *opson,* to prepare victims for] is a process in which microorganisms or other particles are coated by serum components (antibodies and/or complement C3b) thereby preparing them for recognition and ingestion by phagocytic cells. In the **opsonin-dependent** recognition mechanism, it is the serum components that function as a bridge between the microorganisms and the phagocyte. They act by binding to the surface of the microorganism at one end and to specific receptors on the phagocyte surface at the other (**figure 31.15*b–d***).

The **opsonin-independent** mechanism does not require opsonins and uses other nonspecific (figure 31.15*a*) and specific receptors (**figure 31.16*a***) on phagocytic cells that recognize structures expressed on the surface of different microorganisms. Three main forms of recognition in opsonin-independent phagocytosis have been identified (**table 31.2**). One mode, termed lectin phagocytosis, is based on the recognition between surface lectins on one cell and surface carbohydrates on the opposing cell. The second mode is the result of protein-protein interactions between the Arg-Gly-Asp peptide sequence of microorganisms and macrophage receptors. Hydrophobic interactions between bacteria and phagocytic cells also promote phagocytosis. It should be noted that a particular microbial species can express multiple adhesins, each recognized by a distinct receptor present on phagocytic cells.

Once ingested by phagocytosis, membrane-enveloped microorganisms are delivered to a lysosome by fusion of the phagocytic vacuole, called a **phagosome,** with the lysosome membrane, forming a new vacuole called a **phagolysosome** (figure 31.16*b*). Lysosomes contribute to the phagolysosome a variety of hydrolases such as lysozyme, phospholipase A_2, ribonuclease, deoxyribonuclease, and proteases. An acidic vacuolar pH favors the activity of the hydrolases. Collectively these participate in the destruction of the entrapped microorganism.

Besides these oxygen-independent lysosomal hydrolases, macrophage and neutrophil lysosomes contain oxygen-dependent enzymes that can produce toxic **reactive oxygen intermediates (ROIs)** such as the superoxide radical ($O_2^-\cdot$), hydrogen peroxide (H_2O_2), singlet oxygen ($^1O_2$), and hydroxyl radical ($OH\cdot$). The NADPH required for this process is supplied by a large increase in pentose phosphate pathway activity (*see figure 9.6*). Neutrophils also contain myeloperoxidase and produce

Phagocytic cell	Degree of binding	Opsonin
(a) Attachment by nonspecific receptors (Microorganism)	±	–
(b) (Ab; Fc receptor)	+	Antibody
(c) (C3b; C3b receptor)	+ +	Complement C3b
(d)	+ + + +	Antibody and complement C3b

Figure 31.15 Opsonization. (**a**) A phagocytic cell has some intrinsic ability to bind directly to a microorganism through nonspecific receptors. (**b**) This binding ability is enhanced if the microorganism elicits the formation of antibodies (Ab) that act as a bridge to attach the microorganism to the Fc receptor on the phagocytic cell. (**c**) If the microorganism has activated complement (C3b), the degree of binding is further enhanced by the C3b receptor. (**d**) If both antibody and C3b opsonize, binding is greatly enhanced.

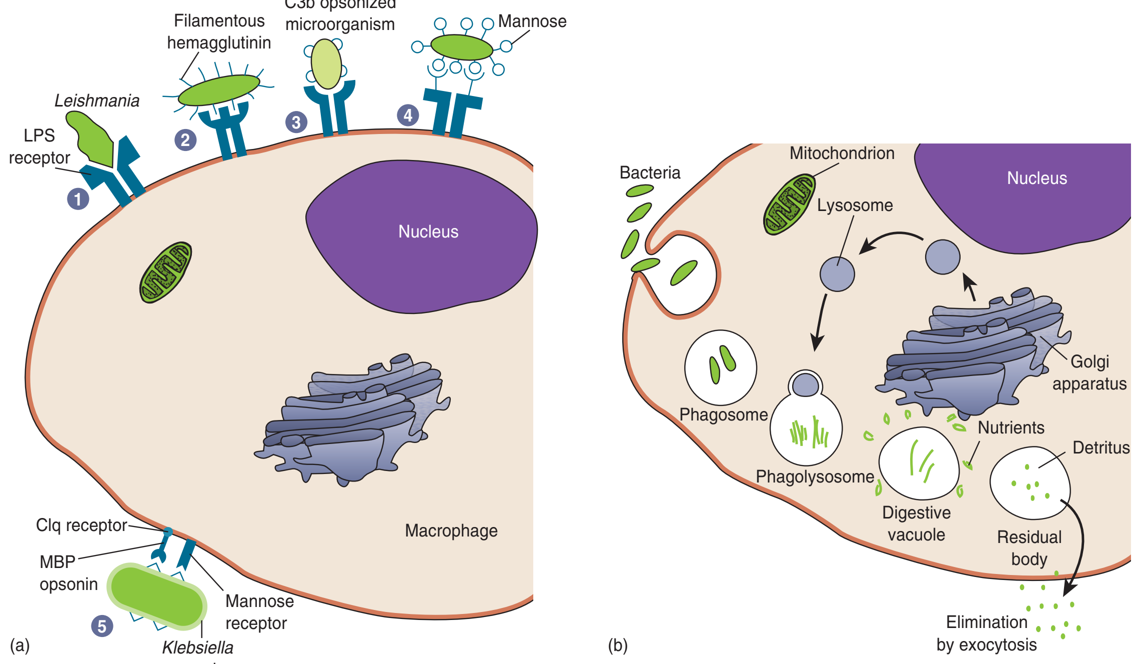

Figure 31.16 Phagocytosis. (**a**) Drawing shows receptors on a phagocytic cell, such as a macrophage, and the corresponding adhesins on microbial surfaces participating in phagocytosis. (1) The LPS binding site for lipophosphoglycan of *Leishmania* spp; (2) filamentous hemagglutinin of *Bordetella pertussis;* (3) binding to C3b on an opsonized cell; (4) the mannose-containing oligosaccharide side chain for lectin phagocytosis mediated by type 1 fimbriated bacteria; and (5) the participation of capsular polysaccharide of *Klebsiella pneumoniae* in nonopsonic binding mediated by the mannose receptor. (**b**) Drawing of phagocytosis, showing ingestion, intracellular digestion, and exocytosis.

Table 31.2 Nonopsonic Modes of Recognition by Phagocytes

Type of Interaction	Bacterial Ligand (and Example)	Phagocytic Receptor (and Example)
Lectin-carbohydrate	Lectin (Type I fimbriae; *see figure 3.30*)	Glycoprotein (integrins)
	Polysaccharide (capsule; *see figure 3.27*)	Lectin (Man/GlcNAc receptors)
Protein-protein	Arginine-glycine-aspartic acid; RGD-containing proteins (filamentous hemagglutinin; *see table 34.3*)	RGC receptor (integrins)
Hydrophobic protein	Glycolipid (lipoteichoic acid: *see figure 3.21*)	Lipid receptors (integrins)

hypochlorous acid. Some reactions forming these toxic products are shown here.

Superoxide formation

$$NADPH + 2O_2 \xrightarrow{\text{NADPH oxidase}} 2O_2^{-}\cdot + H^+ + NADP^+$$

Hydrogen peroxide formation

$$2O_2^{-}\cdot + 2H^+ \xrightarrow{\text{superoxide dismutase}} H_2O_2 + O_2$$

Hypochlorous acid formation

$$H_2O_2 + Cl^- \xrightarrow{\text{myeloperoxidase}} HOCl + OH^-$$

Singlet oxygen formation

$$ClO^- + H_2O_2 \rightarrow {}^1O_2 + Cl^- + H_2O$$

Hydroxyl radical formation

$$O_2^{-}\cdot + H_2O_2 \rightarrow OH\cdot + OH^- + O_2$$

These reactions result from the **respiratory burst** that accompanies the increased oxygen consumption and ATP generation needed for phagocytosis. Because these reactions occur as soon as the phagosome is formed, lysosome fusion is not necessary for the respiratory burst. The toxic oxygen products produced are effective in killing invading microorganisms. Oxygen and microbial growth (pp. 127–29)

Recently macrophages, neutrophils, and mast cells have been shown to form **reactive nitrogen intermediates (RNIs).** These molecules include nitric oxide (NO) and its oxidized forms, nitrite (NO_2^-) and nitrate (NO_3^-). The RNIs are very potent cytotoxic agents, and may be either released from cells or generated within cell vacuoles. Nitric oxide is probably the most effective RNI. Macrophages produce it from the amino acid arginine. Nitric oxide can block cellular respiration by complexing with the iron in electron transport proteins. Macrophage destruction of the herpes simplex virus, the protozoa *Toxoplasma gondii* and *Leishmania major,* the opportunistic fungus *Cryptococcus neoformans,* the metazoan pathogen *Schistosoma mansoni,* and tumor cells involves RNIs.

Neutrophil granules also contain a variety of other microbicidal substances such as several cationic proteins, the bactericidal permeability increasing protein (BPI), and the family of broad-spectrum antimicrobial peptides called **defensins.** There are four human defensins, called human neutrophil proteins (HNPs): HNP-1, 2, 3, and 4. These defensins are synthesized by myeloid precursor cells during their sojourn in the bone marrow, and are then stored in the cytoplasmic granules of mature cells. This compartmentation strategically locates defensins for extracellular secretion or delivery to phagocytic vacuoles. Susceptible microbial targets include a variety of gram-positive and gram-negative bacteria, yeasts and molds, and some viruses. Defensins act against bacteria and fungi by permeabilizing cell membranes. They form voltage-dependent membrane channels that allow ionic efflux. Antiviral activity involves direct neutralization of enveloped viruses; nonenveloped viruses are not affected by defensins.

1. What is the difference between opsonic and nonopsonic phagocytosis?
2. Once a phagolysosome forms, how is the entrapped microorganism destroyed?
3. What is the purpose of the respiratory burst that occurs within macrophages? Describe the nature and function of reactive oxygen and nitrogen intermediates.
4. What are defensins? How do they function?

31.9 Cytokines

Defense against viruses, microorganisms and their products, parasites, and cancer cells is mediated by both nonspecific and specific immunity. Cytokines are required for immunoregulation of both of these immune responses.

The term **cytokine** [Greek *cyto,* cell, and *kinesis,* movement] is a generic term for the soluble protein or glycoprotein released by one cell population that acts as an intercellular (between cells) mediator or signaling molecule. When released from mononuclear phagocytes, these proteins are called **monokines;** when released from T lymphocytes they are called **lymphokines;** when produced by a leukocyte and the action is on another leukocyte, they are **interleukins;** and if their effect is to stimulate the growth and differentiation of immature leukocytes in the bone marrow, they are called **colony-stimulating factors (CSFs).** Recently cy-

Table 31.3 The Four Cytokine Families

Family	Examples	Functions
Chemokines	IL-8, RANTES, MIP (macrophage inflammatory protein)	Cytokines that are chemotactic and chemokinetic for leukocytes. They stimulate cell migration and attract phagocytic cells and lymphocytes. Chemokines play a central role in the inflammatory response.
Hematopoietins	Epo (erythropoietin), various colony-stimulating factors	Cytokines that stimulate and regulate the growth and differentiation processes involved in blood cell formation (hematopoiesis).
Interleukins	IL-1 to IL-18	Cytokines produced by lymphocytes and monocytes that regulate the growth and differentiation of other cells, primarily lymphocytes and hematopoietic stem cells. They often also have other biological effects.
Tumor necrosis factor (TNF) family	TNF-α, TNF-β, Fas ligand	Cytokines that are cytotoxic for tumor cells and have many other effects such as promoting inflammation, fever, and shock; some can induce apoptosis.

tokines have been grouped into the following categories or families: chemokines, hematopoietins, interleukins, and members of the tumor necrosis factor (TNF) family. Some examples of these cytokine families are provided in **table 31.3.**

Cytokines can affect the same cell responsible for their production (an autocrine function), nearby cells (a paracrine function), or can be distributed by the circulatory system to their target cells (an endocrine function). Their production is induced by nonspecific stimuli such as a viral, bacterial, or parasitic infection; cancer; inflammation; or the interaction between a T cell and antigen. Some cytokines also can induce the production of other cytokines.

Knowledge of the biological actions of cytokines has grown enormously over the past two decades. This is due in part to the incredible potency and range of effects on eucaryotic cells exhibited by cytokines, and to the fact that they are involved in all aspects of disease. Cytokines produce biological actions only when they act as ligands and bind to specific, high-affinity receptors called CDs (cell-associated differentiation antigens (*see section 32.2*) on the surface of target cells. The affinity of cytokine receptors for their ligands is very high, and consequently cytokines are effective at concentrations of 10^{-10} to 10^{-15}M. Most cells have relatively few receptors, hundreds to a few thousand, and a maximal cellular response results when only a small number of these are occupied by the cytokine. This binding activates specific intracellular signaling pathways and switches on genes that encode proteins essential to the appropriate target cell functions. Examples of these proteins include other cytokines, cell-to-cell adhesion receptors, proteases, lipid-synthesizing enzymes, and nitric oxide synthase. Cytokines can activate cell proliferation and/or cell differentiation (**figure 31.17**). They also can inhibit cell division and cause apoptosis (programmed cell death). Chemokines, one type of cytokine, stimulate chemotaxis and chemokinesis (i.e., they direct cell movement) and thus play an important role in the acute inflammatory response (figure 31.11). Some examples of important cytokines and their functions are given in **table 31.4.**

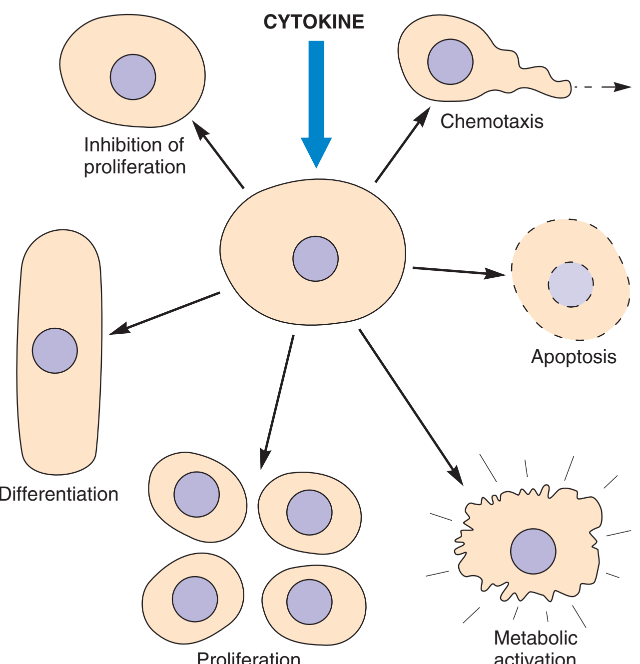

Figure 31.17 Range of Biological Actions That Cytokines Have on Eucaryotic Cells. Chemokines are one family of cytokines that induce leukocyte chemotaxis and migration. Other cytokines activate cell metabolism and synthesis. This can lead to the synthesis of a wide range of proteins including cyclooxygenase II, proteolytic enzymes, NO synthase, and various adhesion receptors. In addition, other cytokines can cause proliferation, inhibition of cell proliferation, or apoptosis.

Interferons

Interferons (IFNs) are a group of related low molecular weight, regulatory cytokines produced by many eucaryotic cells in response to numerous inducers: a virus infection, double-stranded RNA, endotoxins, antigenic stimuli, mitogenic (stimulating mitosis) agents, and many pathogenic organisms capable of intracellular growth (*Listeria monocytogenes,* chlamydiae, rickettsias, protozoa). Interferons usually are species specific but virus nonspecific. Several classes of interferons are recognized: IFN-α is a family of 20 different molecules that can be synthesized by virus-infected leukocytes (table 31.4). IFN-β is derived from virus-infected fibroblasts; and IFN-γ is produced by antigen-stimulated T cells. Probably

Table 31.4 Some of the Cytokines That Mediate Immune Responses

Cytokine	Cell Source	Functions
IL-1 (interleukin-1)	Monocytes/macrophages, endothelial cells, fibroblasts, neuronal cells, glial cells, keratinocytes, epithelial cells	Produces a wide variety of effects on the differentiation and function of cells involved in inflammatory and immune responses; also affects central nervous and endocrine systems; it is an endogenous pyrogen
IL-2 (interleukin-2, T-cell growth factor)	T cells (T_H1)	Stimulates T-cell proliferation and differentiation, enhances cytolytic activity of NK cells, promotes proliferation and immunoglobin secretion of activated B cells
IL-3 (interleukin-3)	T cells, keratinocytes, neuronal cells, mast cells	Stimulates the production and differentiation of macrophages, neutrophils, eosinophils, basophils, mast cells
IL-4 (interleukin-4, B-cell growth factor-1 [BCGF-1], B-cell stimulatory factor-1 [BCSF-1])	T cells (T_H2), macrophages, mast cells, basophils, B cells	Induces the differentiation of naive $CD4^+$ T cells into T-helper-like cells; induces the proliferation and differentiation of B cells; exhibits diverse effects on T cells, monocytes, granulocytes, fibroblasts, endothelial cells
IL-5 (interleukin-5)	T cells (T_H2)	Growth and activation of B cells and eosinophils; activation of eosinophil function; chemotactic for eosinophils
IL-6 (interleukin-6, cytotoxic T-cell differentiation factor, B-cell differentiation factor)	T_H2 cells, monocytes/macrophages, fibroblasts, hepatocytes, endothelial cells, neuronal cells	Activates hematopoietic cells; induces growth of T cells, B cells, hepatocytes, keratinocytes, and nerve cells; stimulates the production of acute-phase proteins
IL-8 (interleukin-8)	Monocytes, endothelial cells, fibroblasts, alveolar epithelium, T cells, keratinocytes, neutrophils, hepatocytes	Chemoattractant for PMNs; causes degranulation and expression of receptors; inhibits adhesion of PMNs to endothelium; promotes migration of PMNs through endothelium; induces adhesion of neutrophils to endothelial cells
IL-10 (interleukin-10)	T cells (T_H2), B cells, macrophages, keratinocytes	Reduces the production of IFN-γ, IL-1, TNF-α, and IL-6 by macrophages; in combination with IL-3 and IL-4, causes mast cell growth; in combination with IL-2, causes growth of cytotoxic T cells and differentiation of $CD8^+$ cells
IFNs α/β (interferons α/β)	T cells, B cells, monocytes/macrophages, fibroblasts	Antiviral activity, stimulates macrophage activity, modulates MHC class I and II protein expression on various cells, regulates the development of the specific immune response
IFN-γ (interferon-γ)	T cells (T_H1, T_C), NK cells	Activation of T cells, macrophages, neutrophils, and NK cells; increases class I and II MHC molecules
TNF-α (tumor necrosis factor-α [cachectin])	T cells, macrophages and NK cells	A wide variety of effects due to its ability to mediate expression of genes for growth factors and cytokines, transcription factors, receptors, inflammatory mediators, and acute-phase proteins; plays a role in host resistance to infection by serving as an immunostimulant and mediator of the inflammatory response; cytotoxic for tumor cells
TNF-β (tumor necrosis factor-β [lymphotoxin])	T cells, B cells	Same as TNF-α
G-CSF (granulocyte colony-stimulating factor)	T cells, macrophages, neutrophils	Enhances the differentiation and activation of neutrophils
M-CSF (macrophage colony-stimulating factor)	T cells, neutrophils, macrophages, fibroblasts, endothelial cells	Stimulates various functions of monocytes and macrophages, promotes the growth and development of macrophage colonies from undifferentiated precursors

many other virus-infected cells can synthesize IFN-α and IFN-β. Some of the ways in which interferon renders cells resistant to virus infections are described in **figure 31.18.**

Fever

From a physiological point of view, fever results from disturbances in hypothalamic thermoregulatory activity, leading to an increase of the thermal "set point." In adult humans **fever** is defined as an oral temperature above 98.6°F (37°C) or a rectal temperature above 99.5°F (37.5°C). The most common cause of a fever is a viral or bacterial infection (or bacterial toxins). In almost every instance there is a specific constituent, the endogenous pyrogen, that directly triggers fever production. Examples of these pyrogens includes interleukin-1, IL-6, and tissue necrosis factor that are produced by host macrophages in response to pathogenic microorganisms. After their release, these pyrogens circulate to the hypothalamus and induce neurons to secrete

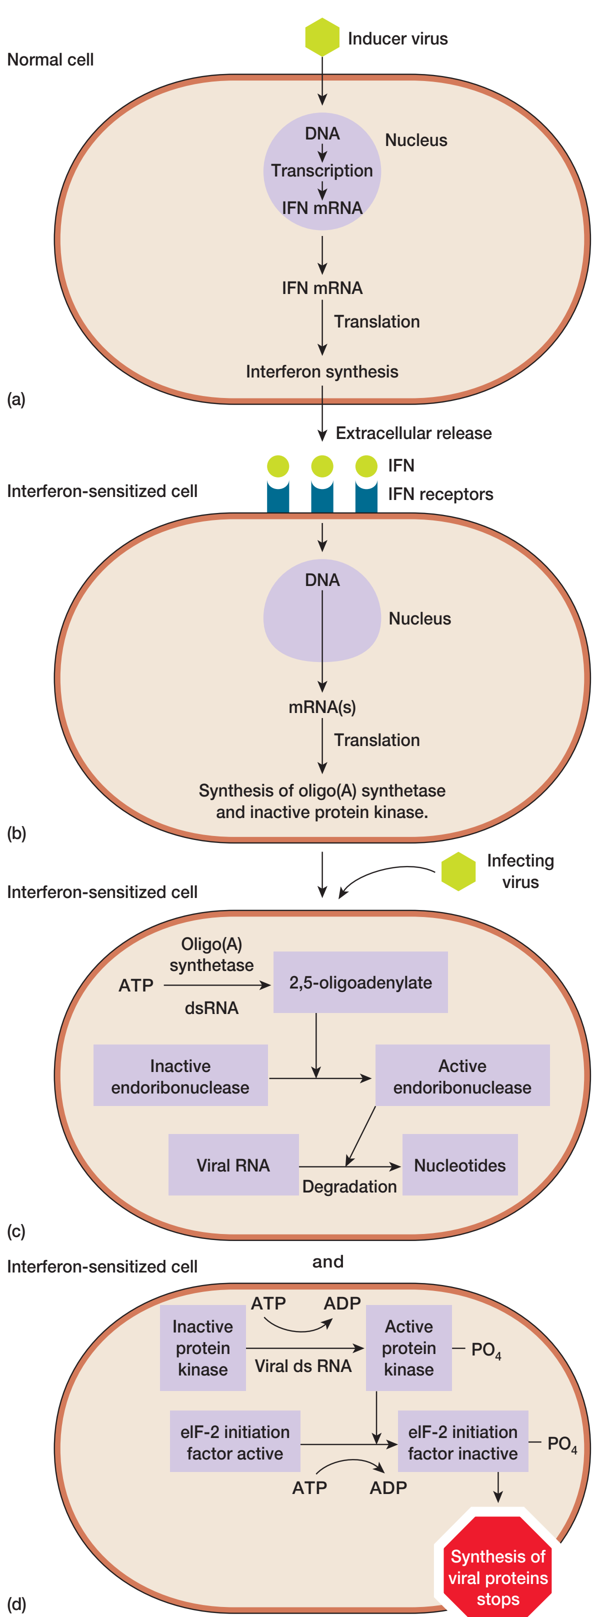

Figure 31.18 The Antiviral Action of Interferon. The arrows indicate the sequence of events. (**a**) Interferon (IFN) synthesis and release is often induced by a virus infection or double-stranded RNA (dsRNA). (**b**) Interferon binds to a ganglioside receptor on the plasma membrane of a second cell and triggers the production of enzymes that render the cell resistant to virus infection. The two most important such enzymes are oligo(A) synthetase and a special protein kinase. (**c**) When an interferon-stimulated cell is infected, viral protein synthesis is inhibited by an active endoribonuclease that degrades viral RNA. (**d**) An active protein kinase phosphorylates and inactivates the initiation factor eIF-2 required for viral protein synthesis.

prostaglandins. Prostaglandins reset the hypothalamic thermostat at a higher temperature, and temperature-regulating reflex mechanisms then act to bring the core body temperature up to this new setting.

The fever induced by a microorganism augments the host's defenses by three complementary pathways (**figure 31.19**): (a) it stimulates leukocytes so that they can destroy the microorganism, (b) it enhances the specific activity of the immune system, and (c) it enhances microbiostasis (growth inhibition) by decreasing available iron to the microorganism. Evidence suggests that some hosts are able to redistribute the iron during a fever in an attempt to withhold it (**hypoferremia**) from the microorganism. Conversely, the virulence of many microorganisms is enhanced with increased iron availability (**hyperferremia**). Gonococci, for example, spread most often during menstruation, a time in which there is an increased concentration of free iron available to these bacteria.

1. What is a cytokine?
2. Define monokine, lymphokine, interleukin, and colony-stimulating factor.
3. Into what four families are cytokines sometimes placed (table 31.3)?
4. How do cytokines play a role as mediators of natural immunity?
5. How do interferons render cells resistant to viruses?
6. How can a fever be beneficial to a host?

31.10 Natural Killer Cells

Natural killer (NK) cells are a small population of large nonphagocytic granular lymphocytes (figure 31.3). Their major function is to destroy malignant cells and cells infected with microorganisms. They recognize their targets in one of two ways. Like many cells, they possess Fc receptors that bind IgG antibody. These receptors link the NK cells to IgG-coated target cells, which they kill by a process called **antibody-dependent**

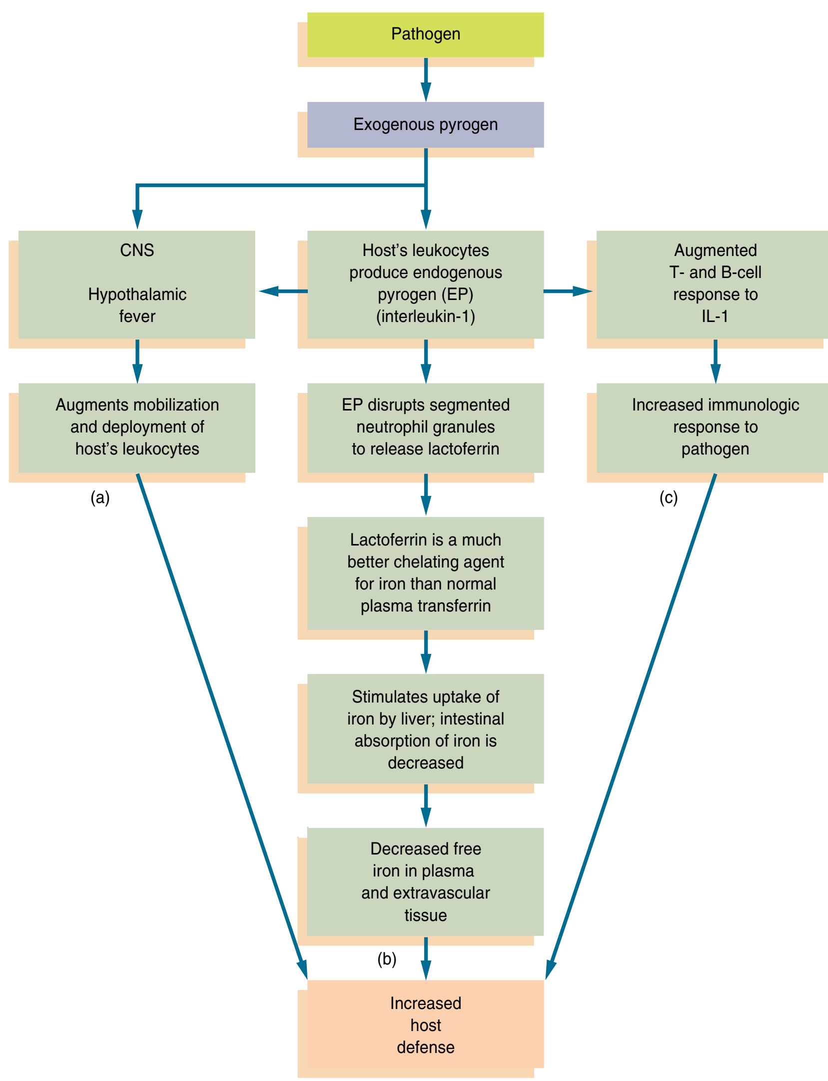

Figure 31.19 Effects of Fever in a Mammalian Host. (**a**) One of the first effects of a fever is to accelerate and augment the mobilization and deployment of the host's leukocytes, which in turn isolate and help destroy the pathogen. (**b**) A fever leads to a reduction of free plasma iron, which limits the growth of those organisms that require a narrow, crucial concentration of iron for their replication and synthesis of toxins. (**c**) One of the immunologic consequences of fever is the production of endogenous pyrogen (IL-1). IL-1 causes the proliferation, maturation, and activation of lymphocytes (T and B cells), which in turn augment the immunologic response of the host to the pathogen.

cell-mediated cytotoxicity (ADCC) (figure 31.20). The second way NK cells recognize infected cells and cancer cells relies on the killer-activating receptors and killer-inhibitory receptors of the NK cells (**figure 31.21**). The killer-activating receptors recognize a number of different molecules present on the surface of all nucleated cells. The killer inhibitory receptors recognize a surface marker known as the major histocompatibility complex (MHC) class I molecule (*see section 32.4*) that is also present on all nucleated cells and is an indicator of "self." If the killer-activating receptors are engaged with a ubiquitous surface molecule, a "kill" instruction is issued to the NK cell. Conversely, when this "kill" signal is overridden by an inhibitory signal sent by the killer inhibitory receptor binding to the MHC class I molecule (which indicates "self"), no killing is done.

Although all nucleated cells normally have the MHC class I molecule on their plasma membrane surface, they can lose this molecule. This loss can occur as a result of a microbial pathogen interfering with the expression mechanism (e.g., after a herpesvirus infection) or from a malignant transformation. Cells that lack this MHC class I molecule are perceived as being abnormal and NK cells do not receive an inhibitory signal. In the absence of an inhibitory signal, NK cells kill these abnormal cells by inserting the pore-forming protein, perforin, into the plasma membrane of the target cell and then injecting it with cytotoxic enzymes called granzymes.

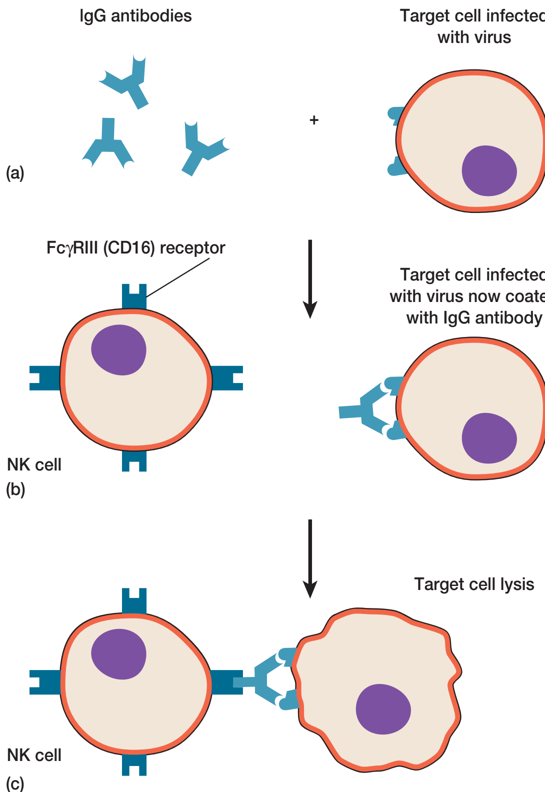

Figure 31.20 Antibody-Dependent Cell-Mediated Cytotoxicity (**a**) In this mechanism, IgG antibodies bind to a target cell infected with a virus. (**b**) NK cells have FcγRIII (CD16) receptors on their surface. (**c**) When the NK cells encounter infected virus cells coated with IgG antibody, they kill the target cell by releasing cytotoxic mediators and/or membrane damage.

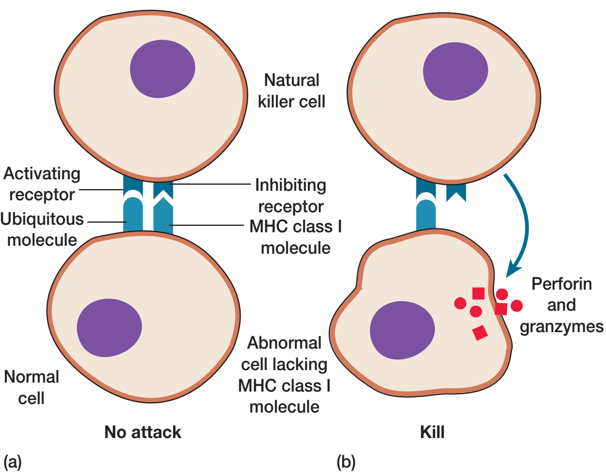

Figure 31.21 The System Used by Natural Killer Cells to Recognize Normal Cells and Abnormal Cells That Lack the Major Histocompatability Complex Class I Surface Molecule. (**a**) The killer-activating receptor recognizes a normal ubiquitous molecule on the plasma membrane of a normal cell. Since the killer-inhibitory receptor recognizes the MHC class I molecule, there is no attack. (**b**) In the absence of the inhibitory signal, the receptor issues an order to the NK cell to attack and kill the abnormal cell. The cytotoxic granules of the NK cell contain perforin and granzymes. With no inhibitory signal, the granules release their contents, killing the abnormal cell.

1. Discuss the role of NK cells in protecting the host.
2. What is the purpose of antibody-dependent cell-mediated cytotoxicity?

Summary

1. Animals and environments that are germfree or have one or more known microorganisms are termed gnotobiotic. Methods are available for rearing gnotobiotic organisms (**figure 31.1**). Gnotobiotic animals and techniques provide good experimental systems with which to investigate the interactions of animals and specific species or microorganisms.
2. Commensal microorganisms living on or in the skin can be characterized as either transients or residents (**figure 31.2**).
3. The normal microbiota of the oral cavity is composed of those microorganisms able to resist mechanical removal.
4. The stomach contains very few microorganisms due to its acidic pH.
5. The distal portion of the small intestine and the entire large intestine have the largest microbial community in the body. Over 400 species have been identified, the vast majority of them anaerobic.
6. The upper genitourinary tract is usually free of microorganisms. In contrast, the adult female genital tract has a complex microbiota.
7. In some instances, after a microorganism contacts or enters a host, a positive mutually beneficial relationship occurs and becomes integral to the health of the host. In other instances, the microorganism may produce disease or even death of the host.
8. Many of the normal host microbiota compete with pathogenic microorganisms.
9. An opportunistic microorganism is generally harmless in its normal environment but becomes pathogenic in a compromised host.
10. There are two fundamentally different types of immune response to invading microorganisms and foreign material. The nonspecific response offers resistance to any microorganism or foreign material. It includes general mechanisms that are a part of the animal's innate structure and function. The nonspecific system has no immunological memory—that is, nonspecific responses occur to the same extent each time. In contrast, the specific response resists a particular foreign agent; moreover, specific immune responses improve on repeated exposure to the agent.

11. The cells responsible for both nonspecific and specific immunity are the white blood cells called leukocytes (**figure 31.3**). Examples include lymphoid cells, mononuclear cells (**figures 31.4** and **31.5**), granulocytes, mast cells, and dendritic cells.
12. Immature undifferentiated lymphocytes generated in the bone marrow mature and become committed to a particular antigenic specificity within the primary lymphoid organs and tissues (**figure 31.6**). In mammals, T cells mature in the thymus and B cells in the bone marrow. The thymus is the primary lymphoid organ and the bone marrow the primary lymphoid tissue.
13. The secondary lymphoid organs and tissues serve as areas where lymphocytes may encounter and bind antigens, whereupon they proliferate and differentiate into fully mature, antigen-specific effector cells. The spleen is a secondary lymphoid organ and the lymph nodes and mucosal-associated tissues (GALT and SALT) are the secondary lymphoid tissues.
14. Many direct factors (age, nutrition) or general barriers contribute in some degree to all host-microbe relationships. At times they favor the establishment of the microorganism; at other times they provide some measure of general defense to the host.
15. Physical and mechanical barriers along with host secretions are the host's first line of defense against pathogens (**figure 31.7**). Examples include the skin (**figure 31.8**) and mucous membranes; the epithelia of the respiratory, gastrointestinal (**figure 31.10**), and genitourinary systems.
16. Mammalian hosts have specific chemical barriers that help combat the continuous onslaught of pathogens. Examples include general chemicals, bacteriocins, and beta-lysins.
17. Inflammation is one of the host's nonspecific defense mechanisms to tissue injury that may be caused by a pathogen (**figures 31.11** and **31.12**). Inflammation can either be acute or chronic.
18. The complement system is composed of a large number of serum proteins (**table 31.1**) that play a major role in the animal's defensive immune response. There are three pathways of complement activation: the classical, alternative, and lectin pathways (**figure 31.13**).
19. Phagocytosis involves the recognition, ingestion, and destruction of pathogens by lysosomal enzymes, superoxide radicals, hydrogen peroxide, defensins, RNIs, and metallic ions (**figure 31.16;** *see also figure 32.31*). Phagocytic cells use two basic mechanisms for the recognition of microorganisms: opsonin-dependent and opsonin-independent.
20. Cytokines (**tables 31.3** and **31.4**) are required for immunoregulation of both the nonspecific and specific immune responses. Cytokines have a broad range of actions on eucaryotic cells (**figure 31.17**)
21. Interferons are a group of cytokines that respond in a defensive way to viral infections, double-stranded RNA, endotoxins, antigenic stimuli, mitogenic agents, and many pathogens capable of intracellular growth (**figure 31.18**).
22. Fever induced by a microorganism augments the host's defenses in three ways (**figure 31.19**): it stimulates leukocytes so they can destroy the invading microorganism; it enhances microbiostasis by decreasing available iron to the microorganism; and it enhances the specific activity of the immune system.
23. Natural killer cells are a small population of large nonphagocytic lymphocytes (**figures 31.20** and **31.21)** that destroy cancer cells and cells infected with microorganisms.

Questions for Thought and Review

1. What are some uses of gnotobiotic animals in microbiology?
2. What has the branch of microbiology known as gnotobiotics taught us about the relationship between the human body and the bacteria found on/in it?
3. Describe why the microenvironment of the skin is both favorable to some microorganisms and unfavorable to others. Explain your answer.
4. What is the relationship between a compromised host and an opportunistic microorganism?
5. Compare and contrast the nonspecific and specific immune responses.
6. Describe the different types of human blood cells and give a function for each one.
7. Describe how each of the following systems contributes to the defense of the host: respiratory, gastrointestinal, and genitourinary.
8. How do the SALT and MALT systems operate?
9. How can inflammation be both beneficial and detrimental to a microorganism?
10. What is the relationship between the respiratory burst and phagocytosis?
11. Why is it difficult to group cytokines into specific categories?
12. Why are most fevers caused by either viruses or bacteria?

Critical Thinking Questions

1. Some patients who take antibiotics for acne develop yeast infections. Explain.
2. Some microorganisms are classified as intracellular pathogens. Explain why the nonspecific immune response to these pathogens differs from the response to pathogens that occur on or in the skin.

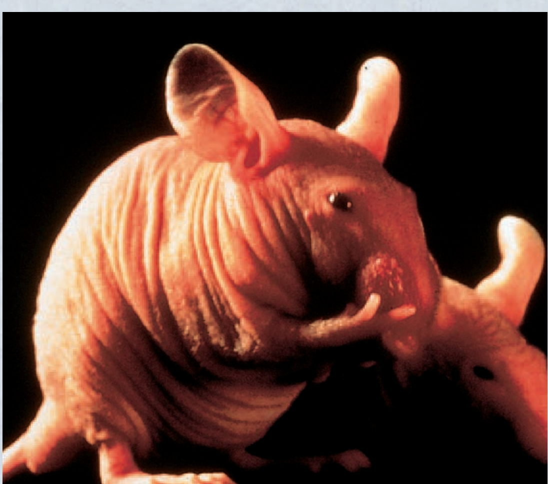
CHAPTER 32

Specific Immunity



Nude (athymic) mice have a genetic defect (*nu* mutation) that affects thymus gland development. Thus T cells do not form. They do have a B-cell component and effective humoral immunity. This unique deficiency provides animals in which to study B/T-cell dichotomy and environmental influences on the maturation and differentiation of T cells, as well as many different immune disorders.

Concepts

1. The major function of the specific immune response in vertebrates is to provide protection (immunity) against harmful microorganisms, cancer cells, and certain macromolecules.
2. Specific immunity has two branches: humoral and cell-mediated. Humoral immunity, or antibody-mediated immunity, involves the production of antibodies by plasma cells derived from B cells. Cell-mediated immunity involves specialized lymphocytes called T cells that act against microorganisms and foreign tissues. They also regulate the activation and proliferation of other immune system cells such as macrophages, B cells, and other T cells.
3. Nonself foreign substances, such as proteins, nucleoproteins, polysaccharides, and some glycolipids to which lymphocytes respond are called antigens.
4. There are five immunoglobulin (Ig) classes based on physicochemical and biological properties. These are IgG, IgM, IgD, IgA, and IgE.
5. Two distinguishing characteristics of immunoglobulins are their diversity and specificity.
6. Various types of antigen-antibody reactions occur in vertebrates that lead to immune product formation. The union of antigen and antibody initiates the participation of other elements that determine the fate of the antigen. For example, the classical complement pathway can be activated, leading to cell lysis or phagocytosis. Other defensive mechanisms include toxin neutralization, opsonization, and immune complex formation.

The remarkable capacity of the immune system to respond to many thousands of different substances with exquisite specificity saves us all from certain death by infection.

—*Martin C. Raff*

The immune system is responsible for the ability of a host to resist foreign invaders. It includes an array of cells and molecules with specialized roles in defending the host against the continuous onslaught of microbial invaders, and cancer cells. Chapter 31 presents a basic discussion of nonspecific host resistance or innate immunity. Chapter 32 continues this discussion of the immune response by describing the system of specific immunity used to protect the host. Specific immunity can be acquired either naturally or artificially and involves antigens, antibodies, T and B cells, and the classical complement pathway. These aspects of immune system function are presented in this chapter in the continuing discussion of the immune system.

32.1 Overview of Specific Immunity

The specific immune system of vertebrates has three major functions: to recognize anything that is foreign to the body ("nonself"), to respond to this foreign material, and to remember the foreign invader. The recognition response is highly specific. The immune system is able to distinguish one pathogen from another, to identify cancer cells, and to recognize the body's own "self" proteins and cells as different from "nonself" proteins, cells, tissues, and organs. After recognition of an invader has occurred, the specific immune system responds by recruiting its defensive molecules and cells to attack the invader. This is called an **effector response.** The effector response either eliminates the foreign material or renders it harmless to the host, thus preventing disease. If the invader is encountered at a later time, the immune system remembers, and mounts a more intense and rapid memory or anamnestic response that eliminates the invader once again and protects the host from disease (p. 743).

Four characteristics distinguish specific immunity from nonspecific resistance:

1. *Specificity.* Immunity is directed against a particular pathogen or foreign substance, and the immunity to this pathogen or substance usually does not confer immunity to others.
2. *Memory.* When reexposed to the same pathogen or substance, the body reacts so quickly that there is no noticeable pathogenesis. By contrast, the reaction time for inflammation and other nonspecific defenses is just as long for a later exposure as it was for the initial one.
3. *Diversity.* The system is able to generate an enormous diversity of molecules such as antibodies that recognize billions of different antigens.
4. *Discrimination between self and nonself.* The specific immune system almost always responds only to nonself antigens and thus does not destroy the organism it is defending.

Two branches or arms of specific immunity are recognized (**figure 32.1**): humoral (antibody-mediated) immunity and cellular (cell-mediated) immunity. **Humoral (antibody-mediated) immunity,** named for the fluids or "humors" of the body, is based on the action of soluble proteins called antibodies that occur in the body fluids and on the plasma membranes of B lymphocytes. Circulating antibodies bind to bacteria, toxins, and extracellular viruses, neutralizing them or "tagging or marking" them for destruction by mechanisms described in section 32.6.

Cellular (cell-mediated) immunity is based on the action of specific kinds of T lymphocytes (*see section 31.4 and figure 31.3*) that directly attack cells infected with viruses or parasites, transplanted cells or organs, and cancer cells. T cells can lyse these cells or release chemicals (cytokines) that enhance specific immunity and nonspecific defenses such as phagocytosis and inflammation.

Types of Acquired Immunity

Acquired immunity refers to the type of specific immunity a host develops after exposure to a suitable antigen, or after transfer of antibodies or lymphocytes from an immune donor. Acquired immunity can be obtained by natural or artificial means and actively or passively (**figure 32.2**).

Naturally Acquired Immunity

Naturally acquired active immunity occurs when an individual's immune system contacts an antigenic stimulus such as an infection. The immune system responds by producing antibodies and activated lymphocytes that inactivate or destroy the antigen. The immunity produced can be either lifelong, as with measles or chickenpox, or last for only a few years, as with tetanus.

Naturally acquired passive immunity involves the transfer of antibodies from one host to another. For example, some of a pregnant woman's antibodies pass across the placenta to her fetus.

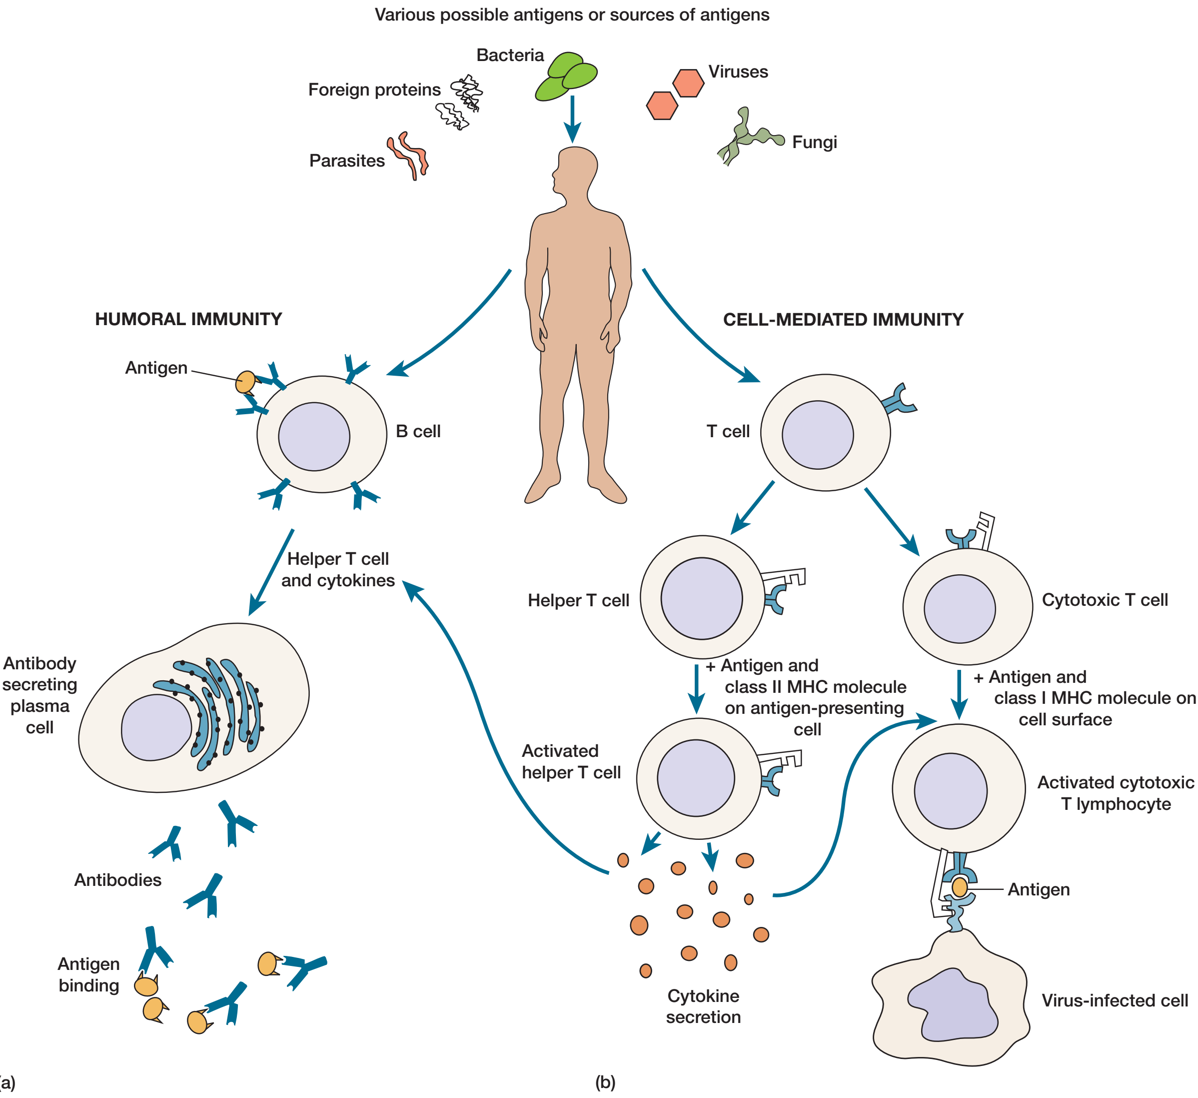

Figure 32.1 The Humoral and Cell-Mediated Branches of Immunity. (**a**) In the humoral branch, B cells interact with antigen and differentiate into antibody-secreting plasma cells. The antibody binds to the antigen and tags it for destruction by other mechanisms. (**b**) In the cell-mediated response, subpopulations of T cells are activated by antigen presented in the presence of a major histocompatibility complex (MHC). Activated helper T cells respond by producing a group of specific chemicals called cytokines that facilitate both the humoral and cell-mediated responses. Cytotoxic T cells respond to the antigen by developing into cytotoxic T lymphocytes that kill virus-infected cells and other altered cells. B cells and T cells also differentiate into memory cells (not shown) that are involved in subsequent responses.

If the female is immune to diseases such as polio or diphtheria, this placental transfer also gives the fetus and newborn immunity to these diseases. Certain other antibodies can pass from the female to her offspring in the first secretions (called colostrum) from the mammary glands. These maternal antibodies are essential for providing immunity to the newborn until its own immune system matures. Unfortunately naturally acquired passive immunity generally lasts only a short time (weeks or months at the most).

Artificially Acquired Immunity

Artificially acquired active immunity results when an animal is given an antigen preparation to induce the formation of antibodies and activated lymphocytes. This preparation is called a vaccine and the procedure is vaccination (immunization). A vaccine consists of a preparation of killed microorganisms; living, weakened (attenuated) microorganisms; or inactivated bacterial toxins

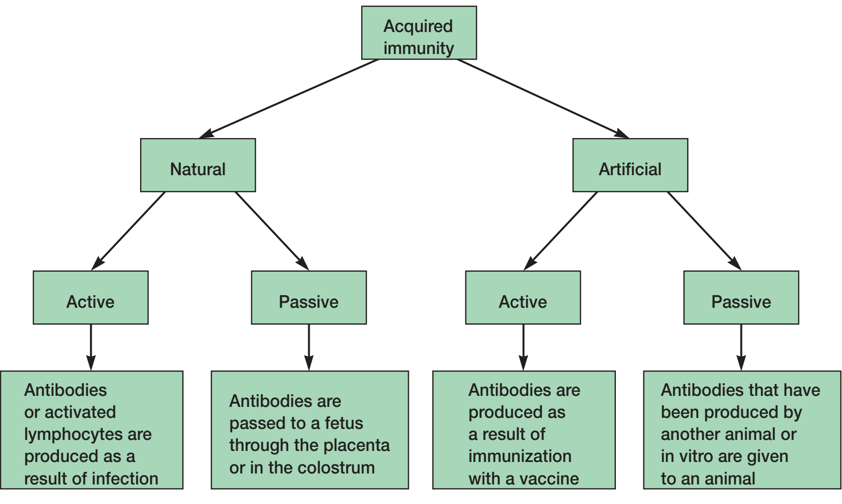

Figure 32.2 Specific Immunity. This illustration can be used as a guide to the text description of acquired immunity. The details of the immune system are astonishingly complex; many events have been omitted so that the overall organization of the immune response can be clearly seen.

(toxoids) that are administered to an animal to induce immunity artificially. Vaccines and immunizations are discussed in detail in section 33.1.

Artificially acquired passive immunity results when antibodies that have been produced either in an animal or by specific methods in vitro are introduced into a host. Although this type of immunity is immediate, it is short lived and lasts only a few weeks to a few months. An example would be botulinum antitoxin produced in a horse and given to a human suffering from botulism food poisoning.

1. The specific immune response can be divided into three related activities. What are these activities?
2. What distinguishes specific immunity from nonspecific resistance?
3. What are the two arms of specific immunity?
4. How does naturally acquired immunity occur? Contrast active and passive immunity.

32.2 Antigens

The immune system distinguishes between "self" and "nonself" through an elaborate recognition process. Prior to birth the body inventories the proteins and various other large molecules present (self) and removes most T cells specific for self-determinants. Subsequently self-substances can be distinguished from nonself substances, and lymphocytes can produce specific immunologic reactions against the latter, leading to their removal.

Substances, such as proteins, nucleoproteins, polysaccharides, and some glycolipids, that elicit an immune response and react with the products of that response are called **antigens** (**an**ti**body gen**erator). Most antigens are large, complex molecules with a molecular weight generally greater than about 10,000. The ability of a molecule to function as an antigen depends on its size and structural complexity.

Each antigen can have several **antigenic determinant sites** or **epitopes** (**figure 32.3**). Epitopes are the regions or sites in the antigen that bind to the antigen-binding site of a specific antibody or with a T cell receptor. Antibodies are formed most readily in response to determinants that project from the foreign molecule or to terminal residues of a specific polymer chain. Chemically, determinants include sugars, organic acids and bases, amino acid side chains, hydrocarbons, and aromatic groups.

The number of antigenic determinant sites on the surface of an antigen is its **valence.** The valence determines the number of antibody molecules that can combine with the antigen at one time. If one determinant site is present, the antigen is monovalent. Most antigens, however, have more than one determinant site or more than one copy of the same epitope, and are termed multivalent. Multivalent antigens generally elicit a stronger immune response than do monovalent antigens.

Haptens

Many small organic molecules are not antigenic by themselves but can become antigenic if they bond to a larger carrier molecule such as a protein (**figure 32.4**). They cannot stimulate antibody formation or T-cell responses by themselves, but can react with antibodies once formed. Such small molecules are termed **haptens** [Latin *haptein,* to grasp]. When lymphocytes are stimulated by the combined molecule, they can react to either the hapten or the larger carrier molecule. Conjugation of a hapten to a carrier protein makes the hapten immunogenic because the carrier protein can be processed and presented to specific T cells. As a result, both hapten-specific

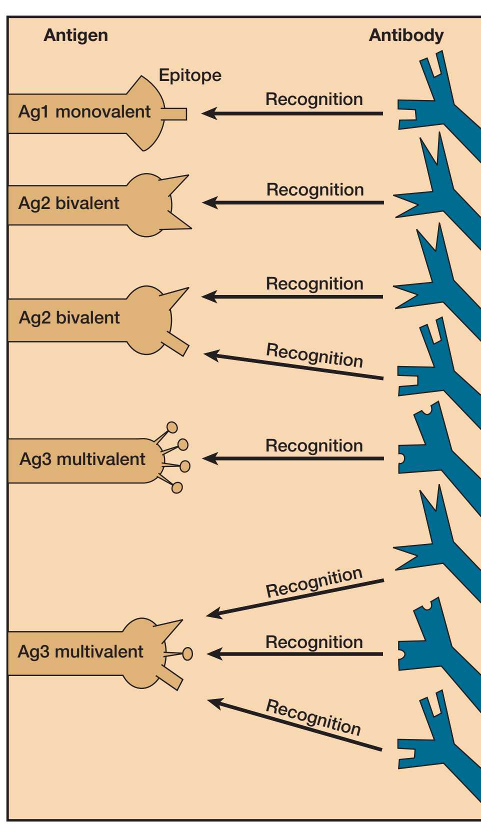

Figure 32.3 The Number of Antigenic Determinant Sites or Epitopes on an Antigen Is Its Valence. Antigen (Ag) molecules each have a set of antigenic determinants or epitopes. There is a single epitope on a monovalent antigen (Ag1). A bivalent antigen (Ag2) may have two of the same epitopes or two different ones, and a multivalent epitope (Ag3) may have many of the same epitopes or three or more different epitopes. In each case, however, a single antibody recognizes only the epitope rather than the whole bivalent or multivalent antigen.

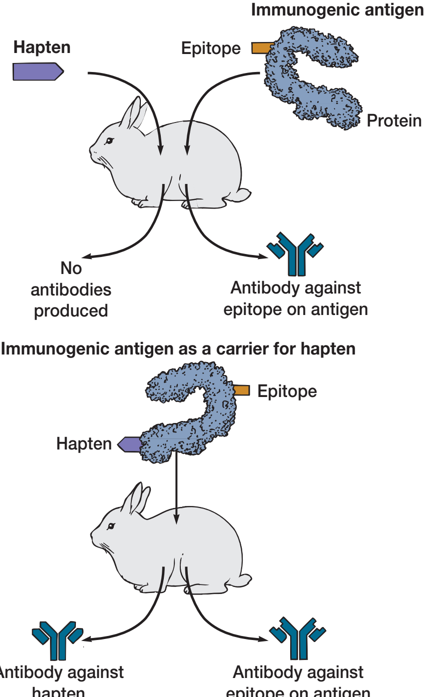

Figure 32.4 Effect of Carrier On Immunogenicity of Hapten. Haptens, as small molecules, are incapable of inducing an immune response when presented alone. This is markedly different from what occurs when a more complex, immunogenic antigen is presented. In this instance antibody directed against the specific epitope(s) of that antigen can be produced. However, if hapten is linked to a large molecule (which is used as a carrier), the hapten may then be immunogenic. Under these conditions antibody is produced, not only against the epitope of the immunogenic carrier molecule but against the epitope of the hapten as well.

and carrier-specific antibodies can be made. One example of a hapten is penicillin. By itself penicillin is not antigenic. However, when it combines with certain serum proteins of sensitive individuals, the resulting molecule does initiate a severe and sometimes fatal allergic immune reaction. In these instances the hapten is acting as an antigenic determinant on the carrier molecule.

Superantigens

Certain antigens provoke such a drastic immune response that they are termed **superantigens.** Superantigens are bacterial proteins. These superantigens nonspecifically stimulate T cells to proliferate by interacting with both class II major histocompatibility complex (section 32.4) products on antigen-presenting cells and the T-cell receptor (**figure 32.5**). Good examples of superantigens are the staphylococcal enterotoxins that cause food poisoning and the toxin that causes toxic shock syndrome. Superantigens cause symptoms by stimulating the release of massive quantities of cytokines from T cells and should be considered possible chronic associates in such diseases as rheumatic fever, arthritis, Kawasaki syndrome, atopic dermatitis, and one type of psoriasis.

Cluster of Differentiation Molecules (CDs)

The involvement of lymphocytes with the immune response and various diseases can be assessed by enumeration of specific cells bearing particular membrane proteins called ***c**luster of **d**ifferentiation molecules* **(CDs).** CDs are functional cell surface proteins or receptors that can be measured in situ and from peripheral blood, biopsy samples, or other body fluids. They often are used as a nomenclature system to differentiate between leukocyte subpopulations. To date, over 200 CDs have been characterized. **Table 32.1** summarizes some of the functions of several CDs.

CDs have both biological and diagnostic significance. In normal individuals the concentration of these molecules in serum is very low. When one's immune system is activated in response to disease, the concentration of these molecules usually rises and fluctuates. Monitoring CD levels may help in the management of the disease. For example, circulating levels of CD54 are directly related to the progress and prognosis of the skin cancer metastatic melanoma. CD23 is a B-cell growth factor, and elevated levels are associated with chronic lymphocytic leukemia. CD35 is a potent agent for the suppression of complement-dependent tissue injury in autoimmune inflammatory disease. Elevated levels of CD8 have been found in childhood lymphoid malignancies and in HIV-infected individuals. It has been established that the CD4 molecule is a cell surface receptor for HIV-1 (*see figure 38.9*), and considerable research is currently being done on the role of both cell-bound and soluble CD4 in AIDS.

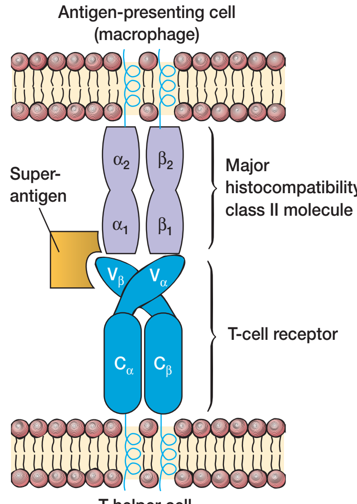

Figure 32.5 Superantigens. The most prevalent antigen receptor of T cells is the T-cell receptor. Superantigens stimulate T cells bearing a particular V_β element of the T-cell receptor, regardless of the nature of the V_α receptor element. They bind directly to the outer surface of the MHC class II molecule without being processed by the antigen-presenting cell. Thus a superantigen can activate many more T cells than a normal antigen does.

1. Define and give several examples of an antigen.
2. What is an antigenic-determinant site or epitope?
3. Describe a hapten.
4. What are some examples of the biological significance of cell-associated differentiation antigens?
5. Distinguish between "self" and "nonself" substances.

Table 32.1 Some Functional Examples of Cluster of Differentiation Molecules (CDs)

CD Molecule	Function
CD2	The CD2 molecule is a glycoprotein present on T cells, thymocytes and NK cells. It functions as an intercellular adhesion molecule and binds to the human leukocyte function-associated antigen-3 or LFA-3 (CD58). CD2 may be involved in the attachment of T_H cells to antigen-presenting cells and cytotoxic T cells to target cells, and in other cellular interactions. It also is a signal-transducing molecule and may help stimulate T cells to proliferate and secrete cytokines.
CD4	The CD4 molecule is a glycoprotein found primarily on T cells associated with helper/inducer regulatory functions and to a lesser degree on monocytes and macrophages. It is a cell adhesion molecule with great affinity for class II MHC.
CD8	The CD8 molecule is a polypeptide found on the surface of cytotoxic T cells. It is a molecule that participates in the interaction of class I MHC found on target cells.
CD23	CD23 is a protein found on the surface of IgM-bearing B cells, eosinophils, macrophages, and platelets. Soluble CD23 is a B-cell growth factor and upregulates IgE synthesis in conjunction with interleukin-4 released from T cells.
CD35	CD35 is a glycoprotein present on erythrocytes, PMNs, monocytes, all B and some T cells, mast cells, and in soluble form in the plasma. It is the receptor for complement C3b/C4b. The functions of CD35 vary according to the cell type possessing the receptor. For example, CD35 on erythrocytes binds immune complexes bearing C3b or C4b and promotes their clearance from the circulation. On B cells, CD35 augments the maturation of these cells into antibody-secreting cells. It also aids leukocytes in binding and phagocytosing C3b- or C4b-coated objects.
CD54	CD54, also known as intercellular adhesion molecule-1 (ICAM-1), is a protein that is an important early marker of immune activation and response. It is a ligand for the lymphocyte function-associated antigen-1 (LFA-1) found on lymphocytes, monocytes, and neutrophils. The CD54/LFA-1 interaction is important in T-cell–antigen-specific responses and lymphocyte emigration into inflammatory sites. CD54 also is found on mucosal epithelial cells and erythrocytes. Recent evidence suggests CD54 is the cellular receptor for the human rhinovirus and *Plasmodium falciparum*–infected erythrocytes.

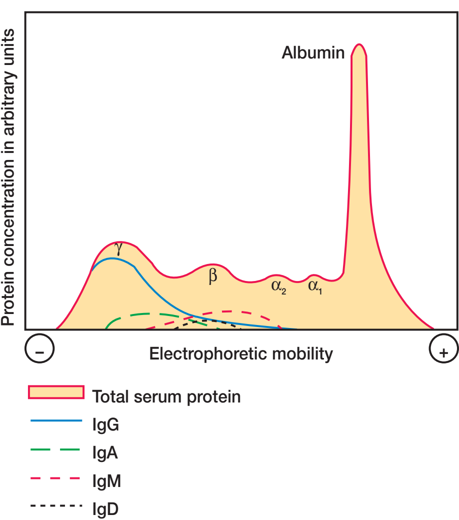

Figure 32.6 Electrophoresis of Human Serum. Schematic representation of electrophoretic results illustrating the distribution of serum proteins and four major classes of immunoglobulins.

32.3 Antibodies

An **antibody** or **immunoglobulin (Ig)** is a glycoprotein that is made in response to an antigen, and can recognize and bind to the antigen that caused its production. Antibodies are present in the blood serum, tissue fluids, and mucosal surfaces of vertebrate animals. Serum glycoproteins can be separated according to their charge by movement through a gel in an electric field and classified as albumin, alpha-1 globulin, alpha-2 globulin, beta globulin, and gamma globulin (**figure 32.6**). The gamma globulin band is relatively wide because it contains a heterogeneous class of immunoglobulins—namely, IgG, IgA, IgM, and IgD. These differ from each other in molecular size, structure, charge, amino acid composition, and carbohydrate content. Most antibodies in serum are in the IgG class. A fifth immunoglobulin class, the IgE class, has a similar mobility to IgD but cannot be represented quantitatively because of its low concentration in serum.

Immunoglobulin Structure

Antibodies have more than one antigen-combining site. For example, most human antibodies have two combining sites or are bivalent (figure 32.3). Some bivalent antibody molecules can combine to form multimeric antibodies that have up to 10 combining sites.

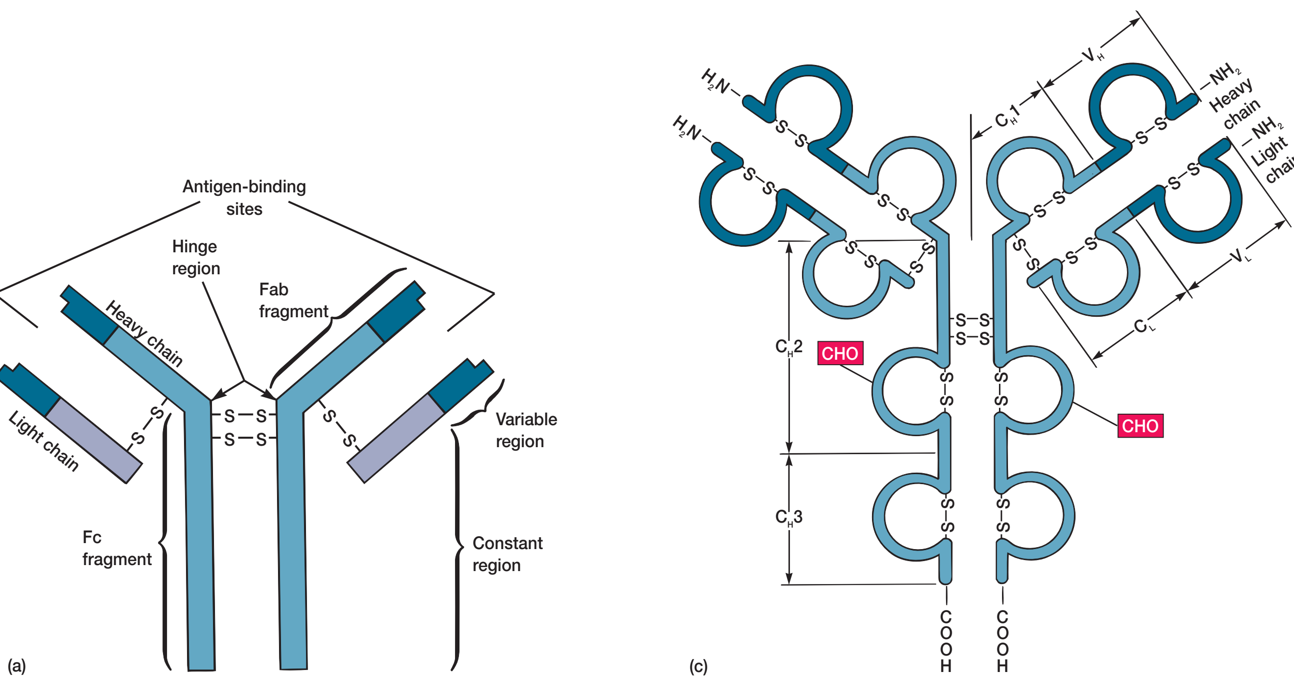
All immunoglobulin molecules have a basic structure composed of four polypeptide chains (**figure 32.7*a,b***) connected to each other by disulfide bonds. Each light chain usually consists of about 220 amino acids and has a mass of approximately 25 kDa. Each heavy chain consists of about 440 amino acids and has a mass of about 50 to 70 kDa. The heavy chains are structurally distinct for each immunoglobulin class or subclass. Both light and heavy chains contain two different regions. **Constant regions (C_L and C_H)** have amino acid sequences that do not vary significantly between antibodies of the same class. The **variable regions (V_L and V_H)** from different antibodies do have different sequences (figure 32.7*a*). It is the variable regions (V_L, V_H) that when folded together form the antigen binding sites.

The four chains are arranged in the form of a flexible Y with a hinge region. This hinge region allows the antibody molecule to assume a T shape. The stalk of the Y is termed the **crystallizable fragment (Fc)** and contains the site at which the antibody molecule can bind to a cell. The top of the Y consists of two **antigen-binding fragments (Fab)** that bind with compatible epitopes (or antigenic determinant sites). The Fc fragments are composed only of constant regions, whereas the Fab fragments have both constant and variable regions. Both the heavy and light chains contain several homologous units of about 100 to 110 amino acids. Within each unit, called a **domain,** disulfide bonds form a loop of approximately 60 amino acids (figure 32.7*c*). Interchain disulfide bonds also link heavy and light chains together.

More specifically the light chain may be either of two distinct forms called kappa (κ) and lambda (λ). These can be distinguished by the amino acid sequence of the carboxyl portion of the chain (**figure 32.8*a***). In human immunoglobulins, the carboxyl-terminal portion of all κ chains is identical; thus this region is termed the constant (C_L) domain. With respect to the lambda chains, there are four very similar sequences that define the subtypes λ_1, λ_2, λ_3, and λ_4 with their corresponding constant regions $C_\lambda1$, $C_\lambda2$, $C_\lambda3$, and $C_\lambda4$. Within the light chain variable domain are hypervariable regions or complementarity-determining regions (CDRs) that differ in amino acid sequence more frequently than the rest of the variable domain.

In the heavy chain the NH_2-terminal domain has a pattern of variability similar to that of the V_κ and V_λ domains and is termed the V_H domain. However, notice in figure 32.8*b* that this domain contains four hypervariable regions. The other domains of the heavy chains are termed constant domains and are numbered C_H1, C_H2, C_H3, and sometimes C_H4, starting with the domain next to the variable domain (figure 32.7*c*). The constant domains of the heavy chain form the constant (C_H) region. The amino acid sequence of this region determines the classes of heavy chains. In humans there are five classes of heavy chains designated by lowercase Greek letters: gamma (γ), alpha (α), mu (μ), delta (δ), and epsilon (ϵ). The properties of these heavy chains determine, respectively, the five immunoglobulin classes—IgG, IgA, IgM, IgD, and IgE. Each immunoglobulin class differs in its general properties, half-life, distribution in the body, and interaction with other components of the host's defensive systems.

Within two of the major human immunoglobulin classes, there are variants. These variations can be classified as (1) **isotypes,** referring to the variations in the heavy chain constant regions associated with the different classes that are normally present in all individuals (**figure 32.9*a***); (2) **allotypes,** the genetically controlled allelic forms of immunoglobulin molecules that are not present in all individuals (figure 32.9*b*); and (3) **idiotypes,**



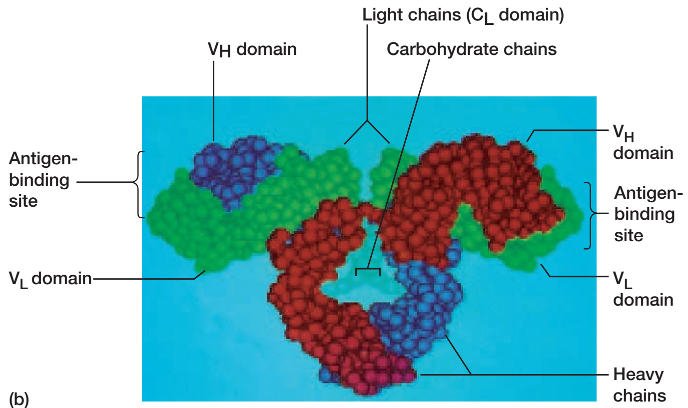


Figure 32.7 Immunoglobulin (Antibody) Structure. (**a**) An immunoglobulin molecule. The molecule consists of two identical light chains and two identical heavy chains held together by disulfide bonds. (**b**) A computer-generated model of antibody structure showing the arrangement of the four polypeptide chains. (**c**) Within the immunoglobulin unit structure, intrachain disulfide bonds create loops that form domains. All light chains contain a single variable domain (V_L) and a single constant domain (C_L). Heavy chains contain a variable domain (V_H) and either three or four constant domains (C_H1, C_H2, C_H3, and C_H4). The variable regions (V_H, V_L), when folded together in three-dimensions, form the antigen-binding sites.

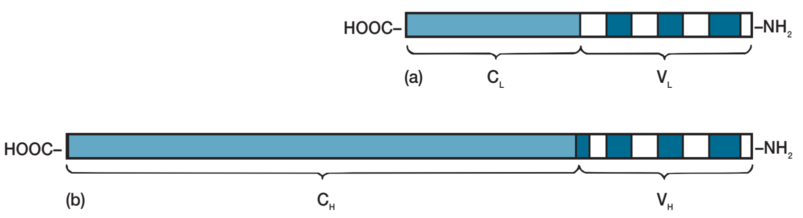

Figure 32.8 Constant and Variable Domains. Location of constant (C) and variable (V) domains within (**a**) light chains and (**b**) heavy chains. The dark blue bands represent hypervariable regions or complementarity-determining regions within the variable domains.

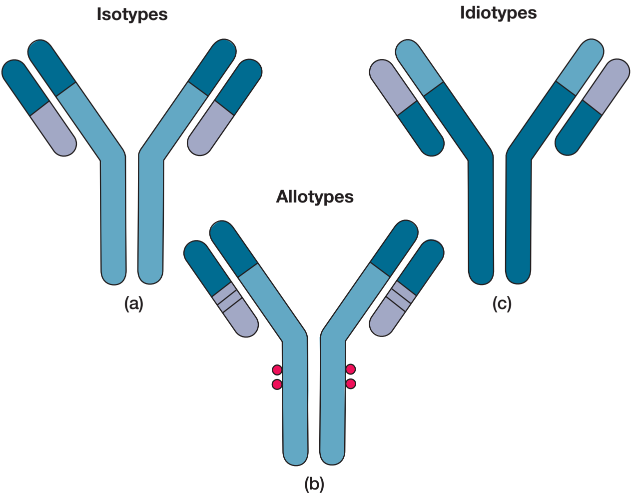

Figure 32.9 Variants of Immunoglobulins. (**a**) Isotypes represent variants present in serum of a normal individual. (**b**) Allotypes represent alternative forms coded for by different alleles and so are not present in all individuals of a population. (**c**) Idiotypes are individually specific to each immunoglobulin molecule.

referring to individual specific immunoglobulin molecules that differ in the hypervariable region of the Fab portion (figure 32.9*c*). The many variations of immunoglobulin structure reflect the diversity of antibodies generated by the immune response.

1. Name the two types of antibody light chains.
2. What is the function of the Fc region of an antibody? The Fab region?
3. What is the variable region of an antibody? The hypervariable or complementarity-determining region? The constant region?
4. What determines the class of heavy chain within an antibody?
5. Name the five immunoglobulin classes.
6. Distinguish between isotype, allotype, and idiotype.

Immunoglobulin Function

Each end of the immunoglobulin molecule has a different role. The Fab region is concerned with binding to antigen, whereas the Fc region mediates binding to host tissue, various cells of the immune system, some phagocytic cells, or the first component of the complement system. The binding of an antibody with an antigen usually does not cause destruction of the antigen or of the microorganism, cell, or agent to which it is attached. Rather the antibody serves to mark and identify the target for immunologic attack and to activate nonspecific immune responses that can destroy the target. For example, bacteria that are covered with antibodies are better targets for phagocytosis by neutrophils and macrophages. The alteration of the surface of bacteria, viruses, and other particles so that they can be more readily phagocytized is termed opsonization (*see section 31.8*). Immune destruction also is promoted by antibody-induced activation of the classical complement system as discussed in section 32.7.

Immunoglobulin Classes

IgG is the major immunoglobulin in human serum, accounting for 80% of the immunoglobulin pool (**figure 32.10*a***). IgG is present in blood plasma and tissue fluids. The IgG class acts against bacteria and viruses by opsonizing the invaders and neutralizing toxins. It is also one of the two immunoglobulin classes that activate complement by the classical pathway (section 32.7; *see also section 31.7*). IgG is the only immunoglobulin molecule able to cross the placenta and provide natural immunity in utero and to the neonate at birth.

There are four human IgG subclasses (IgG1, IgG2, IgG3, and IgG4) that vary chemically in their chain composition and the number and arrangement of interchain disulfide bonds (figure 32.10*b*). About 65% of the total serum IgG is IgG1, and 23% is IgG2. Differences in biological function have been noted in these subclasses. For example, IgG2 antibodies are opsonic and develop in response to antitoxins. Anti-Rh antibodies are of the IgG1 or IgG3 subclass. IgG1 and IgG3, upon recognition of their specific antigens, bind to receptors expressed on monocytes and macrophages and make them better phagocytes. These receptors are termed Fc receptors. The IgG4 antibodies function as skin-sensitizing immunoglobulins (*see section 33.2*).

IgM accounts for about 10% of the immunoglobulin pool. It is usually a polymer of five monomeric units (pentamer), each composed of two heavy chains and two light chains (**figure 32.11**). The monomers are arranged in a pinwheel array with the Fc ends in the center, held together by disulfide bonds and a special **J** (joining) **chain.** IgM is the first immunoglobulin made during B-cell maturation and is expressed as membrane-bound antibody on B cells. IgM is secreted into serum during a primary antibody response (figure 32.19*b*). Since IgM is so large, it does not leave the bloodstream or cross the placenta. IgM agglutinates bacteria, activates complement by the classical pathway, and enhances the ingestion of pathogens by phagocytic cells.

Although most IgM appears to be pentameric, around 5% or less of human serum IgM exists in a hexameric form. This molecule contains six monomeric units but seems to lack a J chain. Hexameric IgM activates complement up to twentyfold more effectively than does the normal pentameric form. It has been suggested that bacterial cell wall antigens such as gram-negative lipopolysaccharides may directly stimulate B cells to form hexameric IgM without a J chain. If this is the case, the immunoglobulins formed during primary immune responses (figure 32.19*a*) are less homogeneous than previously thought.

IgA accounts for about 15% of the immunoglobulin pool. Some IgA is present in the serum as a monomer of two heavy and two light chains. Most IgA, however, occurs in mucous secretions as a polymerized dimer held together by a J chain (**figure 32.12**). IgA has special features that are associated with secretory mucosal surfaces. IgA, when transported from the mucosal-associated

lymphoid tissue to mucosal surfaces, acquires a protein termed the secretory component. **Secretory IgA (sIgA),** as the modified molecule is now called, is the primary immunoglobulin of mucosal-associated lymphoid tissue (*see figure 31.10*). Secretory IgA is also found in saliva, tears, and breast milk. In these fluids and related body areas, sIgA plays a major role in protecting surface tissues against infectious microorganisms by the formation of an immune barrier. For example, in breast milk sIgA helps protect nursing newborns. In the intestine, sIgA attaches to viruses, bacteria, and protozoan parasites such as *Entamoeba histolytica.* This prevents pathogen adherence to mucosal surfaces and invasion of host tissues, a phenomenon known as immune exclusion. In addition, sIgA binds to antigens within the mucosal layer of the small intestine; subsequently the antigen-sIgA complexes are excreted through the adjacent epithelium into the gut lumen. This rids the body of locally formed immune complexes and decreases their access to the circulatory system. Secretory IgA also plays a role in the alternative complement pathway (*see section 31.7*).

IgD is an immunoglobulin found in trace amounts in the blood serum. It has a monomer structure (**figure 32.13**) similar to IgG. IgD antibodies do not fix complement and cannot cross the placenta, but they are abundant in combination with IgM on the surface of B cells and bind antigens, thus signaling the B cell to start antibody production.

IgE (**figure 32.14**) makes up only a small percent of the total immunoglobulin pool. The classic skin-sensitizing and anaphylactic antibodies belong to this class. IgE molecules have four constant region domains ($C_\epsilon1$, $C_\epsilon2$, $C_\epsilon3$, and $C_\epsilon4$) on their heavy chains. The Fc portion of the $C_\epsilon4$ chain can bind to special Fc_ϵ receptors on mast cells and basophils. When two IgE molecules on the surface of these cells are cross-linked by binding to the same antigen, the cells degranulate. This degranulation releases histamine and other pharmacological mediators of anaphylaxis. It also stimulates eosinophilia and gut hypermotility (increased rate of movement of the intestinal contents) that aid in the elimination of helminthic parasites. Thus, though IgE is present in small amounts, this class of antibodies has very potent biological capabilities. Anaphylaxis (pp. 768–69)

Table 32.2 summarizes some of the more important physicochemical properties of the human immunoglobulin classes.

1. What does antigen binding accomplish in a host?
2. Give the major functions of each immunoglobulin class.
3. Why is the structure of IgG considered the model for all five immunoglobulin classes?
4. Which immunoglobulin can cross the placenta?
5. Which immunoglobulin is most prevalent in the immunoglobulin pool? The least prevalent?

Diversity of Antibodies

One unique property of antibodies is their remarkable diversity. According to current estimates each human can synthesize more than 10^{11} (100 billion) different kinds of antibodies. How is this diversity generated? The answer is threefold: rearrangement of antibody gene segments, somatic mutations, and generation of different codons during antibody gene splicing.

Immunoglobulin genes are split or interrupted genes with many gene segments (*see section 12.1*). Embryonic B cells contain a small number of gene segments, close together on the same chromosome, that determine the constant (C) region of the light chains (**figure 32.15**). Separated from them, but on the same chromosome, is a larger cluster of segments that determines the variable (V) region of the light chains. During B-cell differentiation, one segment for the constant region is joined by a process of recombination mediated by specific proteins to one segment for the variable region. This splicing produces a complete light-chain antibody gene. A similar splicing mechanism also occurs to join the constant and variable segments of the heavy chains.

Because the light-chain genes actually consist of three parts, and the heavy-chain genes consist of four, the formation of a finished antibody molecule is slightly more complicated than previ-

Table 32.2 Physicochemical Properties of Human Immunoglobulin Classes

Property	*Immunoglobulin Classes*				
	IgG[a]	IgM	IgA[b]	IgD	IgE
Heavy chain	γ_1	μ	α_1	δ	ε
Mean serum concentration (mg/ml)	9	1.5	3.0	0.03	0.00005
Percent of total antibody	80–85	5–10	5–15	<1	0.002–0.05

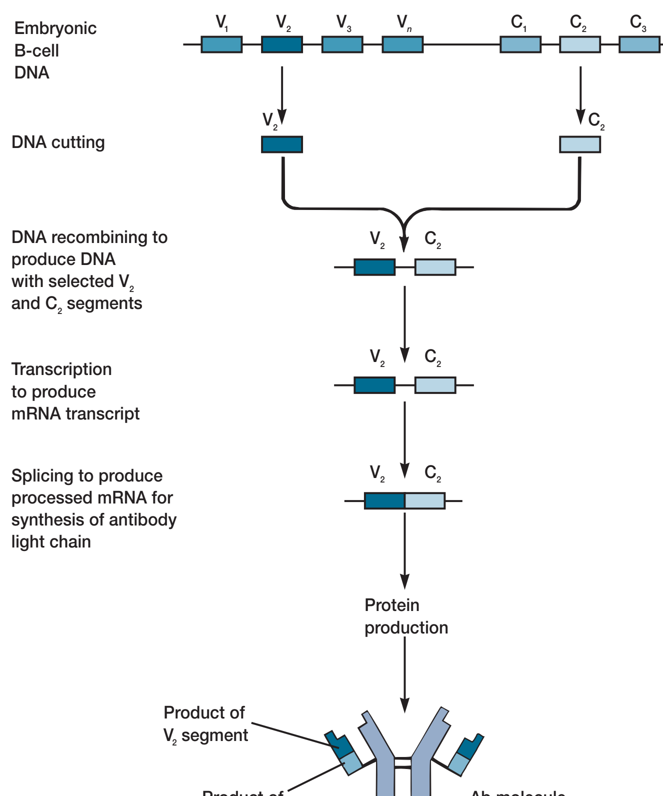
[c]sIgA = 360 – 400 kDa

[d]Time required for half of the antibodies to disappear.



ously outlined (**figure 32.16**). The germ line DNA for the light-chain gene contains multiple coding sequences called V and J (joining) regions. During the differentiation of a B cell, a deletion (which is variable in length) occurs that joins one V gene segment with one J segment. This DNA joining process is termed combinatorial joining because it can create many combinations of the V and J regions. When the light-chain gene is transcribed, transcription continues through the DNA region that encodes for the constant portion of the gene. RNA splicing subsequently joins the VJ and C regions, creating mRNA.

Combinatorial joining in the formation of a heavy-chain gene occurs by means of DNA splicing of the heavy-chain counterparts of V and J along with a third set of D (diversity) sequences (**figure 32.17*a***). Initially, all heavy chains have the μ type of constant region. This corresponds to antibody class IgM (figure 32.17*b*). Another DNA splice joins the VDJ region with a different constant region that can subsequently change the class of antibody produced by the B cell (figure 32.17*c*).

Figure 32.15 Gene Shuffling and Antibody Diversity. Antibody diversity is partly the result of the shuffling of gene sequences that code for both heavy and light chains. This drawing shows the shuffling, cutting, and splicing process used to produce an assembled light chain of the antibody molecule.

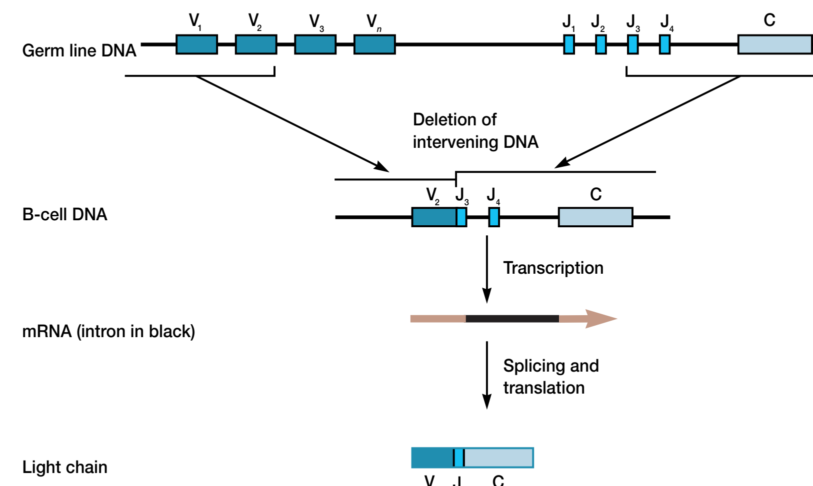


Figure 32.16 Light Chain Production in a Mouse. One V segment is randomly joined with one J-C region by deletion of the intervening DNA. The remaining J segments are eliminated from the RNA transcript during RNA processing. An intron is a segment of DNA occurring between expressed regions of genes.

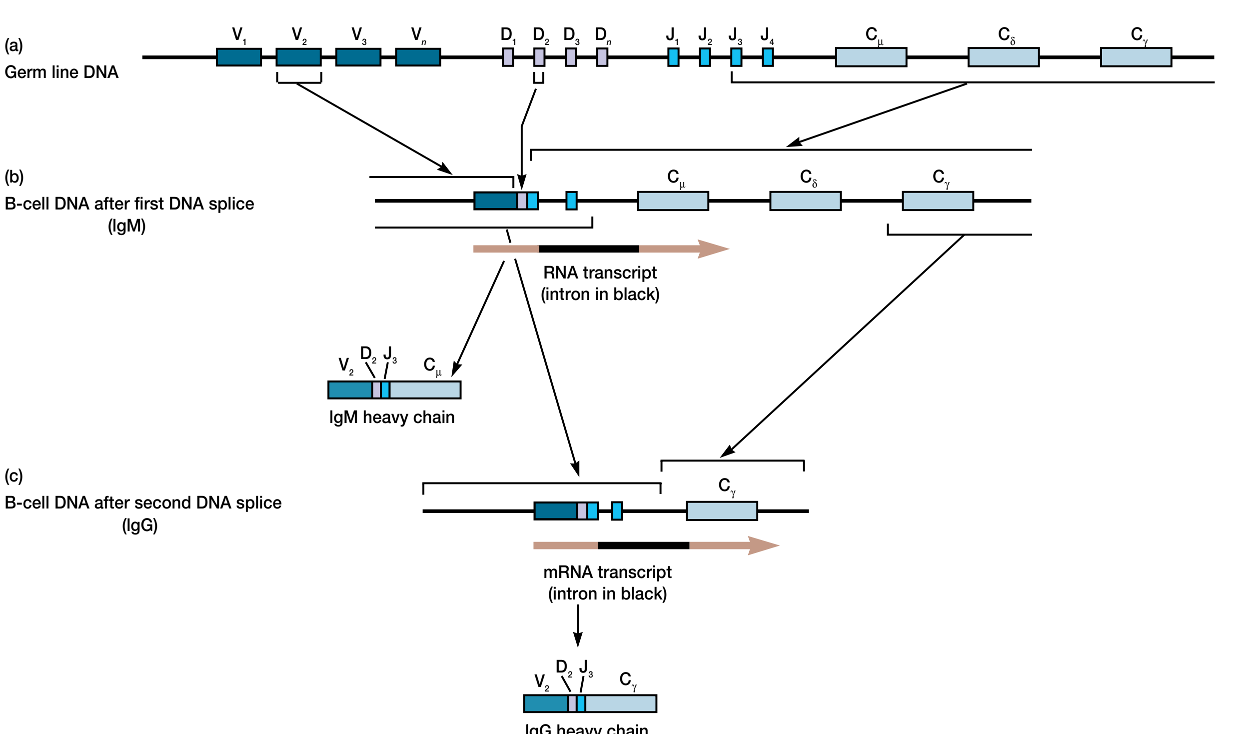

Figure 32.17 The Formation of a Gene for the Heavy Chain of an Antibody Molecule. See text for further details.

The amount of antibody diversity in the mouse that can be generated by combinatorial joining is shown in **table 32.3.** In this animal the κ light chains can be formed from any combination of about 250 to 350 V_κ and 4 J_κ regions giving a maximum of approximately 1,400 different κ chains. The λ chains have their own V_λ and J_λ regions but smaller in number than their κ counterparts (6 different λ chains). The heavy chains have approximately 250 to 1,000 V_H, 10 to 30 D, and 4 J_H regions, giving a maximum of 120,000 different combinations. Because any light chain can combine with any heavy chain, there will be a maximum of 2×10^8 possible κ chain antibody types.

Table 32.3 Number of Antibodies Possible through the Combinatorial Joining of Mouse Germ Line Genes[a]

λ light chains	V regions = 2 J regions = 3 Combinations = 2 × 3 = 6
κ light chains	V_κ regions = 250–350 J_κ regions = 4 Combinations = 250 × 4 = 1,000 = 350 × 4 = 1,400
Heavy chains	V_H = 250–1,000 D = 10–30 J_H = 4 Combinations = 250 × 10 × 4 = 10,000 = 1,000 × 30 × 4 = 120,000
Diversity of antibodies	κ-containing: 1,000 × 10,000 = 10^7 1,400 × 120,000 = 2×10^8 λ-containing: 6 × 10,000 = 6×10^4 6 × 120,000 = 7×10^5

[a]Approximate values.

The value of 2×10^8 different antibodies is actually an underestimate because antibody diversity is further augmented by two processes:

1. The V regions of germ line DNA are susceptible to a high rate of somatic mutation during B-cell development in response to an antigen challenge. These mutations allow B-cell clones to produce antibodies with somewhat different polypeptide sequences.
2. The junction for either VJ or VDJ splicing in combinatorial joining can occur between different nucleotides and thus generate different codons in the spliced gene. For example, one VJ splicing event can join the V sequence CCTCCC with the J sequence TGGTGG in two ways:

   CCTCCC + TGGTGG = CCGTGG,

   which codes for the amino acids proline and tryptophan; and

   CCTCCC + TGGTGG = CCTCGG,

   which codes for proline and arginine. Thus the same VJ joining could produce polypeptides differing in a single amino acid.

1. How many chromosomes encode for antibody production in humans?
2. What is the name of each gene segment set that encodes for the different regions of antibody chains?
3. Describe what is meant by combinatorial joining of VJ and C regions of a chromosome.
4. In addition to combinatorial joining, what other two processes play a role in antibody diversity?

Specificity of Antibodies

As noted previously, combinatorial joinings, somatic mutations, and variations in the splicing process generate the great variety of antibodies produced by mature B cells. From a large, diverse B-cell pool, specific cells are stimulated by antigens to reproduce and form a B-cell clone whose cells contain the same genetic information. This is known as the **clonal selection theory,** a hypothesis to explain immunologic specificity and memory.

The existence of a B-cell **clone** (a population of cells derived asexually from a single parent) that can respond to an antigen by producing the correct antibody is the first tenet of this theory. The lymphoid system is thus considered to contain many B-cell clones, each clone able to recognize a specific antigen. The antigen selects the appropriate B cell to form a clone (hence the phrase "clonal selection"), and the cells with other antigen specificities are unaffected.

According to the second tenet, each B-cell is genetically programmed to respond to its own distinctive antigen before the antigen is introduced. The particular antibody an individual B cell can produce is integrated into the plasma membrane of that B cell and acts as a specific surface receptor for the corresponding antigen molecule. The reaction of the antibody and antigen initiates the differentiation and multiplication of the B cell to form two different cell populations: plasma cells and **memory B cells (figure 32.18).**

Plasma cells are literally protein factories that produce about 2,000 antibodies per second in their brief five- to seven-day life span. Memory B cells can initiate the antibody-mediated immune response upon detecting the particular antigen specific for their antibody molecules. These memory cells circulate more actively from blood to lymph and live much longer (years or even decades) than plasma cells. Memory cells are responsible for the immune system's rapid secondary antibody response (figure 32.19) to the same antigen. Finally, memory B cells and plasma cells are usually not produced unless the B cell has interacted with, and received cytokine signals from, activated helper T cells (figure 32.1).

Sources of Antibodies

The need for pure homogeneous antibodies has increased dramatically in recent years. Currently antibodies are produced either naturally by immunization or artificially through hybridoma formation.

Immunization

Specific antibodies can be produced naturally by the immunization of domestic animals or human volunteers. Whatever the source, purified antigen is injected into the host. The host's immune system recognizes and responds to the antigen, and its B cells proliferate and differentiate to produce specific antibodies. To promote the efficiency of antigen stimulation of antibody production, the antigen may be mixed with an **adjuvant** [Latin *adjuvans,* aiding], which enhances the rate and quantity of antibody produced. Following repeated antigen injections at regular intervals, blood is withdrawn from the host and allowed to clot. The fluid that remains after the

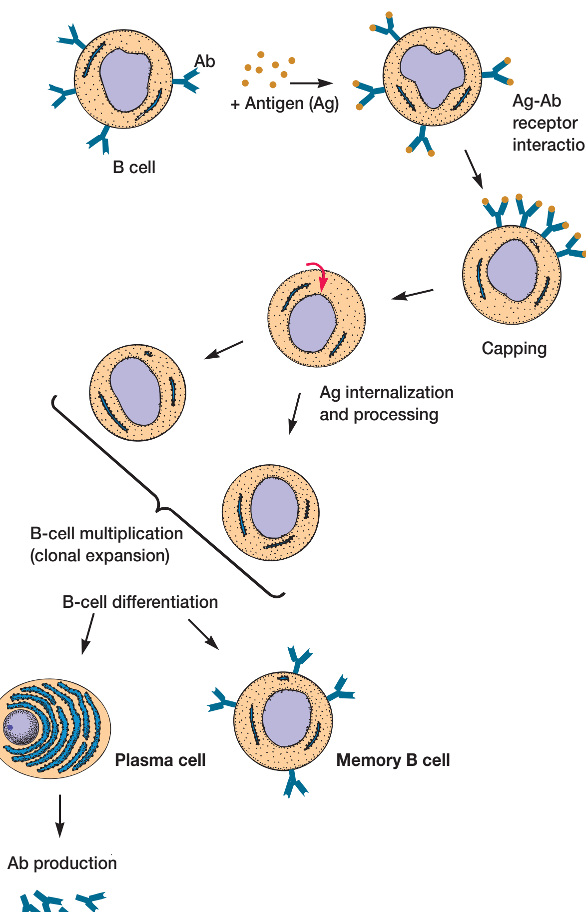

Figure 32.18 Clonal Selection. The immune system can respond specifically to a myriad of possible antigens, whether they are individual molecules or are attached to pathogens and abnormal cells such as cancer cells. B cells or B lymphocytes constantly roam the body, particularly the blood and lymphoid tissues. Each B cell synthesizes only one of the millions of possible antibodies and displays this antibody on its surface. When the antigen meets a B cell having a surface antibody of the proper specificity (top left), it complexes with the antibody and capping occurs. (Capping is the regional aggregation of antibodies on the surface of the cell following Ag-Ab interaction.) The antigen is then internalized; the B cell swells and begins to divide rapidly, producing a B-cell clone. The activated B-cell clone differentiates into plasma cells and memory cells. Plasma cells form the specific antibody that immediately attacks the antigen that provoked its formation. Memory B cells persist in the body and boost the immune system's readiness to eliminate the same antigen if it presents itself in the future. Most antibody responses also require signals from T helper cells (not shown).

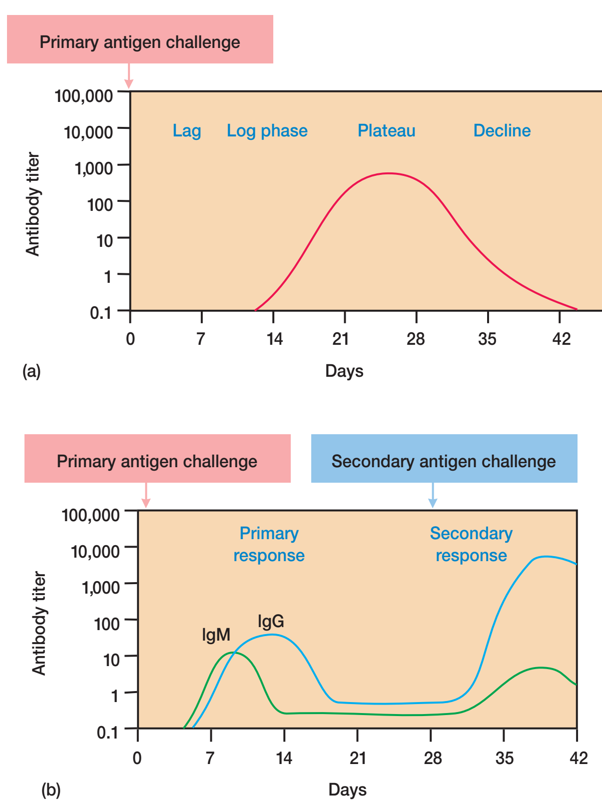

Figure 32.19 Primary and Secondary Antibody Responses. (**a**) The four phases of a primary antibody response. (**b**) Comparison of primary and secondary antibody responses. Note that the secondary response to the antigen is both faster and greater than the primary response. T-cell–mediated responses exhibit similar immunologic memory.

blood clots is the **serum** (Latin "whey"). Because this serum has been obtained from an immunized host and contains the desired antibodies, it is called **antiserum.**

Although antiserum is a major and convenient source of antibodies, its usefulness is limited in three ways:

1. Antibodies obtained by this method are polyclonal; they are produced by several B-cell clones and have different specificities. This decreases their sensitivity to particular antigens and results in some degree of cross-reaction with closely related antigen molecules.
2. Second or repeated injections of antiserum from one species into another can cause serious allergic or hypersensitivity reactions.
3. Antiserum contains a mixture of antibodies (figure 32.6), not all of which are of interest in a given immunization.

The Primary Antibody Response

During immunization procedures (and also in naturally acquired immunity), there is an initial lag phase of several days following a primary challenge with an antigen. During the lag phase no antibody can be detected in the blood (**figure 32.19*a***). The antibody **titer,** which is the reciprocal of the highest dilution of an antiserum that gives a positive reaction in the test being used, rises logarithmically to a plateau during the second or log phase. In the plateau phase the antibody titer stabilizes. This is followed by a decline phase, during which antibodies are naturally metabolized or bound to the antigen and cleared from the circulation. During the primary antibody response, IgM appears first, then IgG (figure

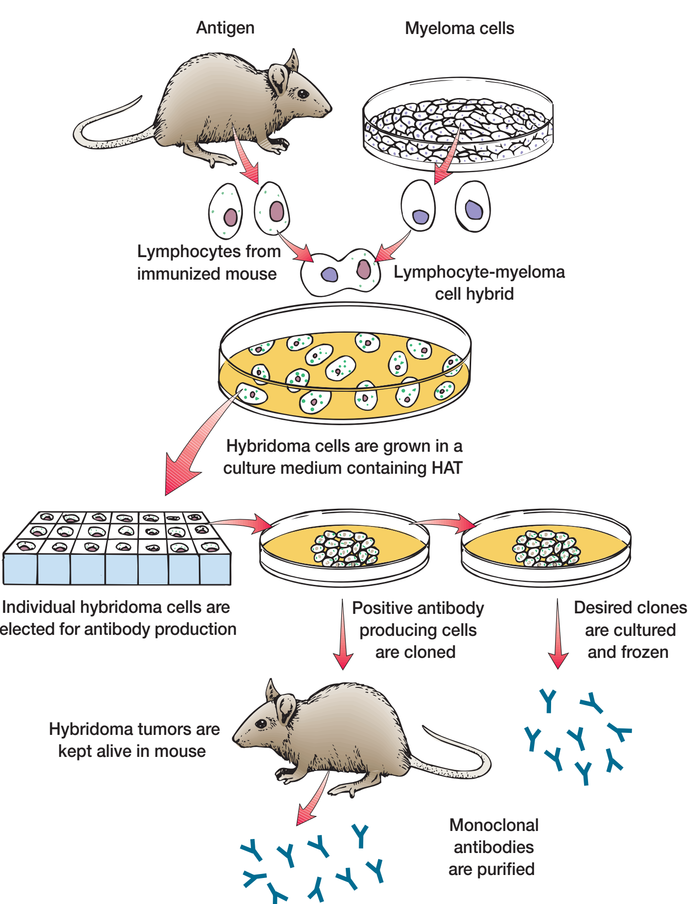

Figure 32.20 Technique for the Production of Monoclonal Antibodies. Lymphocytes are fused with special mutant myeloma cells, yielding hybridomas. Each of them secretes a single, "monoclonal" antibody. Once the hybridoma secreting the desired antigen is identified, it is cloned to generate many antibody-secreting cells that yield the huge quantity of a single antibody needed in medicine or science. Some hybridoma cells may be stored frozen and later cloned for antibody production or kept alive in laboratory animals.

32.19*b*). The affinity of the antibodies for the antigen's determinants is low to moderate during this primary antibody response.

The Secondary Antibody Response

The primary antibody response primes the immune system so that it possesses specific immunologic memory through its clones of memory B cells. Upon secondary antigen challenge (figure 32.19*b*), the B cells mount a heightened secondary or **anamnestic** [Greek *anamnesis,* remembrance] **response** to the same antigen. Compared to the primary antibody response, the secondary antibody response has a shorter lag phase, a more rapid log phase, persists for a longer plateau period, attains a higher IgG titer, and produces antibodies with a higher affinity for the antigen (affinity maturation through somatic hypermutation).

Hybridomas

The limitations of antiserum as a source of antibodies have been overcome with the development of hybridoma techniques to manipulate and culture various mammalian cells that synthesize antibodies in vitro. Each cell and its progeny normally produce a **monoclonal antibody (MAb)** of a single specificity.

The methodology of one of these techniques is illustrated in **figure 32.20.** Animals (usually mice or rats) are immunized with antigens as discussed previously. Once the animals are producing a large quantity of antibodies, their spleens are removed and antibody-producing B and plasma cells (lymphocytes) isolated. These lymphocytes are then fused with myeloma cells by the addition of polyethylene glycol, which promotes membrane fusion. **Myeloma cells** are cancerous plasma cells that can readily be cultivated; mutant myeloma cells incapable of producing immunoglobulins are used. These fused cells, derived from lymphocytes and myeloma cells, are called **hybridomas** (they are hybrids of the two cells).

The fusion mixture is then transferred to a culture medium containing a combination of **h**ypoxanthine, **a**minopterin, and **t**hymidine (HAT). Aminopterin is a poison that blocks a specific metabolic pathway in cells. Myeloma cells lack an enzyme that allows their growth in the presence of aminopterin. However, the pathway is bypassed in lymphoid cells provided with the intermediate metabolites hypoxanthine and thymidine. As a result the hybridomas grow in the HAT medium but the myeloma cells die because they have a metabolic defect and cannot employ the bypass or salvage pathway.

When the culture is initially established using the HAT medium, it contains lymphocytes, myeloma cells, and hybridomas. The unfused lymphoid cells die naturally in culture within a week or two, and the myeloma cells die in the HAT as just described. In contrast, the fused cells survive because they have the immortality of the myeloma and the metabolic bypass of the lymphoid cells. Hybridomas that have the antibody-producing

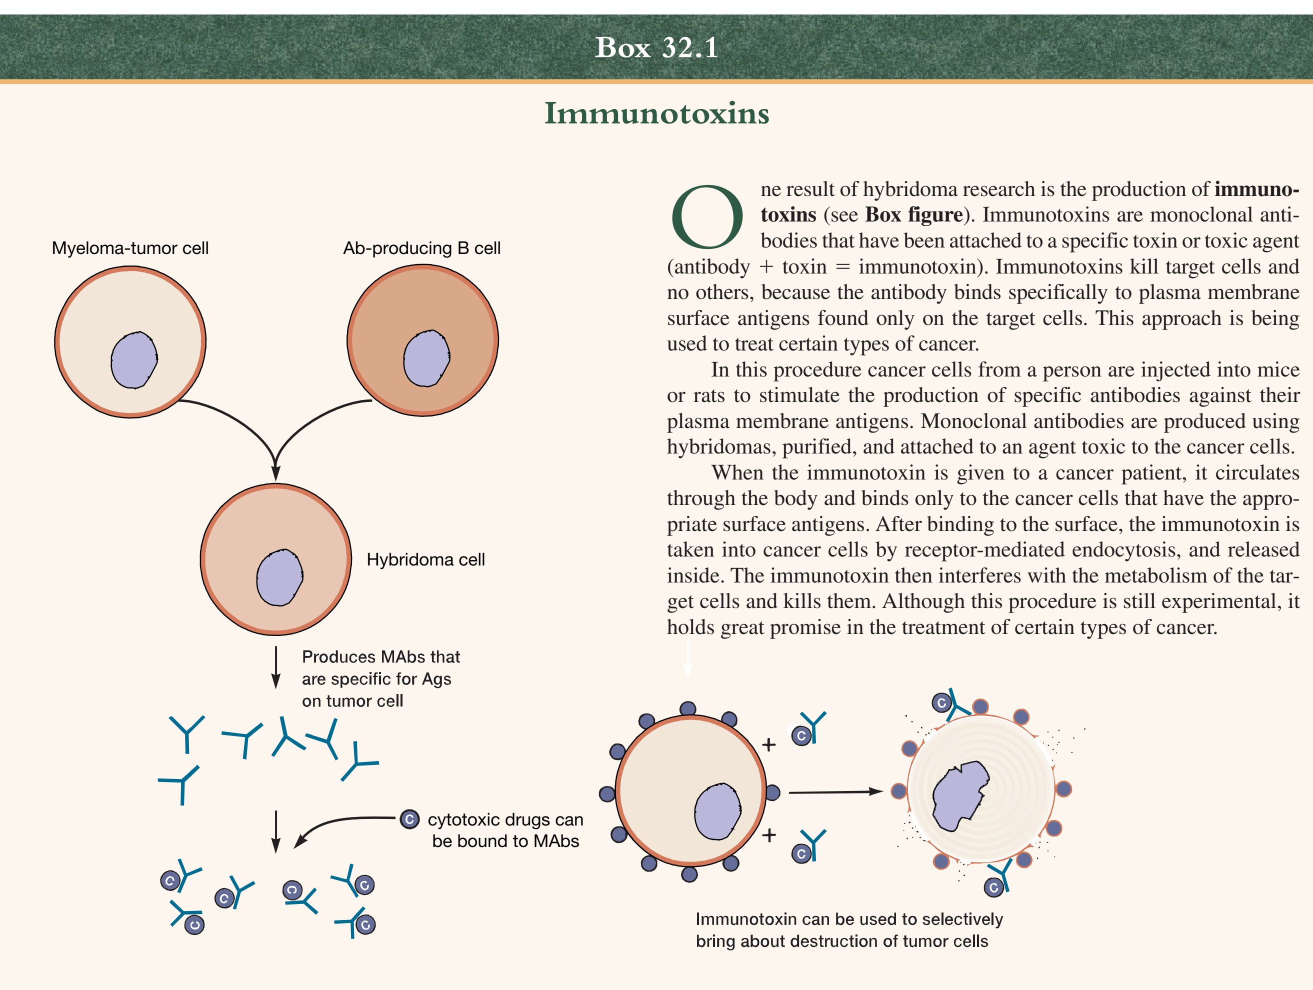
Box 32.1

Immunotoxins

One result of hybridoma research is the production of **immunotoxins** (see **Box figure**). Immunotoxins are monoclonal antibodies that have been attached to a specific toxin or toxic agent (antibody + toxin = immunotoxin). Immunotoxins kill target cells and no others, because the antibody binds specifically to plasma membrane surface antigens found only on the target cells. This approach is being used to treat certain types of cancer.

In this procedure cancer cells from a person are injected into mice or rats to stimulate the production of specific antibodies against their plasma membrane antigens. Monoclonal antibodies are produced using hybridomas, purified, and attached to an agent toxic to the cancer cells.

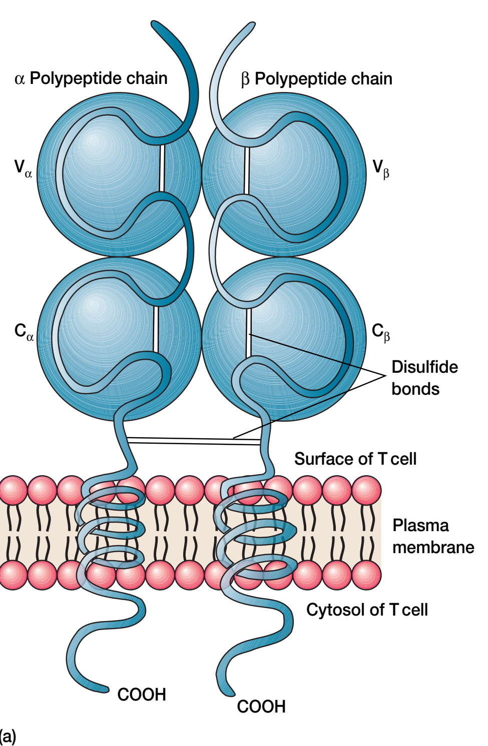
When the immunotoxin is given to a cancer patient, it circulates through the body and binds only to the cancer cells that have the appropriate surface antigens. After binding to the surface, the immunotoxin is taken into cancer cells by receptor-mediated endocytosis, and released inside. The immunotoxin then interferes with the metabolism of the target cells and kills them. Although this procedure is still experimental, it holds great promise in the treatment of certain types of cancer.



capacity of the original lymphoid cells are randomly placed in culture wells. The wells are individually tested for production of the desired antibody, and, if positive, the cells within the well provide clones of immortal cells, all producing the same monoclonal antibody.

Monoclonal antibodies currently have many applications. For example, they are routinely used in the typing of tissue, in the identification and epidemiological study of infectious microorganisms, in the identification of tumor and other surface antigens, in the classification of leukemias, and in the identification of functional populations of different types of T cells. Anticipated future uses include (1) passive immunizations against infectious agents and toxic drugs, (2) tissue and organ graft protection, (3) stimulation of tumor rejection and elimination, (4) manipulation of the immune response, (5) preparation of more specific and sensitive diagnostic procedures, and (6) delivery of antitumor agents (immunotoxins) to tumor cells (**Box 32.1**).

1. Describe the major two tenets of the clonal selection theory.
2. What two cell populations are produced by a B cell after it initially reacts with an antigen?
3. What is the function of an adjuvant?
4. Describe the difference between serum and antiserum.
5. What is a hybridoma? How is it made?



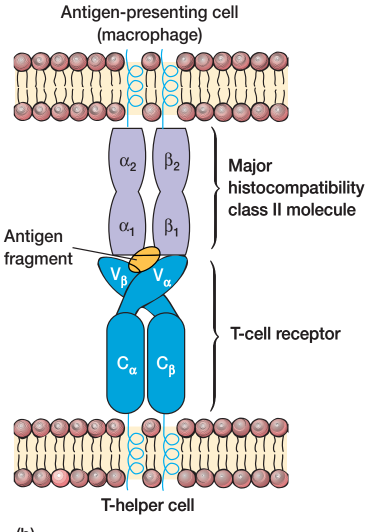


Figure 32.21 The Role of the T-cell Receptor Protein in T helper Cell Activation. (**a**) A schematic illustration of the proposed overall structure of the antigen receptor site on a T-cell plasma membrane. (**b**) An antigen-presenting cell begins the activation process by displaying an antigen fragment (e.g., peptide) on its surface as part of a complex with the histocompatibility molecules. A T-helper cell is activated after the variable region of its receptor (designated V_α and V_β) reacts with the antigen fragment and MHC molecule on the presenting cell surface.

32.4 T-Cell Biology

T cells are major players in the cell-mediated immune response (figure 32.1), and also have a major role in B cell activation. They are immunologically specific, can carry a vast repertoire of immunologic memory, and can function in a variety of regulatory and effector ways.

T-Cell Receptors

T cells have specific **T-cell receptors (TCRs)** for antigens on their plasma membrane surface. The receptor site is composed of two parts, an alpha polypeptide chain and a beta polypeptide chain (**figure 32.21*a***). Each chain is stabilized by disulfide bonds. The receptor is anchored in the plasma membrane and parts of the α and β chains extend into the cytoplasm. The recognition sites of the T-cell receptor extend out from the membrane and have a terminal variable section complementary to antigen fragments. T cells respond to antigen fragments exposed on the surfaces of **antigen-presenting cells (APCs),** most of which are macrophages, dendritic cells, and B cells. These cells scavenge foreign materials (antigens or pathogens) from the blood and tissues and digest them. Inside the cells small pieces of the antigens bind to a special class of proteins called major histocompatibility complex (MHC) class II molecules (section 32.5). The MHC-antigen complex is then transported to the surface of the presenting cell and displayed to passing lymphocytes known as T-helper cells (figure 32.21*b*). Some knowledge of these histocompatibility molecules is thus required before T-cell–macrophage interactions and T-cell biology can be understood.

Major Histocompatibility Complex (MHC)

A woman dies because her body has rejected a kidney transplant; a man is crippled with rheumatoid arthritis; an African child goes into a coma that is brought on by cerebral malaria; and another child dies because of an immunodeficiency. Although these four clinical situations are diverse, they all have one thing in common: the cause of all of them involves the human version of the major histocompatibility complex. Malfunction of this system, which is at the basis of these situations, has such wide-ranging effects not only because of the system's role in the specific immune response, but also because of its genetic complexity.

The **major histocompatibility complex (MHC)** is a collection of genes on chromosome 6 in humans and chromosome 17 in mice. This term is derived from the Greek word for tissue [*histo*] and the ability to get along [compatibility]. The MHC is called the **human leukocyte antigen (HLA) complex** in humans and **H-2 complex** in mice. Almost all human tissue cells contain MHC molecules on their plasma membranes. MHC molecules can be divided into three classes: class I molecules are found on almost all types of nucleated body cells; class II molecules appear only on those leukocytes involved in T helper cell-related immune responses (macrophages, antigen-presenting cells [dendritic cells], and B cells); and class III molecules include various secreted proteins that have immune functions (complement components C2,

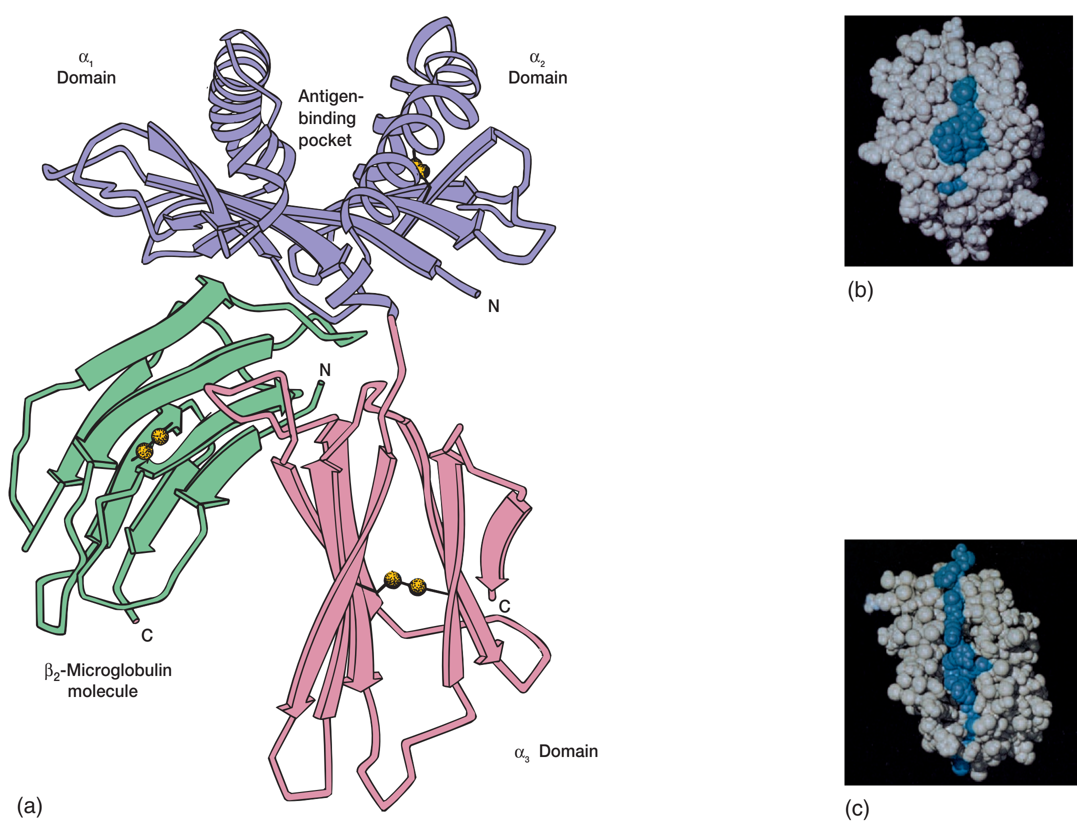

Figure 32.22 Class I Major Histocompatibility Molecule Structure. (**a**) This side view of the molecule shows the arrangement of its three domains (α_1, α_2, α_3) and the β_2-microglobulin molecule. **(b)** Class I MHC molecules (space-filling model) can hold only short peptides (shown in blue) because the binding site is closed off. **(c)** Since the binding site is open on both ends, class II MHC molecules (space-filling model) can bind to peptides (shown in blue) of different lengths.

C4a, and factor B), two steroid 21-hydroxylase enzymes (21-OHA and 21-OHB), the inflammatory cytokines, tumor necrosis factors α and β, and two heat-shock proteins. Unlike class I and II MHC molecules, the class III molecules are not membrane proteins, are not related to class I or II molecules, and have no role in antigen presentation. Thus they will not be discussed further.

Class I MHC molecules (**figure 32.22*a***) consist of a complex of two protein chains, one with a mass of 45 kDa (the heavy chain) and the other with a mass of 12 kDa (β_2-microglobulin). The two chains contain four regions. The outer segment of the heavy chain can be divided into three functional domains, designated α_1, α_2, and α_3. The β_2-microglobulin (β_2m) protein and α_3 segment of the heavy chain are noncovalently associated with one another and are close to the plasma membrane. A small segment of the heavy chain is attached to the membrane by a short amino acid sequence that extends into the cell interior, but the rest of the protein protrudes to the outside. The α_1 and α_2 domains lie to the outside and form the antigen-binding pocket.

Class II MHC molecules are also transmembrane proteins consisting of α and β chains of mass 34 kDa and 28 kDa, respectively. Both chains are folded to give two domains.

Although MHC class I and class II molecules are structurally distinct, both fold into very similar shapes (figure 32.22*b,c*). Each MHC molecule has a deep groove into which a short peptide can bind. Because this peptide is not part of the MHC molecule, it can vary from one MHC molecule to the next. On healthy cells all of these peptides come from self-proteins. The presence of foreign peptides (antigen fragments) in the MHC groove alerts the immune system and activates T cells, which in turn activate macrophages.

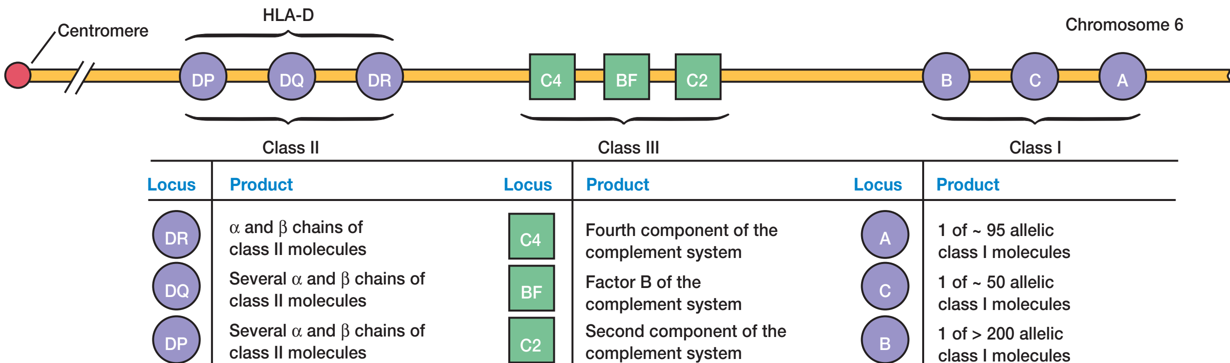

Figure 32.23 **Major Histocompatibility Complex.** The MHC region of human chromosome 6 and the gene products associated with each locus.

Class I and class II molecules present peptides that arise in different places within cells as the result of a process known as antigen processing. Class I molecules bind to peptides that originate in the cytoplasm (e.g., antigens from replicating viruses). Endogenous antigenic proteins are digested inside the cell as part of the natural process by which a cell continually renews its protein contents. The short peptide fragments that result from this process are pumped by a specific transporter protein from the cytoplasm into the endoplasmic reticulum. Within the endoplasmic reticulum the class I MHC alpha chain is synthesized and associates with β_2-microglobulin. This dimer appears to bind peptide as soon as it enters the endoplasmic reticulum. The MHC molecule and peptide are then carried to, and anchored in the plasma membrane. If the peptide is foreign (e.g., short pieces of viral protein), a passing $CD8^+$ T cell (cytotoxic T lymphocyte) whose T cell receptor is specific for the antigenic peptide will bind to the peptide-MHC complex and ultimately kill the infected cell.

Class II MHC molecules bind to fragments that arise from exogenous antigens. This pathway would function with bacteria and viruses that have been taken up endocytotically. The antigen-presenting cell takes in the antigen or pathogen by receptor-mediated endocytosis or phagocytosis and produces antigen fragments by digestion in the phagolysosome. Fragments then combine with preformed class II MHC molecules and are delivered to the cell surface. It is here that the peptide is recognized by $CD4^+$ T-helper cells. Unlike $CD8^+$ T cells, $CD4^+$ T cells do not directly kill target cells. Instead they respond in two distinct ways. One is to enlarge and divide, thereby increasing the number of $CD4^+$ cells that can react to the antigen. The second response is to secrete cytokines (e.g., interleukin-2) that either directly inhibit the pathogen that produced the antigen or recruit and stimulate other cells to join in the immune response.

As previously noted, MHC molecules are coded by a group of genes termed the major histocompatibility complex (**figure 32.23**). The MHC of humans is located on chromosome 6 and contains three major classes of genes. Many forms of MHC genes exist because the presence of multiple alleles that have arisen by high gene mutation rates, gene recombination, and other mechanisms. Each individual has two sets of these genes, one from each parent, and both are expressed (i.e., they are codominant). Thus a person expresses many different MHC products. The MHC proteins will differ between individuals; the closer two people are related, the more similar are their MHC molecules.

Class I molecules are made by all cells of the body except red blood cells and comprise MHC types A, B, and C. Class I molecules serve to identify almost all cells of the body as "self." They also stimulate antibody production when introduced into a host with different class I molecules. This is the basis for MHC typing when a patient is being prepared for an organ transplant (**Box 32.2**).

Class II molecules comprise the D group of the MHC and are produced only by activated macrophages, dendritic cells, mature B cells, some T cells, and certain cells of other tissues. Class II molecules are required for T-cell communication with macrophages and B cells. As discussed in more detail later, part of the T-cell receptor must recognize a peptide and a class II molecule on the antigen-presenting cell before the T cell can secrete cytokines necessary for the immune response.

The class III genes encode the second component of complement (C2), factor B, two forms of the fourth component of complement (C4a and C4b), tumor necrosis factor, heat shock proteins, and other proteins. C2, C4a, and C4b participate in the classical pathway and factor B in the alternative pathway (*see figure 31.13*).

Classes I and II of the MHC are involved in not only the immunologic recognition of microorganisms but also an individual's susceptibility to particular noninfectious diseases. For example, there is evidence of MHC-linked determinants in tuberculoid leprosy, paralytic poliomyelitis, multiple sclerosis,

Box 32.2

Donor Selection for Tissue or Organ Transplants

The likelihood of tissue or organ transplant acceptance can be increased by using persons who have a great degree of genetic similarity. The greater the similarity, the more likely the persons will have similar MHC complexes. The reason for this is that 77 histocompatibility alleles are determined by just four human histocompatibility genes—A, B, C, and D (which includes DQ, DR, and DP). These genes are transmitted from parents to offspring according to Mendelian genetics. For example, two siblings (brother and sister) may have approximately a 25% chance of being B identical, a 50% chance of sharing one B gene, and only a 25% chance of having completely different B genes. Therefore, when tissue or organ transplants are performed, a deliberate attempt is made to use tissues from siblings or other genetically related, histocompatible people.

Once a tissue donor has been selected, various in vitro tests are performed to find how closely the MHCs match. The greater the degree of similarity, the greater the chances are that the transplant will be successful. One such test is the lymphocytotoxic cross-match test. In this test the recipient's serum is mixed with the donor's lymphocytes to determine whether antibodies are present that will cause tissue rejection. The cell-mediated lymphocytosis test, in which recipient leukocytes are mixed with donor serum, is used to test for acute rejection. After a prolonged incubation period, the presence of activated killer cells is an indication that rejection will occur.

Table 32.4 Classes of T Cells

Classes	Function
Class That Kills	
T_C (cytotoxic) cells; also called $CD8^+$ cells	Cause cytolysis and cell death of target cells—virus-infected cells and tumor cells; important in host defense against cytosolic pathogens
Classes That Regulate Other Cells	
T_H (helper) cells; also called $CD4^+$ cells	Help B cells make antibody in response to antigenic challenge; stimulate cell-mediated immunity
T_S (suppressor) cells	When mixed with naive or effector T cells, suppress their activity

and acute glomerulonephritis. The effect of MHC molecule expression on the frequency of these diseases is just beginning to be understood.

Types of T Cells

There are several classes or subpopulations of T cells (**table 32.4**). One class (effector) causes cytolysis and cell death of target cells. The other classes regulate specific cells. These effector and regulatory T cells are now discussed in more detail.

Effector Cells

Cytotoxic T (T_C) cells ($CD8^+$ cells) are activated in a complex process that involves at least three signals. They attach by T-cell receptor proteins to viral antigen-class I MHC complexes on the surface of virus-infected cells (**figure 32.24**). A CD28-B7 costimulatory signal also is involved. Finally the T_C cells require exposure to interleukin-2 from T_H1 cells. The T_C cells then proliferate and differentiate to form active **cytotoxic T lymphocytes (CTLs),** which can attack virus-infected cells. CTLs and T_H1 cells release cytokines such as gamma-interferon (IFN-γ), and both macrophages and T cells release tumor necrosis factor-alpha (TNF-α). These cytokines limit virus reproduction, while also activating macrophages and other phagocytes that can destroy the infected cell.

T_H2 cells secrete cytokines such as IL-4, IL-5, and IL-6, which stimulate B-cell proliferation and differentiation into antibody-forming plasma cells (figure 32.24). Thus activation of T-helper cells by macrophages is required for the production of both CTLs and antibodies.

Cytotoxic T lymphocytes can destroy target cells in at least two ways. The CD95 pathway triggers apoptosis or programmed cell death. The perforin pathway is probably more often employed by CTLs and uses perforin and granzymes to induce both osmotic cytolysis and apoptosis.

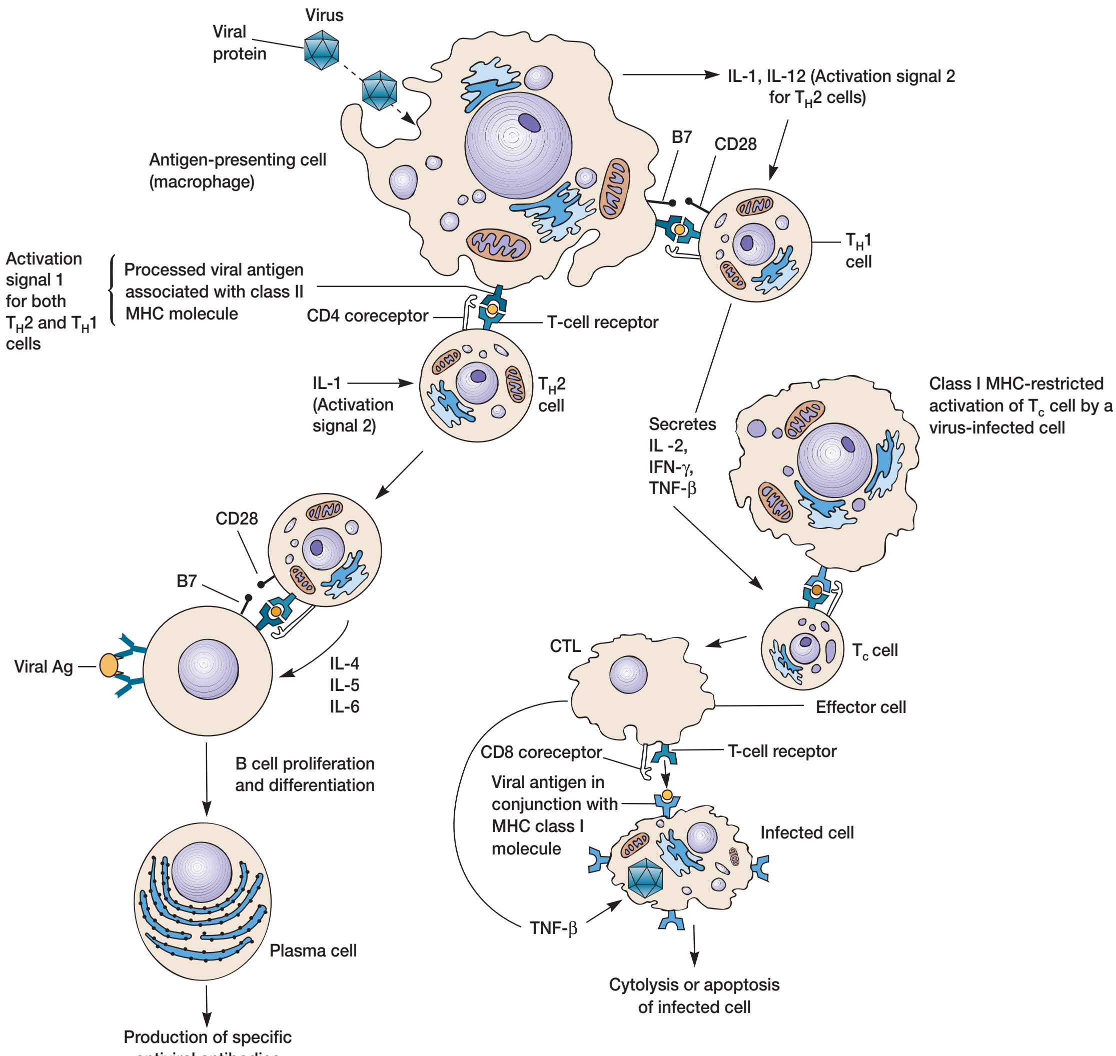

Figure 32.24 Helper T-Cell Responses In Cell-Mediated Immunity. A virus is phagocytosed by a macrophage and a small antigen fragment (peptide) presented to T-helper cells (T_H1 and T_H2) in association with class II MHC molecules. Once activated (activation signals 1 and 2) the T_H2 cell secretes the cytokines IL-4, IL-5, IL-10, and IL-13 that cause B-cell proliferation and secretion of specific antiviral antibodies. Activation signals 1 and 2 also cause the T_H1 cell to secrete IL-2, IFN-γ, and TNF-β. IL-2 regulates the proliferation of cytotoxic T cells. Once the effector T_C cell proliferates, it attacks and causes lysis or programmed cell death (apoptosis) of the virus-infected cell by either the Fas or perforin pathways.

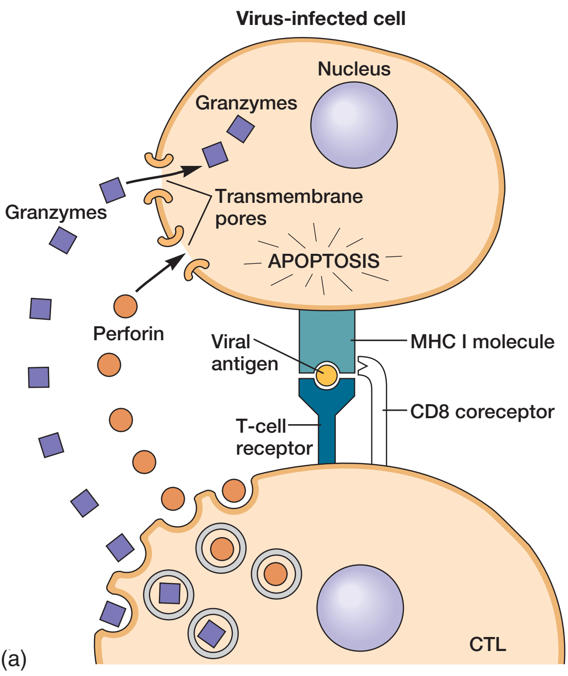
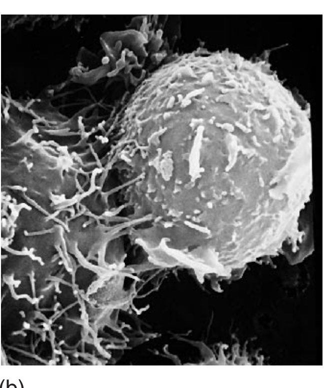
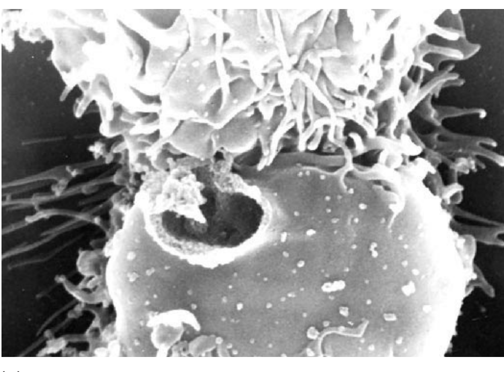




(b)



(c)

Figure 32.25 How an Effector Cytotoxic T Cell Destroys a Virus-Infected Target Cell. (**a**) T-cell cytotoxicity often involves the perforin pathway and leads to apoptosis and cytolysis. (**b**) A cytotoxic T cell (left) contacts a target cell (right) (×5,700). (**c**) The T cell secretes perforin that forms transmembrane pores in the target cell's plasma membrane. These pores allow the contents of the target cell to leak out (cytolysis).

The **CD95 pathway** depends on the CD95 transmembrane Fas protein receptor, which is found on many eucaryotic cells. CD95 or Fas is coded for by the ***fas* gene,** a member of the tumor necrosis factor (TNF) family of genes. When the Fas ligand (CD95L) binds to the target cell Fas protein, the CD95-CD95L complex activates several cytoplasmic proteins that initiate a cellular suicide cascade, leading to apoptosis. CTLs have high concentrations of the Fas ligand or CD95L on their surface. The target cell undergoes apoptosis upon binding of the ligand to Fas.

The **perforin pathway** begins when the CTL binds by its T-cell receptor to a viral peptide–class I MHC complex on the target cell surface (**figure 32.25*a***). The following complex series of events now occur:

1. A Ca^{2+}-dependent sequence first takes place: (a) microtubule assembly; (b) movement of cytoplasmic granules toward the part of the plasma membrane that is in contact with the target cell; (c) reorientation of the Golgi apparatus to the target cell; and (d) movement of the microtubule-organizing center and other cytoskeletal components into the region of the cytoplasm adjacent to the bound target cell.
2. Next the CTL secretes a pore-forming protein, perforin, into the target cell's plasma membrane. Perforin polymerizes in the target cell's membrane to form circular transmembrane pores (figure 32.25*c*). This can lead to osmotic lysis.
3. Finally the CTL secretes granzymes, proteolytic enzymes that enter the target cell and induce apoptosis.

This sequence of events will cause either cytolysis or apoptosis of the target cell. The CTL then disengages from the dying target cell and recycles its cytoplasmic components in preparation for another attack.

Regulator T Cells

Regulator T cells control the development of effector T cells. Two subpopulations exist: T-helper cells ($CD4^+$ cells) and T-suppressor cells. There are three subsets of **T-helper (T_H) cells:** T_H1, T_H2, and T_H0. The T_H1 and T_H2 subsets produce and secrete a specific mixture of cytokines. **T_H1 cells** produce IL-2, IFN-γ, and TNF-β that are involved in cellular immunity. These cytokines are responsible for delayed-type hypersensitivity reactions and macrophage activation. **T_H2 cells** also produce various cytokines (e.g., IL-4, IL-5, IL-10, IL-13) and are involved in humoral immunity. T_H2 cells are helpers for B-cell antibody responses and defense against helminths. **T_H0 cells** are simply undifferentiated precursors of T_H1 and T_H2 cells.

T-helper cells (T_H1) need two signals (costimulation) to be stimulated by an antigen. The first signal is when antigen fragments are effectively presented to a T cell by a macrophage, dendritic cell, or an activated B cell. For example, when a virus infects a host, some particles may be phagocytosed by a macrophage and partially digested (figure 32.24). Some of the antigenic viral protein fragments are then moved to the surface of the macrophage and presented in close association with class II MHC molecules. This combination of viral antigen fragment and class II MHC molecule is needed for recognition by the T-cell receptor protein on the surface of the T_H1 cell and represents activation signal 1. (The abbreviation CD is from cell-associated differentiation antigen; CDs are functional molecules or receptors that serve as surface markers; section 32.2.)

The second signal for activation involves the CD28 protein receptor on T_H1 cells (**figure 32.26**). When CD28 binds to a protein called B7 (CD80) on the surface of a macrophage (an APC), it delivers a second signal to the T_H1 cell. Both of these signals go into the cytoplasm of the T_H1 cell.

Signal 1 activates a tyrosine kinase located in the cytoplasm. Tyrosine kinase adds phosphate groups to the amino acid tyrosine in proteins. When this phosphorylation occurs, the enzyme phospholipase Cγ1 cleaves the phosphatidylinositol bisphosphate located in the T-helper cell plasma membrane. Two cleavage products are formed and two specific pathways now operate.

One of the cleavage products, diacylglycerol, activates protein kinase C. Protein kinase C moves into the nucleus where it catalyzes the formation of a protein complex called AP-1 from separate components. The other cleavage product, inositol trisphosphate, causes a calcium channel to open; calcium ions to rush into the cytoplasm, leading to further enzymatic activity and the activation of calmodulin, calcineurin, and nuclear factor of activated T_H1 cells (NF-AT). NF-AT then migrates into the nucleoplasm where it binds to the newly formed AP-1, forming a NF-AT/AP-1 complex (a transcription factor). This transcription factor binds tightly to a specific gene sequence in the DNA molecule, causing interleukin-2 mRNA to be transcribed. Interleukin-2 mRNA moves out of the nucleus to the ribosomes where the protein interleukin-2 is produced.

Signal 2 is mediated by the CD28 receptor and B7 molecule. This signal activates another tyrosine kinase, causes the formation of the transcription factor CD28RC, and also stabilizes the mRNA transcribed from the interleukin-2 gene. This increases the concentration of interleukin-2.

T_H1 cells that are activated by these two signals secrete large amounts of interleukin-2, which activates cytotoxic T cells (figure 32.24). T_H1 cells also secrete gamma-interferon (IFN-γ), which is capable of activating macrophages and increasing microbicidal activity.

The activity of T_H2 cells is depicted in figure 32.24. They are costimulated by antigen presentation and interleukin-1. The T_H2 cells then release several cytokines that stimulate B-cell proliferation and differentiation into antibody-forming plasma cells.

Although the evidence is not conclusive, many immunologists believe in the existence of **T-suppressor (T_S) cells** that can suppress B-cell and T-cell responses. Subpopulations of T_S cells specific to a given antigen can be stimulated to proliferate by the interleukin-2 from activated T-helper cells. This proliferation occurs at a slow rate to provide negative feedback control for that part of the immune response known as acquired immune tolerance.

1. What is the function of an antigen-presenting cell? What is a T-cell receptor and how is it involved in T-cell activation?
2. What is a histocompatibility molecule? What are MHCs and HLAs? Describe the roles of the three MHC classes.
3. Describe antigen processing. How does this process differ for endogenous and exogenous antigens?
4. Briefly describe the cytotoxic T cell, its general role, how it is activated, and the two ways in which it destroys target cells.
5. Outline the functions of a T-helper cell. How do T_H1 and T_H2 cells differ in function? Briefly describe how T_H cells are activated by costimulation.

32.5 B-Cell Biology

Stem cells in the bone marrow produce B cell precursors (*see figure 31.3*). Mature B cells contain cell surface, transmembrane immunoglobulin molecules associated with Ig-α/Ig-β heterodimer proteins; these complexes are called **B-cell antigen receptors (BCRs).** BCRs can contain IgM and IgD. It is the IgM, however, that is the major receptor for its appropriate antigen. B cells also have receptors for the Fc part of some immunoglobulin classes and may have receptors for complement (C3b). Each B cell may have as many as 50,000 of these membrane-bound immunoglobulins. The total mature B-cell population of each individual thus carries BCRs specific for many antigens; however, each mature B cell possesses BCRs specific only for a particular antigenic determinant.

Antibodies are secreted by plasma cells and bind antigens in solution. The various classes of antibodies (IgG, IgM, IgA, IgD,

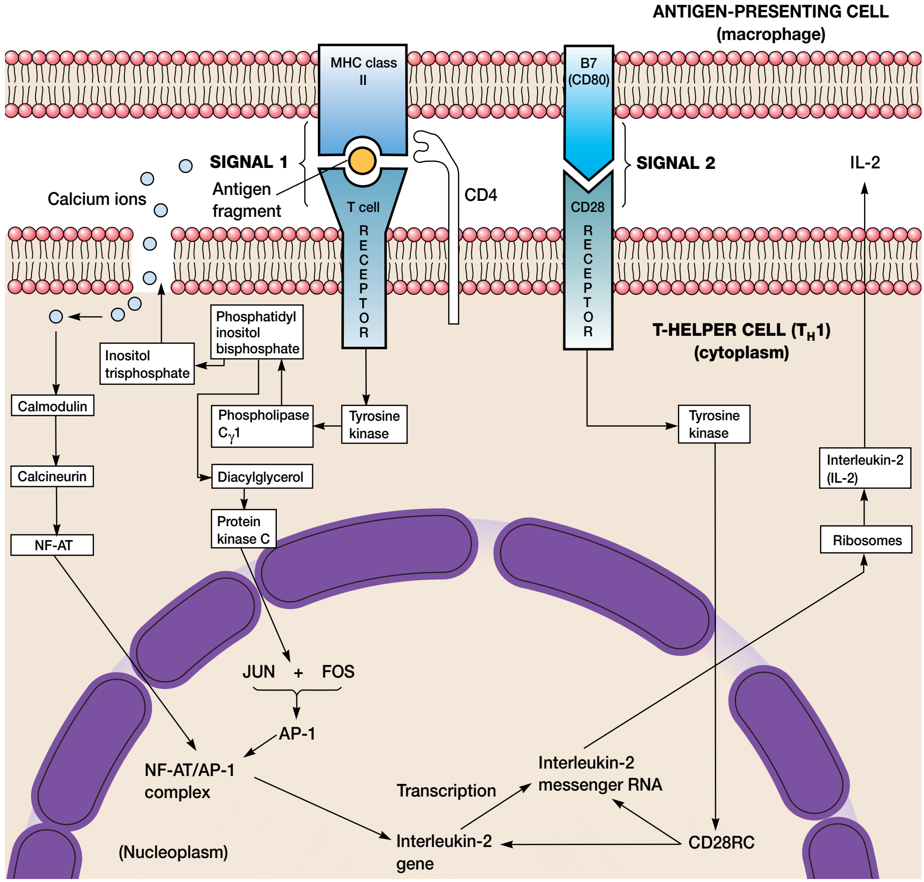


Figure 32.26 Two Signals (Costimulation) Are Essential for T-helper (T_H1) Cell Activation. The first signal is the presentation of the antigen fragment by a macrophage or other antigen-presenting cell along with the MHC class II molecule to the T-helper cell receptor and CD4 protein. The second signal occurs when the macrophage presents the B7 (CD80) protein to the T-helper cell with its CD28 protein receptor. Both signals send information into the cytoplasm of the T-helper cell. The first signal causes interleukin-2 mRNA to be produced. The second signal boosts the production of interleukin-2 to effective concentrations. It now is known that the gene for interleukin-2 is under very tight regulation. It cannot be transcribed unless the NF-AT/AP-1 complex, AP-1, and other transcription factors (e.g., CD28RC) are present. All these factors must be produced anew or activated when the T-helper cell is stimulated through its antigen-specific receptor.

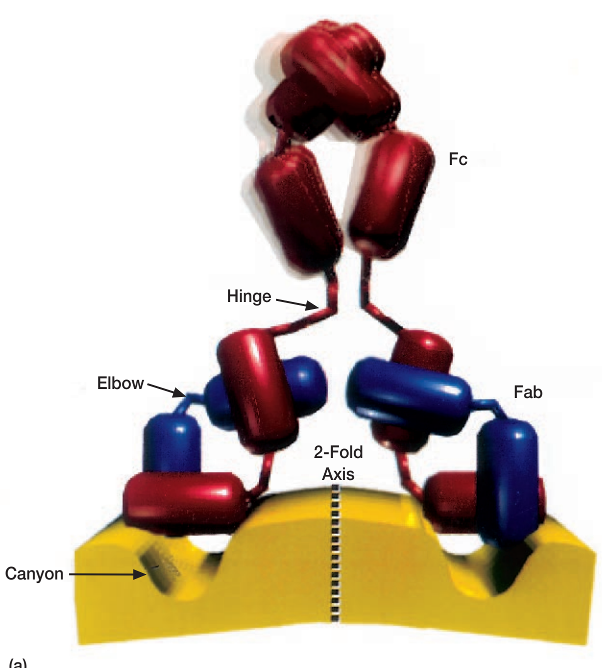
IgE; figures 32.10–32.14) are related to the membrane-bound BCRs. In addition to antigen binding, BCRs also trigger the endocytosis of an antigen leading to it being processed inside the B cell. A small antigen fragment is presented on the surface of the cell in association with major histocompatibility class II molecules. Thus B cells have two immunological roles: (1) they proliferate and differentiate into plasma cells and respond to antigens by making antibodies, and at the same time (2) can act as antigen-presenting cells.

Antigen-Antibody Binding

An antigen binds to an antibody at the antigen-binding site within the Fab region of the antibody. More specifically, a pocket is formed by the folding of the V_H and V_L regions (figure 32.7). At this site, specific amino acids contact the antigen's epitope or haptenic groups and form multiple noncovalent bonds between the antigen and amino acids of the binding site (**figure 32.27**).

Because binding is due to weak, noncovalent bonds such as hydrogen bonds and electrostatic attractions, the antigen's shape



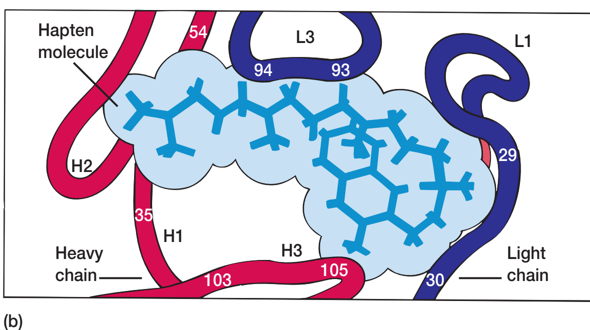


Figure 32.27 Antigen-Antibody Binding. (**a**) An example of antigen-antibody binding is represented in this model of the monoclonal antibody MAb17-IA bound to the surface of the human rhinovirus. The heavy chains are red, light chains are blue, and the antigen capsid protein is yellow. The RNA interior of the virus would be toward the bottom of the diagram. The antibody is bound bivalently across icosahedral twofold axes of the virus. (**b**) Based on X-ray crystallography, the hapten molecule nestles in a pocket formed by the antibody combining site. In the illustration the hapten makes contact with only 10–12 amino acids in the hypervariable regions of the light and heavy chains. The numbers represent contact amino acids.

must exactly match that of the antigen-binding site. If the shape of the epitope (figure 32.3) and binding site are not truly complementary, the antibody will not effectively bind the antigen. Although a lock-and-key mechanism normally may operate, in at least one case the antigen-binding site does change shape when it complexes with the antigen (an induced fit mechanism). Regardless of the precise mechanism, antibody specificity results from the nature of antibody-antigen binding.

B-Cell Activation

Upon activation by appropriate signals, the mature B cell proliferates and differentiates into a plasma cell that secretes antibody. Activation is typically antigen specific, activating a particular clone of cells, but can be nonspecific and polyclonal through treatment with B-cell mitogens.

T-Dependent Antigen Triggering

Most antigens have more than one type of antigenic determinant site (epitope) on each molecule (figure 32.3). B cells specific for a given epitope on the antigen (e.g., epitope X) often cannot develop into plasma cells secreting antibody (anti-X) without the collaboration of helper T cells. In other words, binding of the epitope X to the B cell may be necessary, but it is not sufficient for B-cell activation. Antigens that elicit a response with the aid of T-helper cells are called **T-dependent antigens.** Examples include bacteria, foreign red blood cells, certain proteins, and hapten-carrier combinations (figure 32.4).

The basic mechanism for T-dependent antigen triggering of a B cell is illustrated in **figure 32.28** and involves three cells: (1) a macrophage or other antigen-presenting cell to process and present the antigen; (2) a T-helper cell able to recognize the antigen and respond to it; and (3) a B cell specific for the antigen. When all cells and the antigen are present, the following sequence takes place. The macrophage presents part of the antigen and its own class II MHC to the T-helper cell (signal #1 to the T cell). Costimulation is provided by the B7-CD28 interaction (signal #2). Interleukins 1 and 6 stimulate T cells to divide and make interleukins 2 and 4–6. Interleukin-1 also stimulates the hypothalamus to raise the body temperature (causing a fever), which enhances the activity of T cells. Interleukins 2 and 4–6 stimulate T-helper cells to multiply. These helper cells directly associate with B cells that display the correct antigen–class II MHC complex and secrete cytokines called B-cell growth factors (BCGFs), which cause B cells to multiply. As the number of B cells increase, T-helper cells produce other cytokines, the B-cell differentiation factors (BCDFs). These instruct some B cells to stop replicating, to differentiate into plasma cells, and to start producing antibodies. B-cell activation involves more than T-helper cell activity. The B cell also recognizes the antigen through its surface IgM receptors for the antigen (signal #1 for the B cell) and is subsequently triggered to proliferate and differentiate into plasma cells secreting antibody. (One plasma cell can synthesize more than 10 million antibody molecules per hour!) It should be noted here

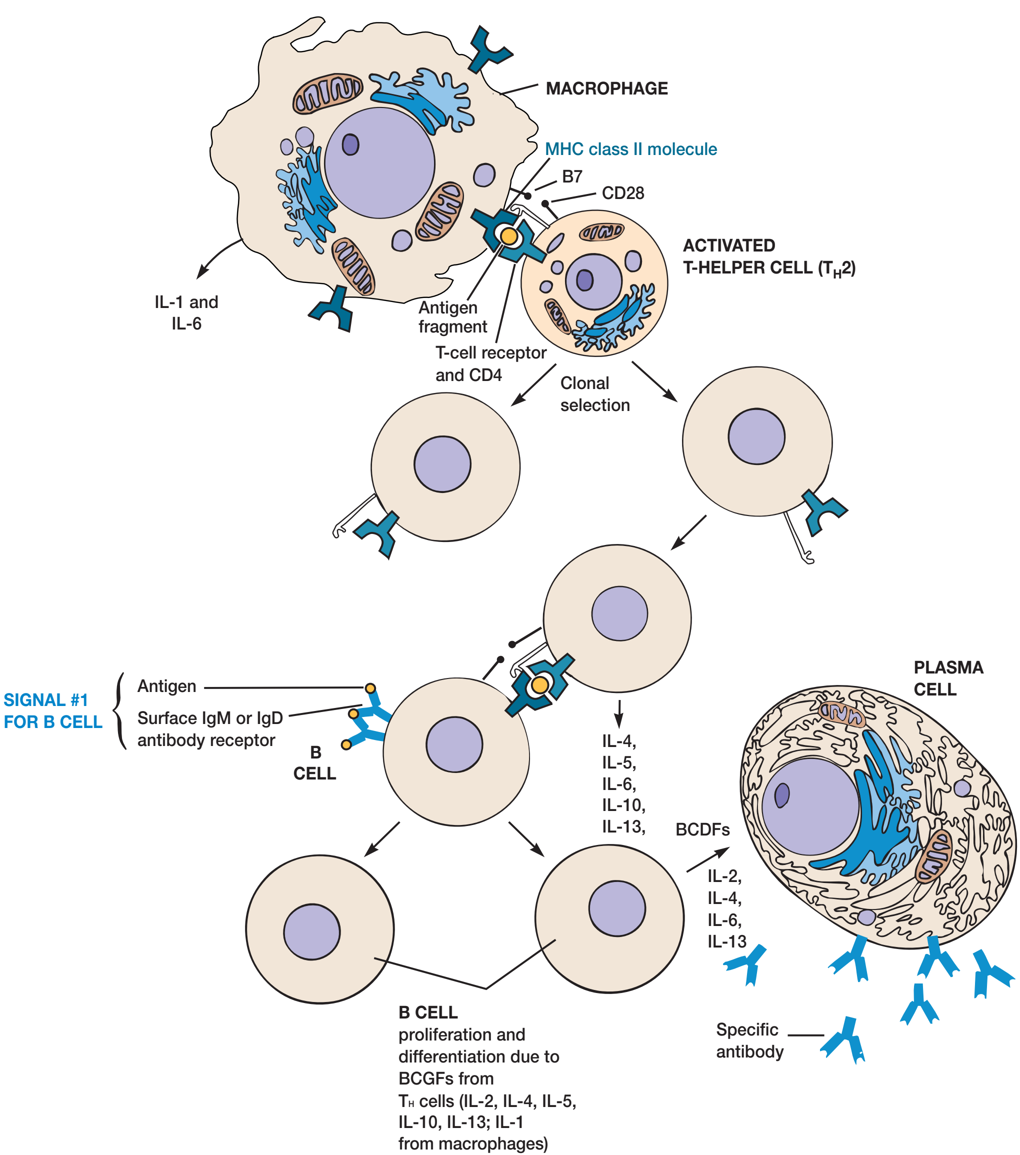

Figure 32.28 T-Dependent Antigen Triggering of a B Cell. Schematic diagram of the events occurring in the interactions of macrophages, T-helper cells, and B cells that produce humoral immunity. Many cytokines (e.g., IL-1, IL-4, IL-5, IL-10, IL-13) stimulate B-cell proliferation and may be called B-cell growth factors (BCGFs). Cytokines such as IL-2, IL-4, IL-6, and IL-13 stimulate B-cell differentiation and are called B-cell differentiation factors (BCDFs).

that B cells are more effective antigen presenters than macrophages at low antigen concentrations if the antigen can bind to surface immunoglobulins. The B cells bind antigen, take it up by receptor-mediated endocytosis, and present it to T-helper cells to activate them. In this situation B cells and T_H cells activate each other. All the immune responses that produce IgG, IgA, and IgE involve this T-dependent antigen triggering. Fever (pp. 722–23)

T-Independent Antigen Triggering

Not all antibody responses require T-cell help. There are antigens that trigger B cells into immunoglobulin production without T-cell cooperation. These are called **T-independent antigens.** Examples include certain tumor-promoting agents, anti-immunoglobulin (anti-Ig), antibodies to certain B-cell differentiation antigens, and

Table 32.5 Comparison of Lymphocytes Involved in the Immune Response

Property	T Cells	B Cells
Origin	Bone marrow in adults	Bone marrow in adults
Maturation and differentiation	Thymus	Lymphoid tissue; bursa of Fabricius in birds
Mobility	Great	Very little (some stages circulate)
Complement receptors	Absent	Present
Surface immunoglobulins	Absent	Present
Proliferation	Upon antigenic stimulation, differentiate into effector and memory cells	Upon antigenic stimulation, proliferate and differentiate into plasma and memory cells
Immunity type	Cell mediated and humoral (B cell activation by T_H cells)	Humoral
Distribution	High in blood, lymph, and lymphoid tissue	High in spleen, lymph nodes, bone marrow, and other lymphoid tissue; low in blood
Secretory product	Cytokines	Antibodies
Subsets and functions	T-helper (T_H) cell: necessary for B-cell activation by T-dependent antigens and T-effector cells. There are three types of T-helper cells: T_H1, T_H2, and T_H0.	Plasma cell: a cell arising from a B cell that manufactures specific antibodies
	T-suppressor (T_S) cell: blocks induction and/or activation of T_H cells and B cells; helps maintain tolerance	Memory cell: a long-lived cell responsible for the anamnestic response
	Cytotoxic T (T_C) cell: differentiates into a CTL that lyses cells recognized as nonself and virus or parasite-infected cells	
	Memory cells	

Table 32.6 Antigen Recognition by T and B Cells

Characteristic	T Cells	B Cells
Binds soluble antigen	No	Yes
Biochemistry of the antigens	Mostly proteins, but some glycolipids presented on MHC molecules	Proteins, glycolipids, polysaccharides
Antigen recognition	Antigens processed internally and presented as linear peptides bound to MHC molecules	Accessible areas of protein structure containing sequential amino acids and nonsequential amino acids
	Involves three partners: T-cell receptor, antigen, and MHC molecule	Immunoglobulin receptor binds antigen in native conformation
		Involves two partners: antigen and membrane immunoglobulin

bacterial lipopolysaccharides. The T-independent antigens are polymeric—that is, composed of repeating polysaccharide or protein subunits. They elicit almost exclusively IgM antibody formation, and there is little switching to IgG; the resulting antibody generally has a low affinity for antigen.

The mechanism for activation by T-independent antigens probably depends on their polymeric structure. These large molecules present a large array of identical epitopes to a B cell specific for that determinant. The multivalent nature of the cell receptor (surface IgM) is such that cell activation occurs and IgM is secreted. Because there is no T-cell help, the B cell cannot switch to high-affinity IgG production, and no memory B cells are formed.

Section 32.4 presented the biology of T-cells and this current section describes B-cell biology. **Tables 32.5** and **32.6** summarize and compare many of the important properties of lymphocytes that were discussed in these two sections.

1. What are B-cell antigen receptors and how are they involved in B-cell activation?
2. Briefly compare and contrast B cells and T cells with respect to their formation, structure, and roles in the immune response.
3. How does antigen-antibody binding occur? What is the basis for antibody specificity?
4. How does T-independent antigen triggering of B cells differ from T-dependent triggering?

32.6 Action of Antibodies

The antigen-antibody interaction is a bimolecular association that exhibits exquisite specificity. The in vivo interactions that occur in vertebrate animals are absolutely essential in protecting the animal against the continuous onslaught of viruses, microorganisms and their products, certain macromolecules, and cancer cells. Outside the animal body (in vitro), this same specificity has led to the development of a variety of immunological assays that can detect the presence of either antibody or antigen. They are important in the diagnosis of diseases; in the identification of specific viruses, bacteria, and parasites; in monitoring the level of the humoral response and immunologic problems; and in identifying molecules of medical and biological interest. Immunological assays differ in their speed and sensitivity; some are qualitative whereas others are quantitative. The rest of this section examines those antigen-antibody interactions that occur in the animal body (in vivo). Antigen-antibody reactions that are routinely dealt with in the laboratory (in vitro) are covered in chapter 33, which is concerned with medical immunology.

Toxin Neutralization

Immunity to a disease like diphtheria depends on the production of specific antibodies that inactivate the toxins produced by the bacteria. This process is termed **toxin neutralization (figure 32.29).** Once neutralized, the toxin-antibody complex is either unable to attach to receptor sites on host target cells, unable to enter the cell, or it is ingested by macrophages. For example, diphtheria toxin inhibits protein synthesis after binding to the cell surface by the B fragment and subsequent passage of the active A fragment into the cytoplasm of the target cell (*see figure 34.5*). Thus the antibody blocks the toxic effect by inhibiting the entry of the A fragment or the binding of the B fragment. An antibody capable of neutralizing a toxin or antiserum containing neutralizing antibody against a toxin is called **antitoxin** (figure 32.29*b*). Exotoxins (pp. 794–99)

Viral Neutralization

IgG, IgM, and IgA antibodies can bind to some viruses during their extracellular phase and inactivate them. This antibody-mediated viral inactivation is called **viral neutralization.** Fixation of the classical pathway (section 32.7) complement component C3b to the virus aids the neutralization process. Viral neutralization prevents a viral infection due to the inability of the virus to bind to its target cell (figure 32.29*c*).

Adherence Inhibition

The capacity of bacteria to colonize the mucosal surfaces of mammalian hosts is dependent in part on their ability to adhere to mucosal epithelial cells. Secretory IgA (sIgA; pp. 736–38) antibodies inhibit certain bacterial adherence promoting factors. Thus sIgA has a unique role in protecting the host against infection by some pathogenic bacteria, and perhaps by other microorganisms on mucosal surfaces.

IgE and Parasitic Infections

Immune reactions against protozoan and helminthic parasites are only partially understood. Parasites that have a tissue invasive phase in their life cycle often are associated with both eosinophilia (an excessive number of eosinophils in the blood) and elevated IgE levels. Recent evidence shows that, in the presence of elevated IgE, eosinophils can bind to the parasites and discharge their granules. Degranulation releases lytic and inflammatory mediators that destroy the parasites (*see figure 33.2*).

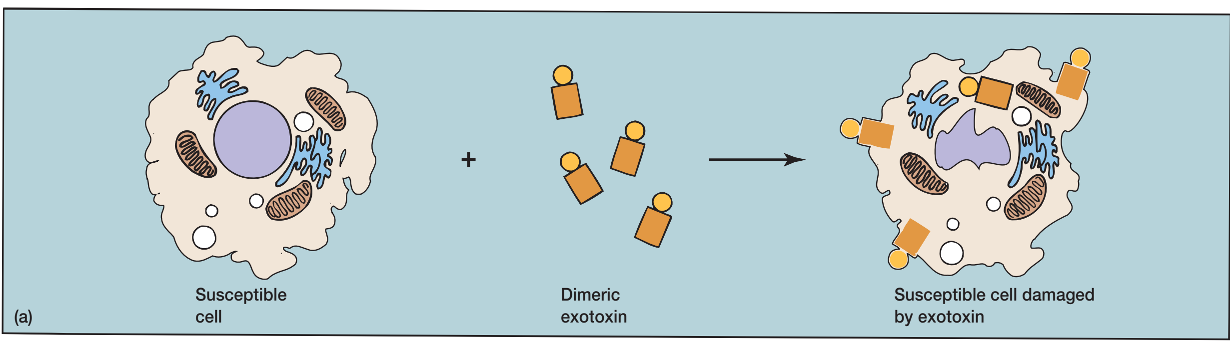
Opsonization

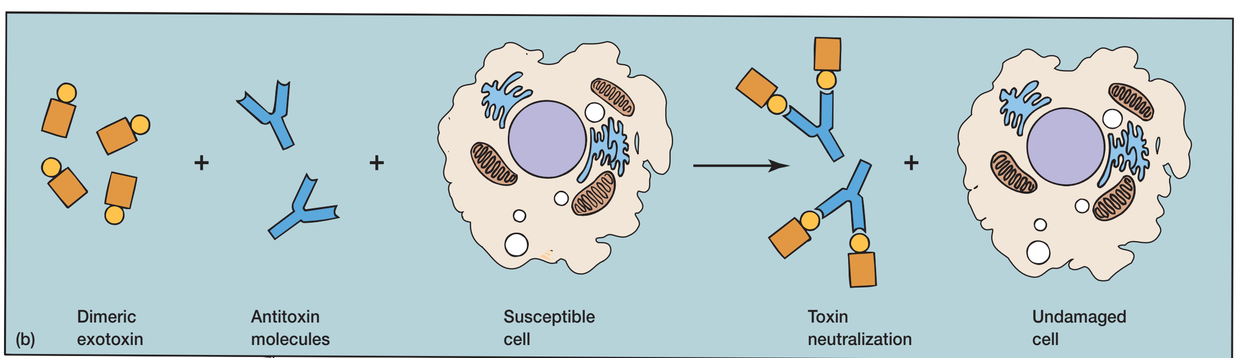
Phagocytes have an intrinsic ability to bind directly to microorganisms by nonspecific cell surface receptors, engulf the microorganisms, form phagosomes, and digest the microorganisms (*see figure 31.16*). This phagocytic process can be greatly enhanced by opsonization. As noted in section 31.8, opsonization is the process in which microorganisms or other particles are coated by antibody and/or complement, and thus prepared for "recognition" and ingestion by phagocytic cells. Opsonizing antibodies, especially IgG1 and IgG3, bind to Fc receptors on the surface of macrophages and neutrophils. This binding forms a bridge between the phagocyte and the antigen. Phagocytosis (pp. 718–20)

Immune Complex Formation

Because antibodies have at least two antigen-binding sites and most antigens have at least two antigenic determinants, crosslinking can occur, producing large aggregates termed **immune complexes (figure 32.30).** If the antigens are soluble molecules and the complex becomes large enough to settle out of solution, a **precipitation** [Latin *praecipitare,* to cast down] or **precipitin reaction** has occurred, and is caused by a **precipitin** antibody. When the immune complex involves the crosslinking of cells or particles, an **agglutination reaction** occurs and the responsible antibody is an **agglutinin.** Agglutination specifically involving red blood cells is a **hemagglutination** reaction and is caused by a **hemagglutinin.** These immune complexes are more rapidly phagocytosed in vivo than are free antigens.

The extent of immune complex formation, whether within an animal or in vitro, depends on the relative concentrations of the precipitin antibody and antigen. If there is a large excess of antibody, separate antibody molecules usually bind to each antigenic determinant and a less insoluble network or lattice forms (*see figure 33.18*a). When antigen is present in excess, two different antigen molecules tend to bind to each antibody and network development or crosslinking also is inhibited. In the equivalence zone the ratio of antibody and antigen concentrations is optimal for the formation of a large network of interconnected antibody and antigen molecules. All antibody and antigen molecules precipitate or agglutinate as an insoluble complex. Precipitin reactions can occur in both solutions and agar gel media. In either case, antibody-antigen equivalence is required for optimal results.





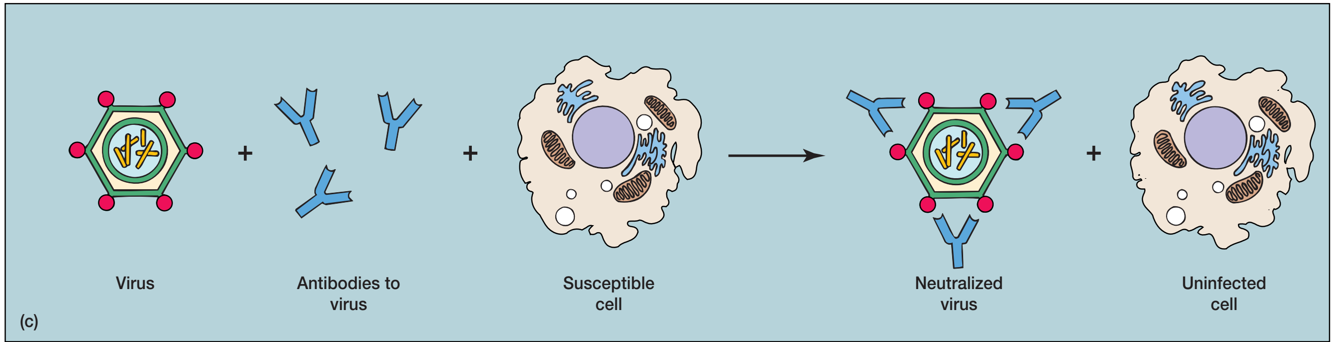


Figure 32.29 Neutralization Reactions. (**a**) Effects of a dimeric exotoxin on a susceptible cell. (**b**) Neutralization of the toxin by antitoxin. (**c**) In viral neutralization the specific antibodies neutralize the virus and prevent it from attaching to the susceptible cells.

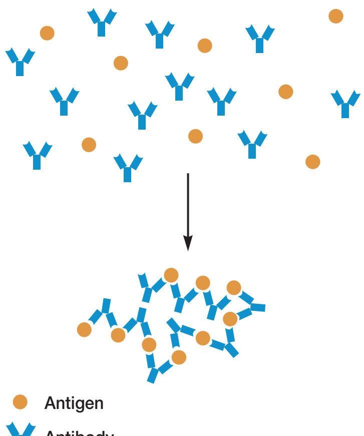

Figure 32.30 Immune Complex Formation. Antibodies cross-link antigens forming an aggregate of antibody and antigen termed an immune complex.

1. How does toxin neutralization occur? Viral neutralization?
2. Describe the role of IgE in resistance to parasitic infections.
3. How does adherence inhibition occur?
4. Describe an immune complex. What two types are formed?

32.7 The Classical Complement Pathway

Activation of the **classical complement pathway** requires initiation by the interaction of antibodies with an antigen that is usually cell bound (**figure 32.31**). The order of effectiveness in activating complement is as follows: IgM > IgG3 > IgG1 > IgG2. However, some microbial products (lipid A of endotoxin and staphylococcal protein A) or plasmin (a proteolytic enzyme that dissolves the fibrin of blood clots) may activate C1 directly without antibody participation. Following binding of antigen to antibody, the C1 complement component, which is composed of three proteins (q, r, and s), attaches to the Fc portion of the antibody molecule through its C1q subcomponent. In the presence of calcium ions, a trimolecular complex (C1qrs · Ag · Ab) that has esterase activity is rapidly formed. The activated C1's subcomponent attacks and cleaves its natural substrates in serum (C2 and C4). This leads to binding of a portion of each molecule (C2b and C4b) to the antigen-antibody-complement complex with the release of small C4a and C2a fragments. (The released C2 fragment traditionally has been called C2a. For consistency, this text will label all larger complement fragments that are bound to the target cell as b fragments.) With the binding of C2b to C4b, an enzyme with trypsinlike proteolytic activity is generated. The natural substrate for this enzyme is C3; thus it is termed a C3 convertase. Through the activity of $\overline{\text{C4b2b}}$ (the bar indicates an active enzyme complex), C3 is cleaved into a bound subcomponent C3b and a C3a soluble component. C3b then absorbs to bound C4b2b, forming the complex $\overline{\text{C4b2b3b}}$, which acts as a C5 convertase and cleaves C5 into fragments C5a and C5b. C6 and C7 rapidly bind to C5b, forming a $\overline{\text{C5b67}}$ complex that possesses an unstable membrane-binding site; once bound to a membrane, this complex is stable. C8 and C9 then bind, forming the **membrane attack complex** ($\overline{\text{C5b6789}}$) that creates a pore in the plasma membrane of the target cell (*see figure 31.14*). It is believed that the actual pore is a doughnut-shaped polymer of C9. (The perforin pores generated by cytotoxic T lymphocytes [figure 32.25] are somewhat similar to complement pores.) If the cell is eucaryotic, Na^+ and H_2O enter through the pore leading to osmotic lysis of the cell. If the cell is a gram-negative bacterium, lysozyme from the blood enters through the pore and digests the peptidoglycan cell wall causing the bacterium to lyse osmotically. In contrast, gram-positive bacteria are resistant to the cytolytic action of the membrane attack complex because they lack an exposed outer membrane and the thick peptidoglycan prevents an attack on the plasma membrane. The complement system and its functions (pp. 714–18)

1. How is the classical complement pathway activated?
2. What effect does the membrane attack complex have on eucaryotic cells? Procaryotic cells?

32.8 Acquired Immune Tolerance

Acquired immune tolerance refers to the body's ability to produce antibodies against nonself antigens such as microbial antigens, while "tolerating" (not producing antibodies against) self-antigens. Some of this tolerance arises early in embryonic life when immunologic competence is being established. Three general tolerance mechanisms have been proposed: negative selection by clonal deletion, the induction of anergy, and inhibition of the immune response by T-suppressor cells (p. 751).

Negative selection is one mechanism that produces immunologic tolerance. Negative selection by clonal deletion removes from the immune system T cells within the thymus that recognize any of the body's own antigens. T cell tolerance induced in the thymus and B cell tolerance in the bone marrow is called central tolerance. However, another mechanism is needed to prevent autoimmunity because many antigens are tissue-specific and are not present in the thymus or bone marrow.

Mechanisms occurring elsewhere in the body are collectively referred to as peripheral tolerance, which supplements central tolerance. Peripheral tolerance is thought to be based largely on incomplete activation signals given to the lymphocyte when it encounters self-antigens in the periphery of the body. This mechanism leads to a state of unresponsiveness called **anergy** [immunologists describe an inactive lymphocyte as "anergic" from the Greek *an,* negative, and *ergon,* without] that is associated with impaired intracellular signaling or apoptosis.

Many autoreactive B cells undergo clonal deletion or become anergic as they mature in the bone marrow. Negative selection occurs in the bone marrow if the B cells encounter large amounts of self-antigen, either in the soluble phase or as cell membrane constituents. The deletion of self-reactive B cells also takes place in secondary lymphoid tissue such as the spleen and lymph nodes. Since B cells recognize native antigen, there is no need for the MHC molecules in any of these processes. For those self-antigens that are present at relatively low concentrations, immunologic tolerance is often maintained only within the T-cell population. Nevertheless, this is sufficient to maintain tolerance because it denies the help essential for antibody production by self-reactive B cells.

1. Describe the three ways acquired immune tolerance develops in the vertebrate host.
2. How would you define the word anergy?

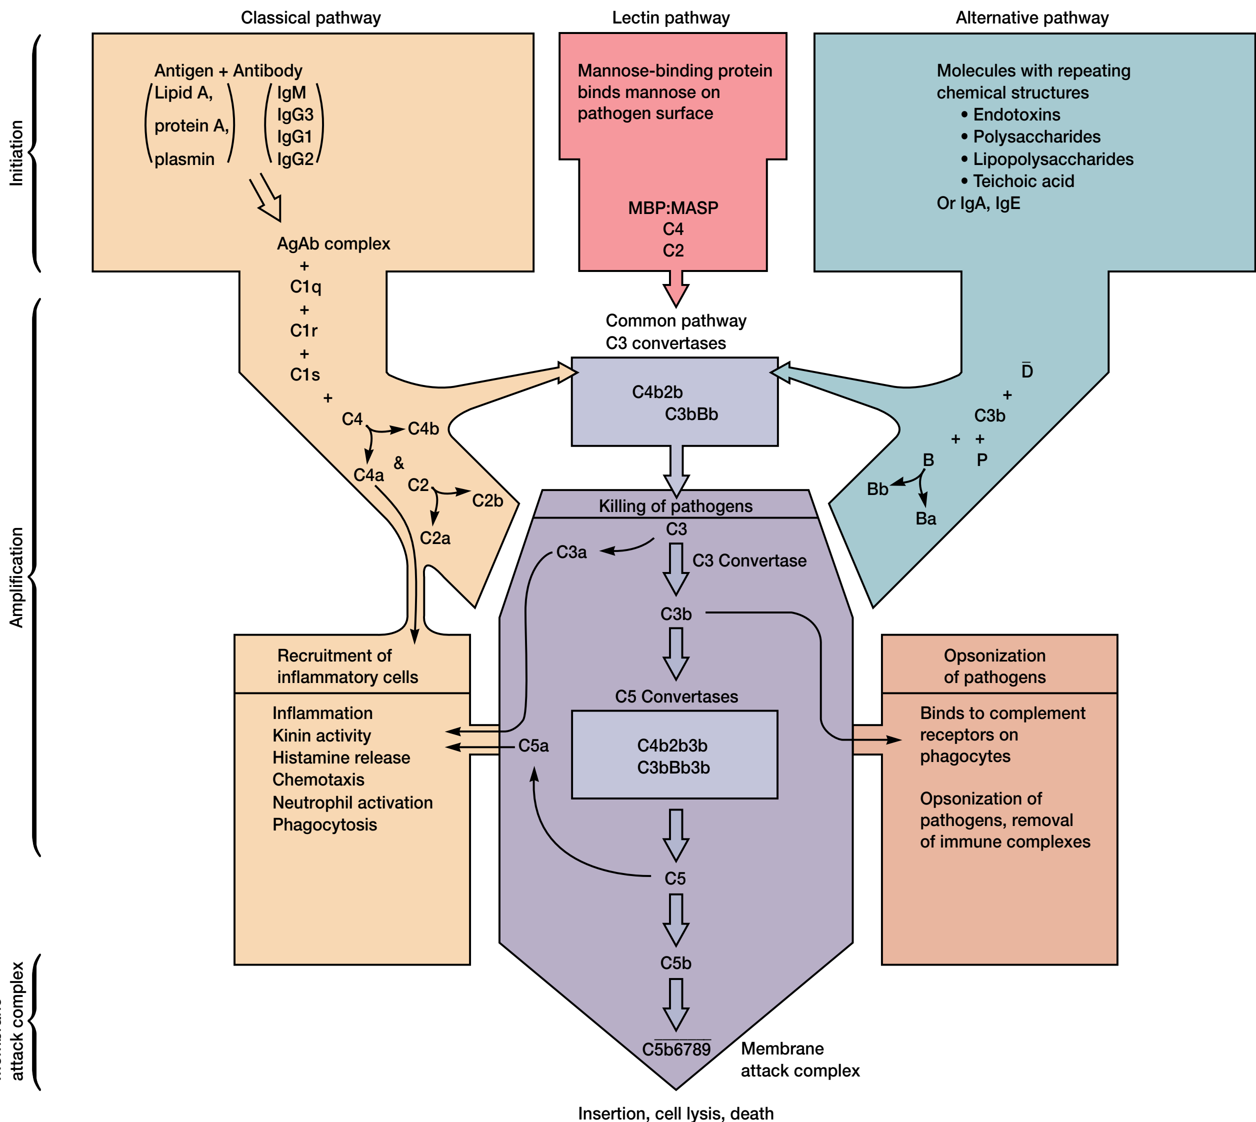

Figure 32.31 Complement Activation. Within each pathway the components are arranged in order of their activation and aligned opposite their functional and structural analogs in the opposite pathway. There are three pathways of complement activation: (1) the classical pathway (yellow), which is mediated by antibody; (2) the lectin-mediated pathway (red), which is triggered by a serum protein that binds to mannose residues of bacteria; and (3) the alternative pathway (blue), which is triggered directly on pathogen surfaces. All three generate a crucial enzymatic activity (common pathway of C3 convertases) that in turn generates the effector activity of complement. The three main consequences of complement activation are recruitment of inflammatory cells (left box), direct killing of pathogens by the membrane attack complex (middle box), and opsonization of pathogens (right box).

32.9 Summary: The Role of Antibodies and Lymphocytes in Resistance

The last part of chapter 31 presented nonspecific host immunity and this chapter described specific immunity. Although both the humoral and cellular arms of the specific immune response have been considered separately, it is important to understand that the response of a host to any particular pathogen may involve a complex interaction between both the host and pathogen, as well as the components of both nonspecific and specific immunity to ensure a maximal survival advantage for the host. This last section summarizes the defense mechanisms vertebrate hosts have against viral and bacterial pathogens. At times, however, these defenses are not enough to protect the host. Chapter 34 continues this discussion by presenting those mechanisms that pathogens have evolved to circumvent many of the following defenses.

Immunity to Viral Infections

Resistance to virus infections involves humoral immunity, interferon sensitization of host cells, and cell-mediated immunity.

1. Antibodies can neutralize viruses by combining with them and interfering with their adsorption and entrance into cells (figure 32.29).
2. Antibodies enhance phagocytosis and destruction of viruses in much the same way as for bacteria (*see figure 31.15*).
3. Interferons are important in resistance when the target cell is reached immediately as in the case of colds and influenza. Interferon-stimulated cells shut down protein synthesis (*see figure 31.18*) and destroy viral mRNA. Some interferons also stimulate the activity of T cells (figure 32.24) and natural killer cells (*see figure 31.21*), thus accelerating the immune response to a viral infection.
4. Cell-mediated immunity to viruses is a major resistance mechanism when enveloped viruses modify host cell membranes and bud off from the surface (e.g., herpesvirus, poxvirus, influenza, mumps, measles, rabies, and rubella viruses). Activated lymphocytes can recognize and destroy virus-infected cells because the target cell's plasma membrane has been altered.
   - CTLs destroy virus-infected cells through FasL, and the production of granzymes and perforin that form channels through the plasma membrane of infected cells causing apoptosis and cytolysis (figure 32.25). The class I MHC proteins are involved in T-cell recognition of infected cells (figure 32.24). Cells displaying both viral antigens and the proper class I MHC will be destroyed. CTLs are also involved in the destruction of cancer cells (**immune surveillance**).
   - Natural killer cells (NK cells) are nonB, nonT lymphocytes that are active without any prior antigen exposure. Interferon and antibodies, however, will stimulate them to greater activity. They also are capable of destroying virus-infected and cancer cells (*see figure 31.21*). They are components of innate immunity and possess no antigen receptors.

Immunity to Bacterial Infections

Humoral immunity appears to be more important than cell-mediated immunity in the defense against most bacterial pathogens. Antibodies and complement attack pathogens in many ways.

1. IgG, and the C3b and C4b components of complement are opsonins. That is, they aid in the phagocytosis of bacteria by macrophages and granulocytes through the process called opsonization (*see figures 31.15 and 31.16*).
2. IgM and IgG will agglutinate bacterial pathogens, thus limiting their spread and enhancing the efficiency of phagocytosis (figure 32.30).
3. Antibodies can trigger complement attack on the wall of gram-negative bacteria by the classical pathway (figure 32.31). Once this pathway is activated, it forms a C5b-9 membrane attack complex (*see figure 31.14*) that forms channel or pore in the bacterial cell, leading to lyses.
4. Complement C3a, C5a, and C5b67 also attract neutrophils and macrophages to a site of infection (*see figure 31.11*).
5. Antibodies called antitoxins (figure 32.29) bind to bacterial exotoxins and block their action (neutralization).
6. Cell-mediated immune responses by activated macrophages and T-cells (figure 32.1) are also important, particularly in resisting intracellular bacterial pathogens. Activated T cells secrete several cytokines, which have a variety of effects (*see figure 31.17 and table 31.4*).
   - The macrophage activating factor stimulates macrophages to become "angry" macrophages and more effectively phagocytose and destroy pathogens. Interferon-γ is a major macrophage activating factor.
   - The macrophage chemotactic factor and migration inhibition factor attract more macrophages and keep them in the area of infection after arrival.
   - Interleukin-2 (IL-2) stimulates the proliferation of activated T cells to increase the population of cells involved in the cell-mediated immune response. It also increases the effectiveness of cytotoxic T cells and NK cells by promoting the synthesis of immune interferon (γ-interferon) by T cells.

Summary

1. The specific immune response system consists of lymphocytes that can recognize foreign molecules (antigens) and respond to them. Two branches or arms of immunity are recognized: humoral (antibody-mediated) immunity and cellular (cell-mediated) immunity (**figure 32.1**).
2. Acquired immunity refers to the type of specific immunity that a host develops after exposure to a suitable antigen. It can be obtained actively or passively by natural or artificial means (**figure 32.2**).
3. An antigen is a substance that stimulates an immune response and reacts with the products of that response. Each antigen can have several antigenic determinant sites or epitopes that stimulate production of and combine with specific antibodies (**figure 32.3**). Haptens are small organic molecules that are not antigenic by themselves but can become antigenic if bonded to a larger carrier molecule (**figure 32.4**).
4. Antibodies or immunoglobulins are a group of glycoproteins present in the blood, tissue fluids, and mucous membranes of vertebrates. All immunoglobulins have a basic structure composed of four polypeptide chains (two light and two heavy) connected to each other by disulfide bonds (**figure 32.7**). In humans five immunoglobulin classes exist: IgG, IgA, IgM, IgD, and IgE (**figures 32.10–32.14** and **table 32.2**).
5. Antibody diversity results from the rearrangement and splicing of the individual gene segments on the antibody coding chromosomes, somatic mutations, the generation of join diversity during splicing, and the independent assortment of light- and heavy-chain genes (**figure 32.15** and **table 32.3**).
6. Immunologic specificity and memory is partly explained by the clonal selection theory (**figure 32.18**).

7. Specific antibodies can be produced naturally by immunized animals. The primary antibody response in a host occurs following initial exposure to the antigen. This response has lag, log, plateau, and decline phases. Upon secondary antigen challenge, the B cells mount a heightened and accelerated anamnestic response (**figure 32.19**).
8. Hybridomas result from the fusion of lymphoid cells with myeloma cells. These cells produce a single monoclonal antibody (**figure 32.20**). Monoclonal antibodies have many uses.
9. T cells are pivotal elements of the immune response. T cells have antigen-specific receptor proteins (**figure 32.21**).
10. Antigen-presenting cells—most of which are macrophages, dendritic cells, and B cells—take in foreign antigens or pathogens, process them, and present antigenic fragments complexed with MHC molecules (**figure 32.22**) to T-helper cells. These MHC molecules are proteins coded by a group of genes termed the major histocompatibility complex.
11. The cytotoxic T lymphocyte recognizes target cells such as virus-infected cells that have foreign antigens and class I MHC molecules on their surface. The CTLs then attack and destroy the target cells using the CD95 pathway and/or the perforin pathway (**figures 32.24** and **32.25**).
12. Regulator T cells control the development of effector T cells. Two types exist: T-helper cells ($CD4^+$) and T-suppressor cells. There are three subsets of T-helper cells: T_H1, T_H2, and T_H0. T_H1 cells produce various cytokines and are involved in cellular immunity (**figure 32.24**). The T_H2 cells also produce various cytokines but are involved in humoral immunity. T_H0 cells are simply undifferentiated precursors of T_H1 and T_H2 cells.
13. B cells defend against antigens by differentiating into plasma cells that secrete antibodies into the blood and lymph, providing humoral or antibody-mediated immunity.
14. B cells can be stimulated to divide and/or differentiate to secrete antibody when triggered by the appropriate signals (**figures 32.24** and **32.27**).
15. B cells have receptor immunoglobulins on their plasma membrane surface that are specific for given antigenic determinants (**figure 32.28**). Contact with the antigenic determinant is required for the B cell to divide and differentiate into plasma cells and memory cells.
16. Various types of antigen-antibody reactions occur in vertebrates and initiate the participation of other body processes that determine the ultimate fate of the antigen. For example, the complement system can be activated, leading to cell lysis, phagocytosis, chemotaxis, or stimulation of the inflammatory response. Other defensive antigen-antibody interactions include toxin neutralization, viral neutralization, adherence inhibition, opsonization, and immune complex formation (**figures 32.29** and **32.30**).
17. Once activated, the classical complement pathway (**figure 32.31**) forms the membrane attack complex that can lyse antibody-coated cells.
18. Acquired immune tolerance is the ability of a host to react against nonself antigens while tolerating self-antigens. It can be induced in several ways.
19. Although both the humoral and cellular arms of the specific immune response have been considered separately, it is important to understand that the response of a vertebrate host to any particular pathogen may involve a complex set of responses. Both humoral and cellular immune responses can join nonspecific defenses to ensure a maximal survival advantage against viral and bacterial pathogens.

Questions for Thought and Review

1. What is the difference between a nonspecific host defense mechanism and a specific host defense mechanism? Give examples.
2. What are the major differences between natural and artificial immunity and between active and passive immunity?
3. Compare humoral and cell-mediated immunity.
4. A person with AIDS has a low T-helper/T-cytotoxic cell ratio. What problem(s) does this create?
5. How do B and T cells cooperate in the immune response? What is the role of macrophages?
6. All antibodies are proteins. What protein property has favored their use as antibodies in preference to some other type of biomolecule?
7. How did the clonal selection theory inspire the development of monoclonal antibody techniques?
8. What is the difference in the kinetics of antibody formation in response to a first and second exposure to the same antigen?
9. What is the basis of immunologic memory?
10. Describe the derivation of B and T cells.
11. Discuss the role of the classical complement pathway in host defense.
12. What is the purpose of acquired immune tolerance?
13. Why are T-cell receptors an important link in T-cell functioning?

Critical Thinking Questions

1. The placenta has many functions and one of them is as an immunosuppressive organ. Why is this necessary?
2. Why, evolutionarily, would sperm cells not express MHC on their surfaces?
3. What functionally important proteins are on the surface of B cells? T cells?
4. One of the main differences between an immature B cell and a plasma cell is the amount of endoplasmic reticulum. Explain which has more and why.
5. How would you distinguish a stem cell from a B cell at the DNA level?

Concepts

1. Vaccines and immunizations are among the most cost-effective weapons for microbial disease prevention. Vaccines constitute one of the greatest achievements of modern medicine.
2. Some individuals experience harmful overreactions of the immune system known as hypersensitivities. There are four types: type I is characterized by the release of physiological mediators from IgE-bound mast cells and basophils; type II results from complement-dependent lysis of cells; type III involves the formation of immune complexes that are deposited on basement membranes; and type IV arises from the reaction of T_H1 cells, cytokines, and macrophages.
3. The union of antigen and antibody in vitro produces either a visible reaction or one that can be made visible in a variety of ways. These techniques can be used to identify viruses, microorganisms, and their products; to quantitate and identify antigens and antibodies; to follow the course of a disease; to determine the serotype of a microorganism; and to determine the amount of protection from disease an animal possesses.

Box 33.1

The First Immunizations

Since the time of the ancient Greeks, it has been recognized that people who have recovered from plague, smallpox, yellow fever, and various other infectious diseases rarely contract the diseases again. The first scientific attempts at artificial immunizations were made in the late eighteenth century by Edward Jenner (1749–1823): a country doctor from Berkley, Gloucestershire, England. Jenner investigated the basis for the widespread belief of the English peasants that anyone who had vaccinia (cowpox) never contracted smallpox. Smallpox was often fatal—10 to 40% of the victims died—and those who recovered had disfiguring pockmarks. Yet most English milkmaids, who were readily infected with cowpox, had clear skin because cowpox was a relatively mild infection that left no scars.

It was on May 14, 1796, that Jenner extracted the contents of a pustule from the arm of a cowpox-infected milkmaid, Sarah Nelmes, and injected it into the arm of eight-year-old James Phipps. As Jenner expected, immunization with the cowpox virus caused only mild symptoms in the boy. When he subsequently inoculated the boy with smallpox virus, the boy showed no symptoms of the disease.

Jenner then inoculated large numbers of his patients with cowpox pus, as did other physicians in England and on the European continent (see **Box figure**). By 1800 the practice known as vaccination had begun in America, and by 1805 Napoleon Bonaparte had ordered all French soldiers to be vaccinated.

Further work on immunization was carried out by Louis Pasteur (1822–1895). Pasteur discovered that if cultures of chicken cholera bacteria were allowed to age for two or three months the bacteria produced only a mild attack of cholera when inoculated into chickens. Somehow the old cultures had become less pathogenic (attenuated) for the chickens. He then found that fresh cultures of the bacteria failed to produce cholera in chickens that had been previously inoculated with old, attenuated cultures. To honor Jenner's work with cowpox, Pasteur gave the name vaccine to any preparation of a weakened pathogen that was used (as was Jenner's "vaccine virus") to immunize against infectious disease.

Nineteenth-Century Physicians Performing Vaccinations on Children.

The three greatest discoveries of medicine in the last 200 years are antisepsis, antibiotics, and vaccines.

—*Stanley A. Plotkin*

Chapters 31 and 32 describe the various ways in which the immune system responds in vivo to protect the host by nonspecific resistance and specific immunity. Given the spectrum of diseases that result from inadequate or inappropriate immunity, clinical microbiologists are continually searching for ways to manipulate the immune response to benefit humankind. This chapter examines three areas of medical immunology in which this quest is being pursued: vaccines and immunizations, immune disorders, and antigen-antibody interactions in vitro.

33.1 Vaccines and Immunizations

Active immunization is the protection of susceptible humans and domestic animals from communicable diseases by the administration of vaccines (vaccination). A **vaccine** [Latin *vacca,* cow] is a preparation from an infectious agent that is administered to humans and other animals to induce protective immunity. It may consist of a preparation of killed microorganisms; living, weakened (attenuated) microorganisms; inactivated bacterial toxins (toxoids); purified macromolecules; recombinant vectors (e.g., modified polio vaccine); or DNA vaccines (none approved yet) that are administered to an animal to induce immunity artificially.

The modern era of vaccines and vaccination began in 1798 with Edward Jenner's use of cowpox as a vaccine against smallpox (**Box 33.1**) and in 1881 with Louis Pasteur's anthrax vaccine. Vaccines for other diseases did not emerge until the latter part of the nineteenth century, when largely through a process of trial and error, methods for inactivating and attenuating microorganisms were developed and vaccines were produced. Vaccines were eventually developed against most of the epidemic diseases that had plagued western Europe and North America (diphtheria, measles, mumps, whooping cough, German measles, polio). Indeed, toward the end of the twentieth century it began to seem that the combination of vaccines and antibiotics would temper the problem of microbial infections. Such optimism was cut short by the emergence of new or previously unrecognized diseases (*see section 37.8*) and antibiotic resistance to old ones (*see section 35.7*). Nevertheless, vaccination is still one of the most cost-effective weapons for microbial disease prevention,

Table 33.1 Examples of Vaccines Used in the United States to Prevent Viral and Bacterial Diseases in Humans

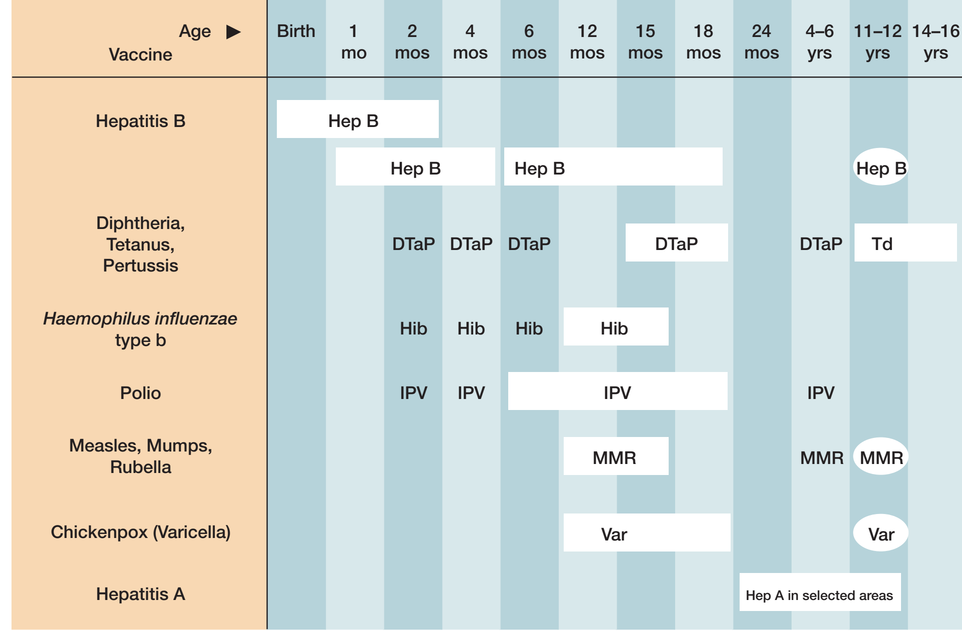
Disease	Vaccine	Booster	Recommendation
Viral Diseases			
Chickenpox	Attenuated Oka strain (Varivax)	None	Children 12–18 months; older children who have not had chickenpox
Hepatitis A	Inactivated virus (Havrix)	6–12 months	International travelers
Hepatitis B	HB viral antigen (Engerix-B, Recombivax HB)	None	High-risk medical personnel; children, birth to 18 months and 11–12 years of age
Influenza	Inactivated virus or viral components	Yearly	Chronically ill individuals and those over 65
Measles, Mumps, Rubella	Attenuated viruses (combination MMR vaccine)	None	Children 15–19 months old
Poliomyelitis	Attenuated (oral poliomyelitis vaccine, OPV) or inactivated vaccine	Adults as needed	Children 2–3 years old
Rabies	Inactivated virus	None	For individuals in contact with wildlife, animal control personnel, veterinarians
Yellow fever	Attenuated virus	10 years	Military personnel and individuals traveling to endemic areas
Bacterial Diseases			
Anthrax	Extracellular components of unencapsulated *B. anthracis*	None	Agricultural workers, veterinary personnel
Cholera	Fraction of *Vibrio cholerae*	6 months	Individuals in endemic areas, travelers
Diphtheria, Pertussis, Tetanus	Diphtheria toxoid, acellular or killed *Bordetella pertussis,* tetanus toxoid (DPT vaccine)	10 years	Children 2–3 months old
Haemophilus influenzae type b	Polysaccharide-protein conjugate (HbCV) or bacterial polysaccharide (HbPV)	None	Children under 5 years of age
Lyme disease	Single surface antigen (lipoprotein Osp A)	None	Individuals in endemic area of microorganism or of vector
Meningococcal infections	Bacterial polysaccharides of serotypes A/C/Y/W-135	None	Military; high-risk individuals
Plague	Fraction of *Yersinia pestis*	Yearly	Individuals in contact with rodents in endemic areas
Pneumococcal pneumonia	Purified *S. pneumoniae* polysaccharide of 23 pneumococcal types	None	Adults over 50 with chronic disease
Tuberculosis	Attenuated *Mycobacterium bovis* (BCG vaccine)	3–4 years	Individuals exposed to TB for prolonged periods of time
Typhoid fever	Killed *Salmonella typhi*	3–4 years	Individuals in endemic areas
Typhus fever	Killed *Rickettsia prowazekii*	Yearly	Scientists and medical personnel in areas where typhus is endemic

and vaccines arguably constitute one of the greatest achievements of modern medicine. **Table 33.1** summarizes the principal vaccines used to prevent viral and bacterial diseases in humans.

Vaccination of most children should begin at about 2 months of age. Before that age, they are protected by passive natural immunity. The recommended program of childhood immunizations for the United States is outlined in **figure 33.1.** Vaccination of adults depends on their risk group. For individuals living in close quarters (military personnel), the elderly, and those individuals with reduced immunity (transplant patients, people with sickle-cell anemia), vaccines for influenza, meningitis, and pneumonia are given. Depending on the country of travel, international travelers are routinely immunized against cholera, hepatitis, plague, polio, typhoid, typhus, and yellow fever. Health care personnel and people exposed through life-style patterns are immunized against hepatitis B. Immunization against anthrax is reserved for individuals (veterinarians or agricultural workers) who might come into contact with infected animals or products from the animals. Veterinarians, forest rangers, and others whose jobs involve contact with animals are vaccinated against rabies, plague, and Lyme disease. Recently, suspected use of anthrax spores by terrorists or in biological warfare (*see section 37.10*) has prompted the military to vaccinate military personnel against anthrax. This procedure, however, is very controversial.

Passive immunization, artificially acquired passive immunity (*see figure 32.2*), can be produced by injecting an animal or human with preformed antibodies that have been produced in another animal, in another human, or in vitro (*see section 32.3*). This type of immunization is called passive because protection does not require participation of the recipient's immune system. Passive immunization is routinely administered to individuals exposed to certain microbial pathogens that cause diseases such as botulism, diphtheria, hepatitis, measles, rabies, and tetanus as well as to protect them against snake and spider bites (**table 33.2**). However, this form of immunization should be used only when absolutely necessary because of the risks involved such as developing anaphylaxis, serum sickness, or a type III hypersensitivity reaction. Furthermore, the protection lasts only as long as the antibody molecules survive in the recipient—months with antibodies from another human, but only weeks with antibodies from animals or in vitro methods.

Figure 33.1 Recommended Regimen and Indications for Vaccinations of Children in the United States. *(Data from The American Academy of Pediatrics.)*



Bars indicate range of recommended ages for immunization. Ovals indicate vaccine to be given if previous recommended doses were missed or given earlier than the recommended age.

Table 33.2 Immune Globulins and Antitoxins Used for Passive Immunization against Specific Organisms and Diseases in the United States

Organism/Disease	Agent[a]
Black widow spider bite	Horse antivenom
Snakebite	Horse antivenom
Acute respiratory failure (respiratory syncytial virus)	Monoclonal antibodies
Botulism	Botulinum antitoxin (equine)
Diphtheria	Diphtheria antitoxin (equine)
Hepatitis A and B	Pooled human immune gamma globulin
Measles	Pooled human immune gamma globulin
Rabies	Rabies immune globulin administered around the wound in addition to being injected intramuscularly
Tetanus	Tetanus immune globulin
Eczema	Vaccinia immune globulin
Immunocompromised individuals	Varicella-zoster immune globulin

[a]Immune globulins and antitoxins are administered intramuscularly unless otherwise noted.

Types of Vaccines and Their Characteristics

As previously noted, the diseases for which we already have vaccines are ones in which the infection is acute and either resolves in several weeks or causes death of the infected individual. In the absence of vaccination, many individuals would survive as a result of the immune system defeating the invader. For these diseases, the vaccine mimics the pathogen and causes an immune response similar to that raised by the pathogen. These vaccines have eradicated smallpox, pushed polio to the brink of extinction, and spared countless individuals from hepatitis A and B, measles, rotavirus disease, tetanus, typhus, and other dangerous diseases.

In contrast, successful vaccines have yet to be developed for too many deadly or debilitating diseases (AIDS, herpes, hepatitis C, malaria, tuberculosis) because they are due to chronic infections. In a chronic infection, the pathogen is able to evade the immune system or subvert it into making ineffective responses. Successful vaccines against these chronic diseases must be able to stimulate immune responses that are similar to those resulting from most natural exposures to the pathogen. To date, this has been an unsolvable challenge in medical immunology and vaccine development.

In the remainder of this section, various approaches to the design of vaccines, both currently used vaccines and experimental ones, are described and examined in terms of their ability to induce humoral and cell-mediated immunity and the production of memory cells. **Vaccinomics,** the application of genomics and bioinformatics to vaccine development, is bringing a fresh approach to the Herculean problem of making vaccines against various microorganisms and parasites.

Whole-Organism Vaccines

Many of the current vaccines in use for humans that are effective against viral and bacterial diseases consist of whole microorganisms that are either inactivated (killed) or **attenuated** (live but avirulent) (table 33.1). These are termed **whole-organism vaccines.** The major characteristics of these vaccines are compared

Table 33.3 A Comparison of Inactivated (Killed) and Attenuated (Live) Vaccines

Major Characteristic	Inactivated Vaccine	Attenuated Vaccine
Booster shots	Multiple boosters required	Only a single booster
Production	Virulent microorganism inactivated by chemicals or irradiation	Virulent microorganism grown under adverse conditions or passed through different hosts until avirulent
Reversion tendency	None	May revert to a virulent form
Stability	Very stable, even where refrigeration is unavailable	Less stable
Type of immunity induced	Humoral	Humoral and cell-mediated

Source: Adapted from Goldsby, T. J. Kindt, and B. A. Osborne, *Kuby Immunology.* 2000, New York: W. H. Freeman.

and contrasted in **table 33.3.** Inactivated vaccines are effective, but they often require several boosters and normally do not adequately stimulate cell-mediated immunity or secretory IgA production. In contrast, attenuated vaccines usually are given in a single dose and stimulate both humoral and cell-mediated immunity.

Even though whole-organism vaccines are considered the “gold standard” of existing vaccines, they can be problematic in their own way. For example, whole-organism vaccines fail to shield against some diseases. Attenuated vaccines that do work can also cause full-blown illness in individuals whose immune system is compromised (AIDS patients, cancer patients undergoing chemotherapy, the elderly). These same individuals may also contract the disease from healthy people who have been vaccinated recently. Moreover, attenuated viruses can at times mutate in ways that restore virulence, as has happened in some monkeys given an attenuated simian form of the AIDS virus. In the case of very lethal diseases, the risk of reversion to virulence is intolerable. Whole-organism vaccines, whether live or dead, have another big drawback. Since they are composed of complete pathogens, they retain molecules that are not involved in evoking immunity. These molecules, as well as contaminants that are unavoidable byproducts of the manufacturing process, can trigger allergic or other disruptive reactions.

Purified Macromolecules as Vaccines

A few of the common risks associated with whole-organism vaccines can be avoided by using only specific, purified macromolecules derived from pathogenic microorganisms. Currently, there are three general forms of **macromolecule vaccines:** (1) capsular polysaccharides, (2) recombinant surface antigens, and (3) inactivated exotoxins called **toxoids** (*see p. 796*). The purified macromolecule vaccines that are currently available for humans are listed in **table 33.4.**

Table 33.4 Purified Macromolecule Vaccines Currently Available for Human Use

Type of Purified Macromolecule (Disease or Microorganism)	Form of Vaccine
Capsular polysaccharide	
Haemophilus influenzae type b	Polysaccharide-protein conjugate (HbCV) or bacterial polysaccharide (HbPV)
Neisseria meningitidis	Polysaccharides of serotypes A/C/Y/W-135
Streptococcus pneumoniae	23 distinct capsular polysaccharides
Surface antigen	
Hepatitis B	Recombinant surface antigen (HbsAg)
Toxoids	
Diphtheria	Inactivated exotoxin
Tetanus	Inactivated exotoxin

Recombinant-Vector Vaccines

Genetic vaccines are quite different in structure from whole-organism vaccines. It is now possible to isolate genes that encode major antigens from a pathogen and insert them into nonvirulent viruses or bacteria. The vaccines are usually delivered by needle injection or by a device called a gene gun. The attenuated microorganism serves as a vector, replicating within the host and expressing the gene product of the pathogen–encoded antigenic proteins. The antigens can elicit humoral immunity when they escape from the vector, and they can also elicit cellular immunity when they are broken down and properly displayed on the cell surface (just as occurs when cells harbor an active pathogen).

Recently several microorganisms have been used in the production of these **recombinant-vector vaccines.** Examples include adenovirus, vaccinia virus, canarypox virus, attenuated poliovirus, and attenuated strains of *Salmonella* and *Mycobacterium.*

DNA Vaccines

A more complicated genetic vaccine to emerge in recent years is the DNA vaccine. A **DNA vaccine** elicits protective immunity against a microbial pathogen by activating both branches of the immune system: humoral and cellular. Long-lasting memory cells also are generated.

The immunization procedure begins with the injection into muscle of a plasmid preparation that contains genes for pathogen antigens. The plasmids are taken up by muscle cells, enter the cell nuclei, and express their antigen genes. The muscle cells commence protein synthesis and produce the pathogen’s antigenic proteins.

In the humoral response, the antigenic proteins are released from the muscle cell and bind to B-cell antigen receptors. At the same time, antigen-presenting cells ingest the antigenic proteins, break them down, and display the fragments on a class II MHC molecule. Helper T cells then recognize the antigen and secrete T_H2 cytokines that activate B cells containing bound antigen. The activated B cells multiply and differentiate into plasma cells that release antibodies which bind to the pathogen and neutralize it or mark it for destruction. Other B cells become memory cells that will protect the host against future infections with the same pathogen.

The cellular immune response begins when the muscle cells display the same antigenic proteins or protein fragments (peptides) on MHC class I molecules. The plasmid vaccine vector also becomes incorporated into antigen-presenting cells, which synthesize the encoded antigens and express fragments of the antigens on MHC I molecules along with co-stimulatory molecules. Cytotoxic T cells recognize these signals and are additionally stimulated by cytokines (this time, T_H1 cytokines) from helper T cells. The activated cytotoxic T cells multiply and attack cells infected by the pathogen. Some activated T cells also develop into memory T cells and protect against future infections.

At present, there are human trials under way with several different DNA vaccines against malaria, AIDS, influenza, hepatitis B, and herpesvirus. Vaccines against a number of cancers (lymphomas, prostate, colon) are also being tested.

1. What is a vaccine? Briefly describe and contrast active and passive immunization.
2. Describe the major differences between inactivated and attenuated vaccines. Discuss the advantages and disadvantages of using attenuated microorganisms as vaccines.
3. Give the three types of purified macromolecules that are currently used as vaccines.
4. What are some advantages of genetically engineered vaccines? Some disadvantages?

33.2 Immune Disorders

Chapters 31 and 32 presented the awesome power of the immune system in protecting the host against the continual onslaught of microbial invaders and cancer cells. Like any system in a vertebrate host, disorders (malfunctions) also occur in the immune system. Immune disorders can be categorized as hypersensitivities, autoimmune diseases, transplantation (tissue) rejection, and immunodeficiencies. Each of these immune disorders is now discussed.

Hypersensitivities

Hypersensitivity is an exaggerated immune response that results in tissue damage and is manifested in the individual on second or subsequent contact with an antigen. Hypersensitivity reactions can be classified as either immediate or delayed. Obviously immediate reactions appear faster than delayed ones, but the main difference between them is in the nature of the immune response to the antigen. Realizing this fact, Peter Gell and Robert Coombs developed a classification system for reactions responsible for hypersensitivities in 1963. Their system correlates clinical symptoms with information about immunologic events that occur during hypersensitivity reactions. The Gell-Coombs classification system divides hypersensitivity into four types: I, II, III, and IV.

Type I Hypersensitivity

Allergic reactions occur when an individual who has produced IgE antibody in response to an inocuous antigen (**allergen**) subsequently encounters the same allergen. An **allergy** [Greek *allos,* other and *ergon,* work] is one kind of type I hypersensitivity reaction.

Type I hypersensitivity is characterized by an allergic reaction occurring immediately following an individual's second contact with the responsible antigen (the allergen). Upon initial exposure to a soluble allergen, B cells are stimulated to differentiate into plasma cells and produce specific IgE with the help of T cells (**figure 33.2**). This IgE is sometimes called a **reagin,** and the individual has a hereditary predisposition for its production. Once synthesized, IgE binds to the Fc receptors of mast cells (basophils and eosinophils can also be activated) and sensitizes these cells, making the individual allergic to the allergen. When a second exposure to the allergen occurs, the allergen attaches to the surface-bound IgE on the sensitized mast cells causing degranulation. Degranulation releases physiological mediators such as histamine, leukotrienes, heparin, prostaglandins, PAF (platelet-activation factor), ECF-A (eosinophil chemotactic factor of anaphylaxis), and proteolytic enzymes. These mediators trigger smooth muscle contractions, vasodilation, increased vascular permeability, and mucous secretion. The inclusive term for these responses is **anaphylaxis** [Greek *ana,* up, back, again; and *phylaxis,* protection]. Anaphylaxis can be divided into systemic and localized reactions.

Systemic anaphylaxis is a generalized response that occurs when an individual sensitized to an allergen receives a subsequent exposure to it. The reaction is immediate due to the large amount of mast cell mediators released over a short period. Usually there is respiratory impairment caused by smooth muscle constriction in the bronchioles. The arterioles dilate, which greatly reduces arterial blood pressure and increases capillary permeability with rapid loss of fluid into the tissue spaces. Because of these reactions the individual can die within a few minutes from reduced venous return, asphyxiation, reduced blood pressure, and circulatory shock. Common examples of allergens that can produce systemic anaphylaxis include drugs (penicillin), passively administered antisera, peanuts, and insect venom from the stings or bites of wasps, hornets, or bees (**figure 33.3**).

Localized anaphylaxis is called an atopic ("out of place") allergy. The symptoms that develop depend primarily on the route by which the allergen enters the body. **Hay fever** (allergic rhinitis) is a good example of an atopic allergy involving the upper respiratory tract. Initial exposure involves airborne allergens—such as plant pollen, fungal spores, animal dander, and house dust mites—that sensitize mast cells located within the mucous membranes. Reexposure to the allergen causes the typical localized anaphylactic response: itchy and tearing eyes, congested nasal

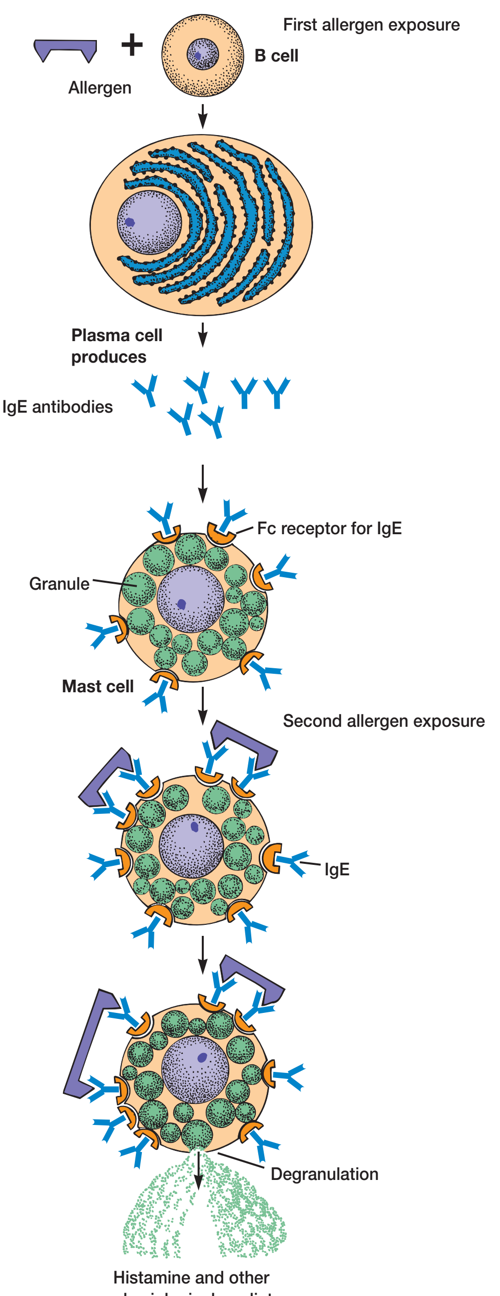


Figure 33.2 Type I Hypersensitivity. This type of hypersensitivity occurs when IgE antibodies attach to mast cells. The combination of these antibodies with allergens stimulates the mast cell (or basophil) to degranulate and produce the physiological mediators that cause the anaphylactic reaction, asthma, or hay fever.

passages, coughing, and sneezing. Antihistamine drugs are used to help alleviate these symptoms.

Bronchial asthma (asthma means panting) is an example of an atopic allergy involving the lower respiratory tract. Common allergens are the same as for hay fever. In bronchial asthma, however, the air sacs (alveoli) become overdistended and fill with fluid and mucus; the smooth muscle contracts and narrows the walls of the bronchi. Bronchial constriction produces a wheezing or whistling sound during exhalation. Symptomatic relief is obtained from bronchodilators that help relax the bronchial muscles, and from expectorants and liquefacients that dissolve and expel mucous plugs that accumulate.

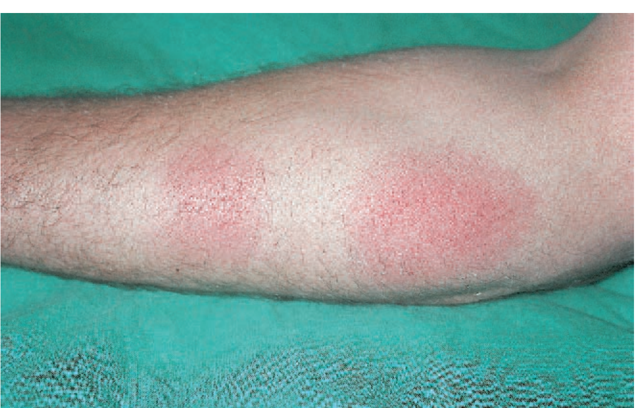

Figure 33.3 The Anaphylactic Response to Bee Venom. This person has been stung on the arm by a bee, leading to type I hypersensitivity in a generalized area.

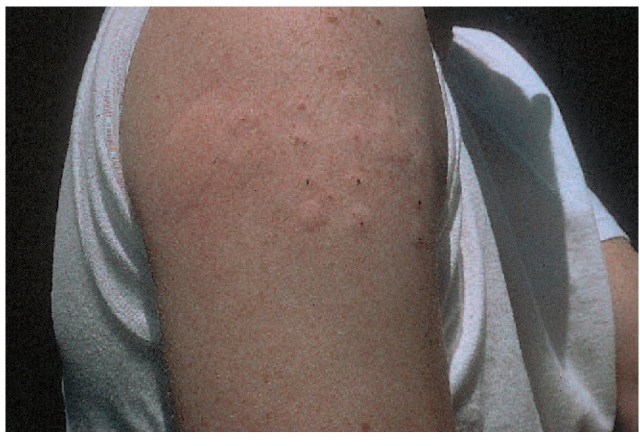
Allergens that enter the body through the digestive system may cause food allergies. **Hives** (eruptions of the skin) are a good diagnostic sign of a true food allergy. Once established, type I food allergies are usually permanent but can be partially controlled with antihistamines or by avoidance of the allergen.

Skin testing can be used to identify the allergen responsible for allergies. These tests involve inoculating small amounts of suspect allergen(s) into the skin. Sensitivity to the antigen is shown by a rapid inflammatory reaction characterized by redness, swelling, and itching at the site of inoculation (**figure 33.4**). The affected area in which the allergen-mast cell reaction takes place is called a wheal and flare reaction site.

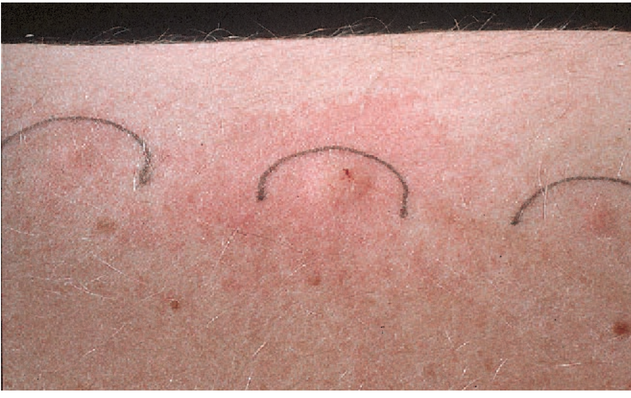
Once the responsible allergen has been identified, the individual should avoid contact with it. At times this is not possible, and **desensitization** is warranted. This procedure consists of a series of allergen doses injected beneath the skin to stimulate the production of IgG antibodies rather than IgE antibodies. The circulating IgG antibodies can then act as blocking antibodies to intercept and neutralize allergens before they have time to react with mast cell-bound IgE. Recent evidence suggests that suppressor T-cell activity also may cause a decrease in IgE synthesis. Desensitizations are about 65 to 75% effective in individuals whose allergies are caused by inhaled allergens.

Type II Hypersensitivity

Type II hypersensitivity is generally called a cytolytic or cytotoxic reaction because it results in the destruction of host cells,



(a)



(b)

Figure 33.4 In Vivo Skin Testing. (**a**) Skin prick tests with grass pollen in a person with summer hay fever. Notice the various reactions with increasing dosages (from top to bottom). (**b**) Skin patch test. The surface of the skin (left) is abraded and the suspect allergic extract placed on the skin. After 48 hours (center) it is eczematous and positive for the suspect antigen.

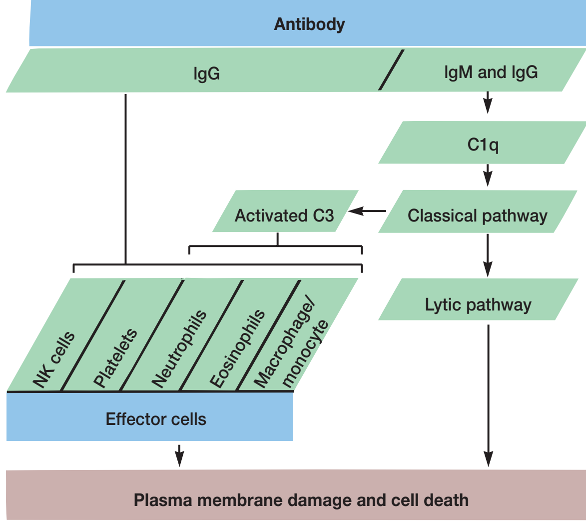


Figure 33.5 Type II Hypersensitivity. The action of antibody occurs through effector cells or the membrane attack complex, which damages target cell plasma membranes, causing cell destruction.

either by lysis or toxic mediators. In type II hypersensitivity, IgG or IgM antibodies are directed against cell surface or tissue-associated antigens. They usually stimulate the complement pathway and a variety of effector cells (**figure 33.5**). The antibodies interact with complement (Clq) and the effector cells through their Fc regions. The damage mechanisms are a reflection of the normal physiological processes involved in interaction of the immune system with pathogens. A classic example of type II hypersensitivity is that resulting when a person receives a transfusion with blood from a donor with a different blood group.

Type III Hypersensitivity

Type III hypersensitivity involves the formation of immune complexes (**figure 33.6*a***). Normally these complexes are removed effectively by the fixed monocytes and macrophages of the monocyte-macrophage system. In the presence of excess amounts of some soluble antigens, the antigen-antibody complexes may not be efficiently removed. Their accumulation can lead to a hypersensitivity reaction from complement that triggers a variety of inflammatory processes. This inflammation causes damage, especially of blood vessels (vasculitis; figure 33.6*b*), kidney glomerular basement membranes (glomerulonephritis), joints (arthritis), and skin.

Diseases resulting from type III reactions can be placed into three groups. First, a persistent viral, bacterial, or protozoan infection, together with a weak antibody response, leads to chronic immune complex formation and eventual deposition of the complex in host tissues. Second, the continued production of autoantibody to self-antigen during an autoimmune disease can lead to prolonged immune complex formation. This overloads the monocyte-macrophage system, and tissue deposition of the complexes occurs (e.g., in the disease **systemic lupus erythematosus**). Third, immune complexes can form at body surfaces (such as the lungs), following repeated inhalation of allergens from molds, plants, or animals. For example, in Farmer's lung disease, an individual has circulating antibodies to fungi after being exposed repeatedly to moldy hay. These antibodies are primarily IgG. When the allergens (fungal spores) enter the alveoli of the lungs, local immune complexes form, leading to inflammation.

Some group A streptococcal infections can produce an immunologically mediated acute glomerulonephritis. Although the mechanism is not completely understood, it is believed that complexes of antibody and streptococcal antigen are deposited within the kidney glomeruli and generate a type III hypersensitivity reaction.

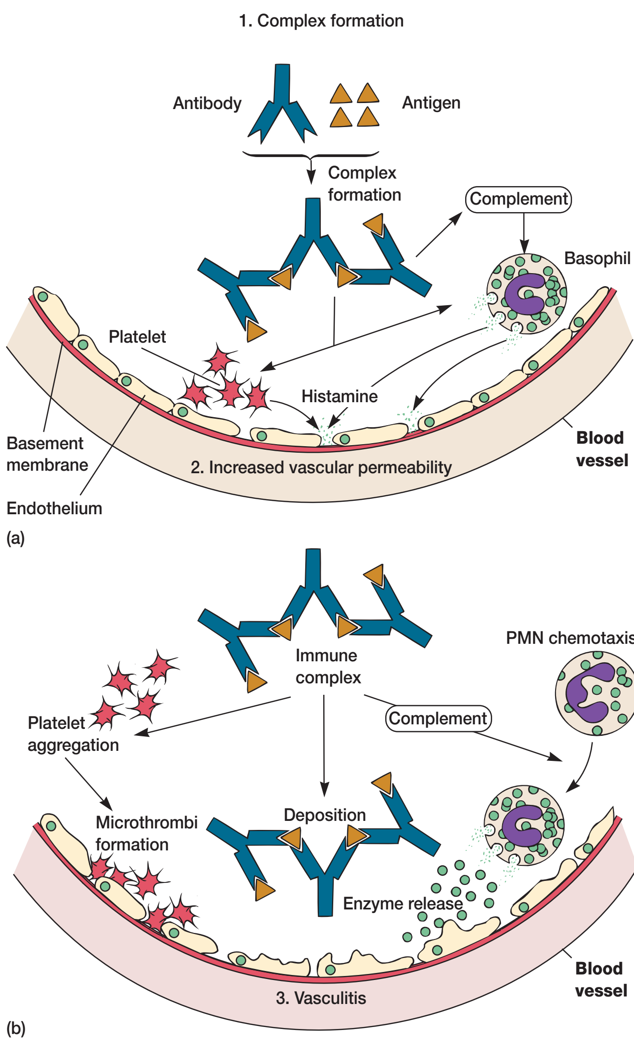

Figure 33.6 Type III Hypersensitivity. Deposition of immune complexes in blood vessel walls. (**a**) Antibody and antigen combine to form immune complexes. These activate complement, which causes basophils and platelets to degranulate and release histamine and other mediators. These mediators increase vascular permeability. (**b**) The increased permeability allows the immune complexes to be deposited in the blood vessel wall. This induces platelet aggregation to form microthrombi (blood clots) on the vessel wall. PMNs, stimulated by complement, degranulate causing enzymatic damage to the blood vessel wall.

Type IV Hypersensitivity

Type IV hypersensitivity involves delayed T-cell-mediated immune reactions. A major factor in the type IV reaction is the time required for a special subset of T_H1 cells (often called delayed-type hypersensitivity [T_{DTH}] cells) to migrate to and accumulate near the antigens. This usually takes a day or more.

Type IV reactions occur when antigens, especially those binding to tissue cells, are phagocytosed by macrophages and then presented to receptors on the T_H1 cell surface in the context of class I MHC. Contact between the antigen and T_H1 cell causes the cell to proliferate and release cytokines. Cytokines attract lymphocytes, macrophages, and basophils to the affected tissue. Extensive tissue damage may result. Examples of type IV hypersensitivities include tuberculin hypersensitivity (the **TB skin test**), allergic contact dermatitis, some autoimmune diseases, transplantation rejection, and killing of cancer cells.

In tuberculin hypersensitivity a partially purified protein called tuberculin, which is obtained from the bacillus that causes tuberculosis (*Mycobacterium tuberculosis; see section 39.1*), is injected into the skin of the forearm (**figure 33.7*a***). The response in a tuberculin-positive individual begins in about 8 hours, and a reddened area surrounding the injection site becomes indurated (firm and hard) within 12 to 24 hours. The T_H1 cells that migrated into the injection site are responsible for the induration. The reaction reaches its peak in 48 hours and then subsides. The size of the induration is directly related to the amount of antigen that was introduced and to the degree of hypersensitivity of the tested individual. Other microbial products used in type IV skin testing are histoplasmin for histoplasmosis, coccidioidin for coccidioidomycosis, lepromin for leprosy, and brucellergen for brucellosis.

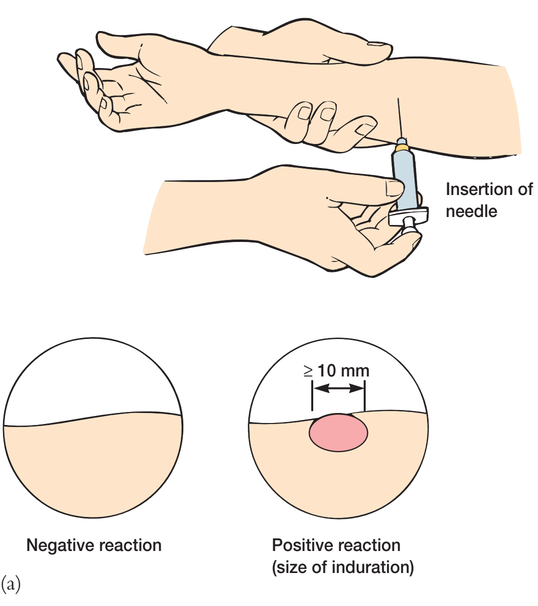
Allergic contact dermatitis is caused by haptens (*see figure 32.4*) that combine with proteins in the skin to form the allergen that elicits the immune response. The haptens are the antigenic determinants, and the skin proteins are the carrier molecules for the haptens. Examples of these haptens include cosmetics, plant materials (catechol molecules from poison ivy and poison oak; figure 33.7*b*), topical chemotherapeutic agents, metals, and jewelry (especially jewelry containing nickel).

Several important chronic diseases involve cell and tissue destruction by type IV hypersensitivity reactions. These diseases are caused by viruses, mycobacteria, protozoa, and fungi that produce chronic infections in which the macrophages and T cells are continually stimulated. Examples are leprosy, tuberculosis, leishmaniasis, candidiasis, and herpes simplex lesions.

1. Discuss the mechanism of type I hypersensitivity reactions and how these can lead to systemic and localized anaphylaxis.
2. What causes a wheal and flare reaction site?
3. Why are type II hypersensitivity reactions called cytolytic or cytotoxic?
4. What characterizes a type III hypersensitivity reaction? Give an example.
5. Characterize a type IV hypersensitivity reaction.
6. What is the TB skin test used for?

Autoimmune Diseases

As discussed earlier, the body is normally able to distinguish its own self-antigens from foreign nonself antigens and does not mount an immunologic attack against the former. This phenomenon is called immune tolerance. At times the body loses tolerance and mounts an abnormal immune attack, either with antibodies or T cells, against a person's own self-tissue antigens.



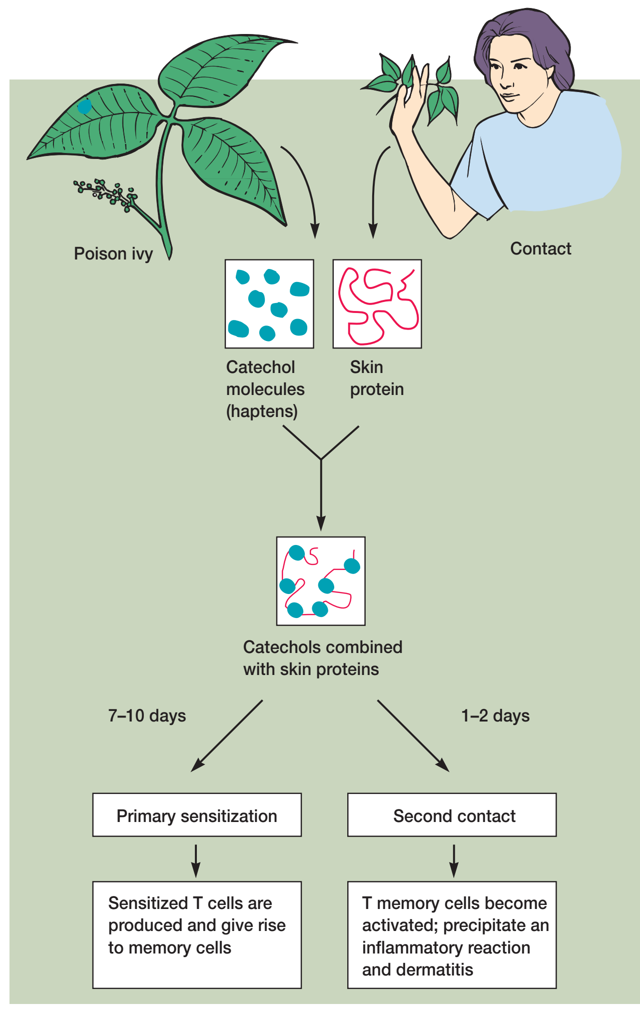


Figure 33.7 Mechanism of Type IV Hypersensitivity. (**a**) The tuberculin skin test. A positive reaction is one in which the diameter of induration is 10 mm or more. (**b**) In this example of contact dermatitis to poison ivy, a person initially becomes exposed to the catechol molecules from the poison ivy plant. The catechols combine with high molecular weight skin proteins and act as haptens. After 7–10 days sensitized T cells are produced and give rise to memory T cells. Upon second contact, the catechols bind to the same skin proteins, and the T memory cells become activated in only 1–2 days, leading to the inflammatory reaction (contact dermatitis).

It is important to distinguish between autoimmunity and autoimmune disease. Autoimmunity often is benign, whereas autoimmune disease often is fatal. **Autoimmunity** is characterized only by the presence of serum autoantibodies. It is a normal consequence of aging; is readily inducible by infectious agents, organisms, or drugs; and is potentially reversible (it disappears when the offending "agent" is removed or eradicated). **Autoimmune disease** results from the activation of self-reactive T and B cells that, following stimulation by genetic or environmental triggers, cause actual tissue damage (**table 33.5**).

Four factors influence the development of autoimmune disease. Two major factors are genetic and viral. The third factor is endocrine; the hormone estrogen promotes autoimmune disease, and androgens act as natural immunosuppressive agents. These physiological modulatory effects of sex hormones acting on normal immune responses partially explain the marked female predominance of autoimmune diseases. The fourth factor is psychoneuroimmunological—that is, the influence of stress and neurochemicals on the immune response. Overall, all four of these factors can affect gene expression, which directly or indirectly interferes with important immunoregulatory actions.

Although their causal mechanism is not well known, these diseases are more common in older people and may involve viral or bacterial infections. Some investigators believe that the release of abnormally large quantities of antigens may occur when the infectious agent causes tissue damage. The same agents also may cause body proteins to change into forms that stimulate antibody production or T-cell activation. Simultaneously the activity of T-suppressor cells, which normally limits this type of reaction, seems to be repressed. Many autoimmune diseases have a genetic component. For example, there is a well-known association between an individual's susceptibility to Graves' disease and multiple sclerosis and specific determinants on the major histocompatibility complex.

Table 33.5 Some Autoimmune Diseases in Humans

Disease	Autoantigen	Pathophysiology
Type II Hypersensitivity: Antibody to Cell-Surface or Cell Matrix Antigens (Cytotoxic)		
Acute rheumatic fever	Streptococcal cell wall antigens; antibodies cross-react with cardiomyocytes	Arthritis, scarring of heart valves, myocarditis
Autoimmune hemolytic anemia	Rh blood group, I antigen	Red blood cells are destroyed by complement and phagocytosis, anemia
Autoimmune thrombocytopenia purpura	Platelet integrin	Perfuse bleeding
Goodpasture's syndrome	Basement membrane collagen	Glomerulonephritis, pulmonary hemorrhage
Grave's disease	Thyroid-stimulating hormone receptor	Hyperthyroidism
Myasthenia gravis	Acetycholine receptor	Progressive muscular weakness
Pemphigus vulgaris	Cadherin in epidermis	Skin blisters
Type III Hypersensitivity: Immune Complex Disease		
Systemic lupus erythematosus	DNA, histones, ribosomes	Arthritis, glomerulonephritis, vasculitis
Type IV Hypersensitivity: T-Cell–Mediated Disease		
Type 1 diabetes mellitus	Pancreatic beta cell antigen	Beta cell destruction
Multiple sclerosis	Myelin basic protein	Demyelination of axons
Rheumatoid arthritis[a]	Unknown synovial joint antigen	Joint inflammation and destruction

[a] Type III hypersensitivity processes also may be involved.

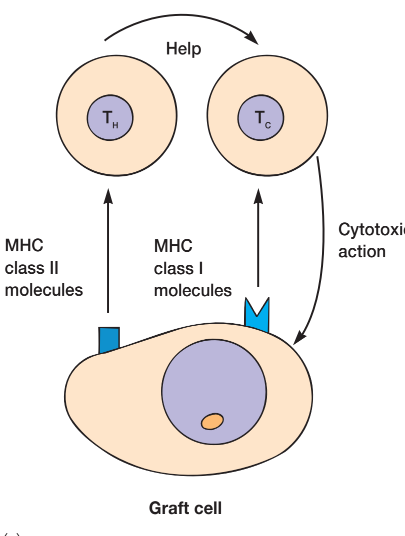
Transplantation (Tissue) Rejection

Tissue transplant rejection is the third area (after hypersensitivity and autoimmunity) in which the immune system can act detrimentally. It is occasionally desirable to replace a nonfunctional or damaged body part by transplanting a tissue or organ from one person to another. Transplants between genetically different individuals within a species are termed **allografts** [Greek *allos,* other]. Some transplants do not stimulate an immune response. For example, a transplanted cornea is rarely rejected since lymphocytes do not circulate into the anterior chamber of the eye. This site is considered an immunologically privileged site. Another example of a privileged tissue transplant is the heart valve transplanted from a pig to a human. Such a graft between different species is termed a **xenograft** [Greek *xenos,* strayed].

With allografts, there is the possibility that the recipient's cells will recognize the donor's tissues as foreign. This triggers the recipient's immune mechanisms, which may destroy the donor tissue. Such a response is called a tissue rejection reaction. A tissue rejection reaction can occur by two different mechanisms. First, foreign major histocompatibility complex (MHC) class II molecules on the graft stimulate host T-helper cells to aid cytotoxic T cells in graft destruction (**figure 33.8*a***). Cytotoxic T cells recognize the graft through the foreign MHC class I molecules. A second mechanism involves the T-helper cells reacting to the graft and releasing cytokines (figure 33.8*b*). The cytokines stimulate macrophages to enter the graft and destroy it.

As presented in figure 33.8, the major histocompatibility complex molecules play a dominant role in tissue rejection reactions because of their unique association with the recognition system of T cells. Unlike antibodies, T cells cannot recognize or react directly with non-MHC molecules (viruses, allergens). They recognize these molecules only in association with, or complexed to, an MHC molecule. There are two classes of MHC molecules. Class I MHC molecules are present on every cell in the body and consequently are important targets of the rejection reaction. Class II MHC molecules are involved in T-helper cell activation as previously discussed. The greater the antigenic difference between class I molecules of the recipient and donor tissues, the more rapid and severe the rejection reaction is likely to be. However, the reaction can sometimes be minimized if recipient and donor tissues are matched as closely as possible.

Immunosuppression in organ transplant cases also can lead to **graft-versus-host disease.** This occurs when the transplanted tissue contains immunocompetent cells that recognize host antigens and attack the host. The immunosuppressed recipient cannot control the response of the grafted tissue. Graft-versus-host disease is a common problem in allogenic bone marrow transplants. The transplanted bone marrow contains many mature post-thymic T cells. These cells recognize the host MHC antigens and attack the immunosuppressed recipient's normal tissue cells. Currently one way to prevent graft-versus-host disease is to deplete the bone marrow of mature T cells by using immunosuppressive techniques. Examples include drugs that



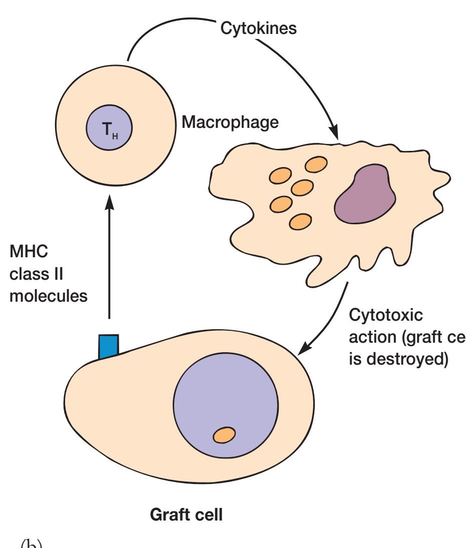


Figure 33.8 Graft Cell Destruction. (**a**) Foreign MHC class II molecules on the graft cell stimulate host T-helper cells to help cytotoxic T cells destroy the target graft cell. Cytotoxic T cells recognize the graft cell by its foreign MHC class I molecules. (**b**) T-helper cells reacting to the graft cell release cytokines that stimulate macrophages to enter the graft and destroy it by cytotoxic action.

Table 33.6 Some Congenital Immune Deficiencies in Humans

Condition	Symptoms	Cause
Chronic granulomatous disease	Defective monocytes and neutrophils leading to recurrent bacterial and fungal infections	Failure to produce reactive oxygen intermediates due to defective NADPH oxidase
X-linked agammaglobulinemia	Plasma cell or B-cell deficiency and inability to produce adequate specific humoral antibodies	Defective B cell differentiation due to loss of tyrosine kinase
DiGeorge syndrome	T-cell deficiency and very poor cell-mediated immunity	Lack of thymus or a poorly developed thymus
Severe combined immunodeficiency disease (SCID)	Both antibody production and cell-mediated immunity impaired due to a great reduction of B- and T-cell levels	Various mechanisms (e.g., defective B- and T-cell maturation because of X-linked gene mutation; absence of adenosine deaminase in lymphocytes)

attack T cells (azathioprine and cyclophosphamide), immunosuppressive drugs (cyclosporin), anti-inflammatory drugs (corticosteroids), irradiation of the lymphoid tissue, and antibodies directed against T-cell antigens.

Immunodeficiencies

Defects in one or more components of the immune system can result in its failing to recognize and respond properly to antigens. Such **immunodeficiencies** can make a person more prone to infection than those people capable of a complete and active immune response. Despite the increase in knowledge of functional derangements and cellular abnormalities in the various immunodeficiency disorders, the fundamental biological errors responsible for them remain largely unknown. To date, most genetic errors associated with these immunodeficiencies are located on the X chromosome and produce primary or congenital immunodeficiencies (**table 33.6**). Other immunodeficiencies can be acquired because of infections by immunosuppressive microorganisms (chronic mucocutaneous candidiasis) or by some viruses (HIV).

1. What is an autoimmune disease and how might it develop?
2. What is an immunologically privileged site and how is it related to transplantation success?
3. How does a tissue rejection reaction occur?
4. Describe an immunodeficiency. How might immunodeficiencies arise?

33.3 Antigen-Antibody Interactions In Vitro

In the previous chapter, section 32.6 (*see pp. 756–57*) deals with those antigen-antibody interactions that occur within an animal (in vivo). Many of these same reactions can take place outside the animal (in vitro) under controlled laboratory conditions and are extensively used in diagnostic testing. The branch of medical immunology concerned with antigen-antibody reactions in vitro is **serology** [serum and -ology].

Box 33.2

The Rapid Detection of Drugs in Urine

Historically, drug-screening assays were done by classical chemical methods such as thin-layer chromatography (TLC) or liquid chromatography (LC) which, though accurate, are laborious procedures. Assays currently employed in limited drug testing are based on antigen-antibody reactions. Some examples are the radioimmunoassay, enzyme immunoassay, and fluorescence immunoassay methods, all of which depend on sophisticated instrumentation. With the requirement for massive drug testing in sports, federal civilian employment, the military, and other fields, rapid procedures bypassing the need for expensive equipment are needed.

One such rapid procedure uses a latex agglutination immunoassay for the detection of cocaine, morphine, barbiturates, THC (marijuana), methadone, pencyclidine, and amphetamines. This method provides the accuracy of the immunoassay approach without the need for expensive equipment, and gives accurate on-site "yes" and "no" results within 3 minutes.

The latex agglutination-inhibition test relies on competition for the antibody between a latex-drug conjugate and any drug that may be present in the urine. A urine sample is placed in the mixing well of a slide containing antibody reagent, buffer, and latex reagent. If the drug is absent, the latex-drug conjugate binds to the antibody and forms large particles that agglutinate. Therefore agglutination is evidence for the absence of drugs in the urine specimen (see **Box figure,** parts *a,c*). If a drug is present in the urine sample, it competes with the latex conjugate for the small amount of available antibody. A sufficient quantity of the drug will prevent the formation of particles and agglutination (see Box figure, part *b*), and a positive urine sample does not change the appearance of the test mixture (see Box figure, part *c*).

As medical immunology enters the new millennium, there has been a marked increase in the number, sensitivity, and specificity of serological tests. The increase results from a better understanding of the cell surface of various lymphocytes, the production of monoclonal antibodies, the development of radioactive and enzyme-linked assays, and the use of fluorescence technology. In this section some more common serological tests employed in the diagnosis of microbial and immunologic diseases are presented.

Agglutination

As noted in figure 32.30, when an immune complex is formed by cross-linking cells or particles with specific antibodies, it is called an agglutination reaction. Agglutination reactions usually form visible aggregates or clumps (**agglutinates**) that can be seen with the unaided eye. Direct agglutination reactions are very useful in the diagnosis of certain diseases. For example, the **Widal test** is a reaction involving the agglutination of typhoid bacilli when they are mixed with serum containing typhoid antibodies from an individual who has typhoid fever. Immune complex formation (pp. 756–57)

Techniques have also been developed that employ microscopic synthetic latex spheres coated with antigens. These coated microspheres are extremely useful in diagnostic agglutination reactions. For example, the modern pregnancy test detects the elevated level of human chorionic gonadotropin (HCG) hormone that occurs in female urine and blood early in pregnancy (**figure 33.9**). Latex agglutination tests are also used to detect antibodies that develop during certain mycotic, helminthic, and bacterial infections, and in drug testing (**Box 33.2**).

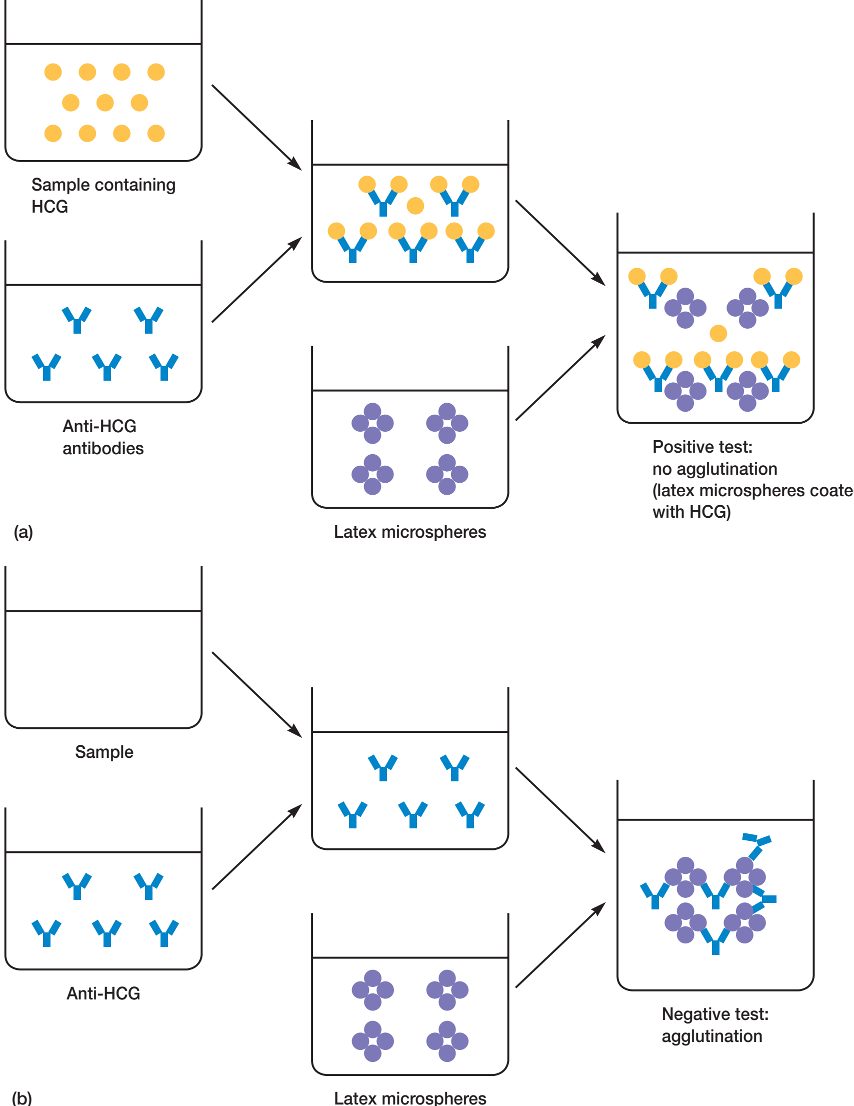

Figure 33.9 Latex Agglutination Test for Pregnancy. (**a**) In a positive test, urine from the female containing HCG is mixed with a solution of antibody specific for HCG. In the second step latex microspheres coated with HCG are added. If HCG is present, it binds to HCG-specific antibodies, thereby preventing them from agglutinating the microspheres. (**b**) In a negative test the microspheres coated with antigen are agglutinated by HCG-specific antibody.

Hemagglutination usually results from antibodies cross-linking red blood cells through attachment to surface antigens and is routinely used in blood typing. In addition, some viruses can accomplish **viral hemagglutination.** For example, if a person has a certain viral disease, such as measles, antibodies will be present in the serum to react with the measles viruses and neutralize them. Normally, hemagglutination occurs when measles viruses and red blood cells are mixed but is not seen when the person's serum is added to the mixture; this shows that the serum antibodies have neutralized the measles viruses and is considered a positive test (**figure 33.10**). This hemagglutination inhibition test is widely used to diagnose influenza, measles, mumps, mononucleosis, and other viral infections (*see chapter 38*).

Agglutination tests are also used to measure antibody titer (*see figure 32.19*). In the tube or well agglutination test, a specific amount of antigen is added to a series of tubes (**figure 33.11*a***) or shallow wells in a microtiter plate (figure 33.11*b*). Serial dilutions of serum (1/20, 1/40, 1/80, 1/160, etc.) containing the antibody are then added to each tube or well. The greatest dilution of serum showing an agglutination reaction is determined, and the reciprocal of this dilution is the serum antibody titer.

1. What is serology?
2. When would you use the Widal test?
3. Why does hemagglutination occur and how can it be used in the clinical laboratory?
4. Describe how latex agglutination tests work.

© The McGraw−Hill Companies, 2002

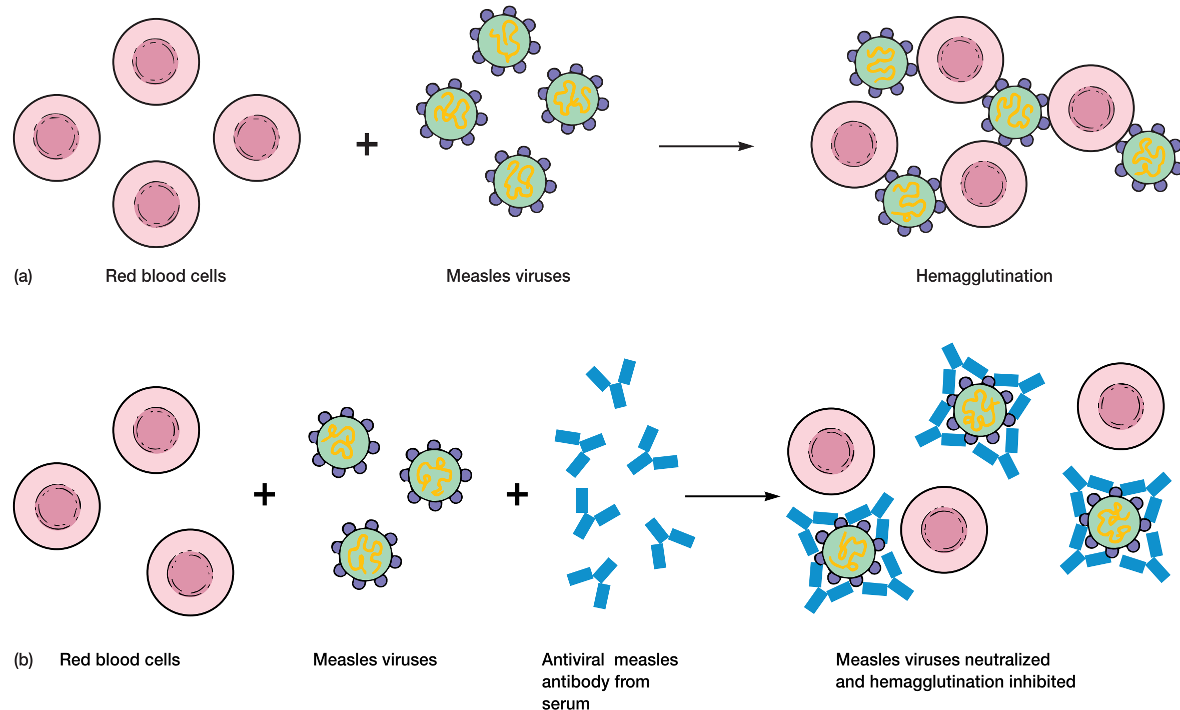

Figure 33.10 Viral Hemagglutination. (**a**) Certain viruses can bind to red blood cells causing hemagglutination. (**b**) If serum containing specific antibodies to the virus is mixed with the red blood cells, the antibodies will neutralize the virus and inhibit hemagglutination (a positive test).

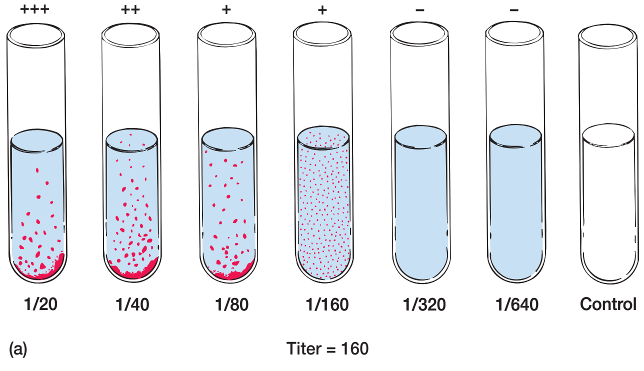

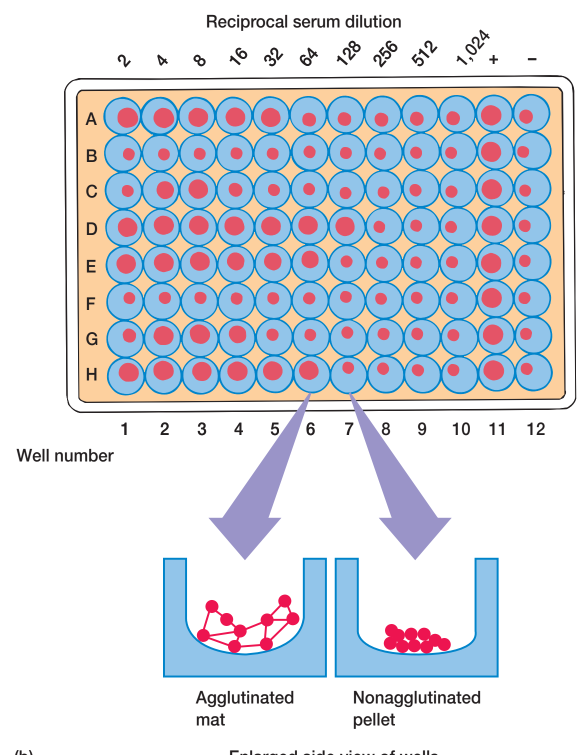

Figure 33.11 Agglutination Tests. (**a**) Tube agglutination test for determining antibody titer. The titer in this example is 160 since there is no agglutination in the next tube in the dilution series (1/320). The color in the dilution tubes indicates the presence of the patient's serum. (**b**) A microtiter plate illustrating hemagglutination. The antibody is placed in the wells (1–10). Positive controls (row 11) and negative controls (row 12) are included. Red blood cells are added to each well. If sufficient antibody is present to agglutinate the cells, they sink as a mat to the bottom of the well. If insufficient antibody is present, they form a pellet at the bottom. Can you read the different titers in rows A–H?

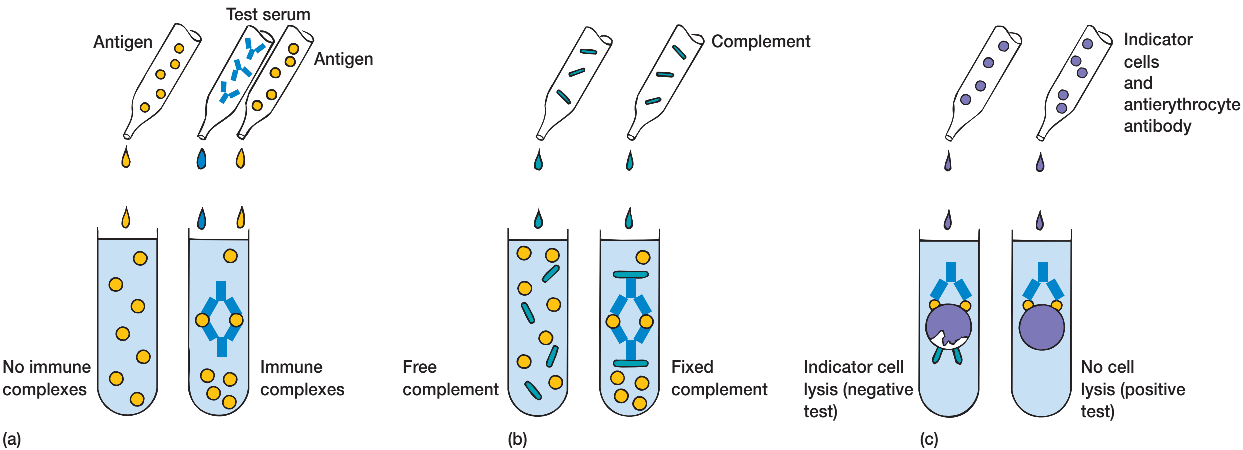

Figure 33.12 Complement Fixation. (**a**) Test serum is added to one test tube. A fixed amount of antigen is then added to both tubes. If antibody is present in the test serum, immune complexes form. (**b**) When complement is added, if complexes are present, they fix complement and consume it. (**c**) Indicator cells and a small amount of antierythrocyte antibody are added to the two tubes. If there is complement present, the indicator cells will lyse (a negative test); if the complement is consumed, no lysis will occur (a positive test).

Complement Fixation

When complement binds to an antigen-antibody complex, it becomes "fixed" and "used up." Complement fixation tests are very sensitive and can be used to detect extremely small amounts of an antibody for a suspect microorganism in an individual's serum. A known antigen is mixed with test serum lacking complement (**figure 33.12*a***). When immune complexes have had time to form, complement is added (figure 33.12*b*) to the mixture. If immune complexes are present, they will fix and consume complement. Afterward, sensitized indicator cells, usually sheep red blood cells previously coated with complement-fixing antibodies, are added to the mixture. Lysis of the indicator cells (figure 33.12*c*) results if immune complexes do not form in part *a* of the test because the antibodies are not present in the test serum. In the absence of antibodies, complement remains and lyses the indicator cells. On the other hand, if the specific antibodies are present in the test serum and complement is consumed by the immune complexes, insufficient amounts of complement will be available to lyse the indicator cells. Absence of lysis shows that specific antibodies are present in the test serum.

Complement fixation was once used in the diagnosis of syphilis (the Wassermann test) and is currently used in the diagnosis of certain viral, fungal, rickettsial, chlamydial, and protozoan diseases.

Enzyme-Linked Immunosorbent Assay

The ***e**nzyme-**l**inked **i**mmuno**s**orbent **a**ssay* **(ELISA)** has become one of the most widely used serological tests for antibody or antigen detection. This test involves the linking of various "label" enzymes to either antigens or antibodies. Two basic methods are used: the double antibody sandwich assay and the indirect immunosorbent assay.

The double antibody sandwich assay is used for the detection of antigens (**figure 33.13*a***). In this assay, specific antibody is placed in wells of a microtiter plate (or it may be attached to a membrane). The antibody is absorbed onto the walls, coating and sensitizing the plate. A test antigen is then added to each well. If the antigen reacts with the antibody, the antigen is retained when the well is washed to remove unbound antigen. An antibody-enzyme conjugate specific for the antigen is then added to each well. The final complex is formed of an outer antibody-enzyme, middle antigen, and inner antibody—that is, it is a layered (Ab-Ag-Ab) sandwich. A substrate that the enzyme will convert to a colored product is then added, and any resulting product is quantitatively measured by optical density scanning of the plate. If the antigen has reacted with the absorbed antibodies in the first step, the ELISA test is positive. If the antigen is not recognized by the absorbed antibody, the ELISA test is negative because the unattached antigen has been washed away, and no antibody-enzyme is bound. This assay is currently being used for the detection of *Helicobacter pylori* infections, brucellosis, salmonellosis, and cholera. Many other antigens also can be detected by the sandwich method. For example, there are ELISA kits on the market that can test for many different food allergens.

The indirect immunosorbent assay detects antibodies rather than antigens. In this assay, antigen in appropriate buffer is incubated in the wells of a microtiter plate (figure 33.13*b*) and is absorbed onto the walls of the wells. Free antigen is washed away. Test antiserum is added, and if specific antibody is present, it binds to the antigen. Unbound antibody is washed away. Alternatively the test sample can be incubated with a suspension of latex beads that have the desired antigen attached to their surface. After allowing time for antibody-antigen complex formation, the beads are trapped on a filter and unbound antibody is washed

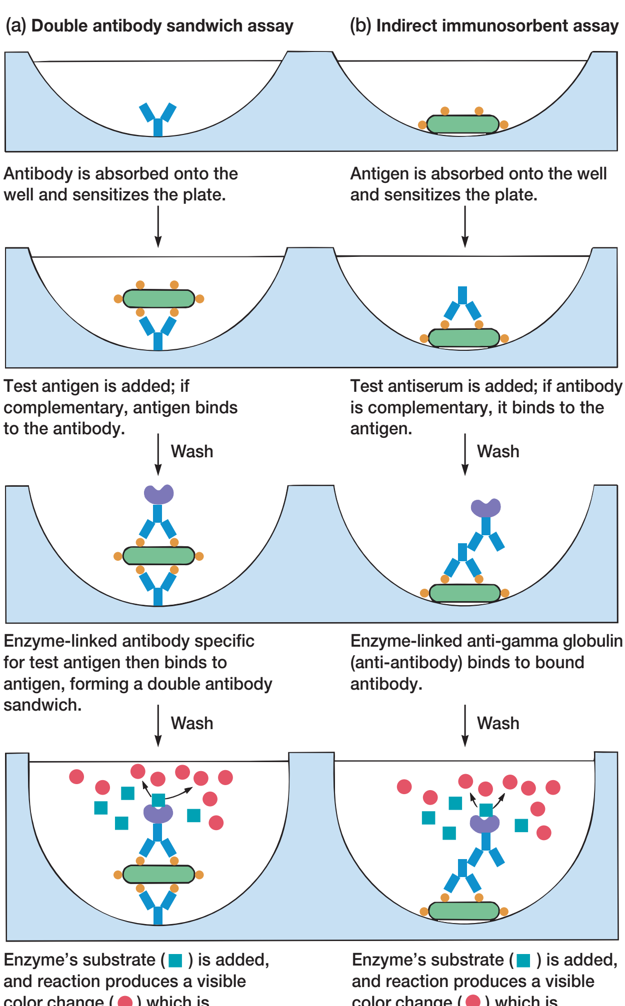

Figure 33.13 The ELISA or EIA Test. (**a**) The double antibody sandwich method for the detection of antigens. (**b**) The indirect immunosorbent assay for detecting antibodies. See text for details.

away. An anti-antibody that has been covalently coupled to an enzyme, such as horseradish peroxidase, is added next. The antibody-enzyme complex (the conjugate) binds to the test antibody, and after unbound conjugate is washed away, the attached ligand is visualized by the addition of a chromogen. A **chromogen** is a colorless substrate acted on by the enzyme portion of the ligand to produce a colored product. The amount of test antibody is quantitated in the same way as an antigen is in the double antibody sandwich method. The indirect immunosorbent assay currently is being used to test for antibodies to human immunodeficiency virus (the causative agent of AIDS) and rubella virus (German measles), and to detect certain drugs in serum. For example, antigen-coated latex beads are used in the SUDS HIV-1 test to detect HIV serum antibodies in about 10 minutes.

Flow Cytometry and Fluorescence

Classical microbiological techniques (*see section 36.2*) are relatively slow in comparison to analytical techniques, in many cases due to the need to culture microorganisms. Furthermore, classical techniques are not useful in identifying those microorganisms that can't be cultured. The recent emergence of molecular biological techniques, particularly those using antibodies and nucleic acid probes combined with amplification techniques, has provided the clinical laboratory with rapid and very specific techniques for microbiological diagnosis. One such new technique is flow cytometry and fluorescence.

Flow cytometry allows single- or multiple-microorganism detection in clinical samples (*see section 36.1*) in an easy, reliable, fast way. In flow cytometry, microorganisms are identified on the basis of their peculiar cytometric parameters or by means of fluorochromes that can be used either independently or bound to specific antibodies or oligonucleotides. The flow cytometer forces a suspension of cells through a laser beam and measures the light they scatter or the fluorescence the cells emit as they pass through the beam. For example, cells can be tagged with a fluorescent antibody directed against a specific surface antigen. As the stream of cells flows past the laser beam, the fluorescent cells can be detected, counted, and even separated from the other cells in the suspension. The cytometer also can measure a cell's shape, size, and content of DNA and RNA. This technique has permitted the development of quantitative methods to access antimicrobial susceptibility and drug cytotoxicity in a rapid, accurate, and highly reproducible way. The most outstanding contribution of this technique is the ability to detect the presence of heterogenous microbial populations with different responses to antimicrobial treatments.

Immunoblotting (Western Blot)

Another immunologic technique used in the clinical microbiology laboratory is **immunoblotting.** Immunoblotting involves polyacrylamide gel electrophoresis of a protein specimen followed by transfer of the separated proteins to nitrocellulose sheets (*see figure 14.5*). Protein bands are then visualized by treating the nitrocellulose sheets with solutions of enzyme-tagged antibodies. This procedure demonstrates the presence of common and specific proteins among different strains of microorganisms (**figure 33.14**). Immunoblotting also can be used to show strain-specific immune responses to microorganisms, to serve as an important diagnostic indicator of a recent infection with a particular strain of microorganism, and to allow for prognostic implications with severe infectious diseases.

Immunodiffusion

Immunodiffusion refers to a precipitation reaction that occurs between an antibody and antigen in an agar gel medium. Two techniques are routinely used: single radial immunodiffusion and double diffusion in agar.

The **single *r*adial *i*mmuno*d*iffusion (RID) assay** or Mancini technique quantitates antigens. Monospecific antibody is added to agar, then the mixture is poured onto slides and allowed to set.

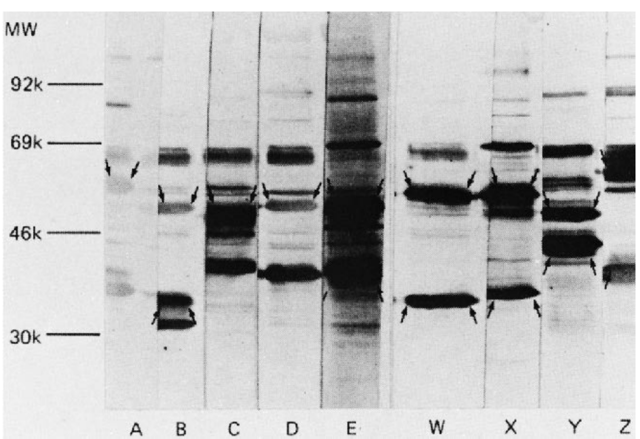

Figure 33.14 Immunoblotting (Western Blot). Immunoblot of the standard strains of *Clostridium difficile.* Arrows indicate strain-specific bands (specific molecular weights) of the various proteins in different lanes (A–E). The molecular weight of the protein is indicated on the left.

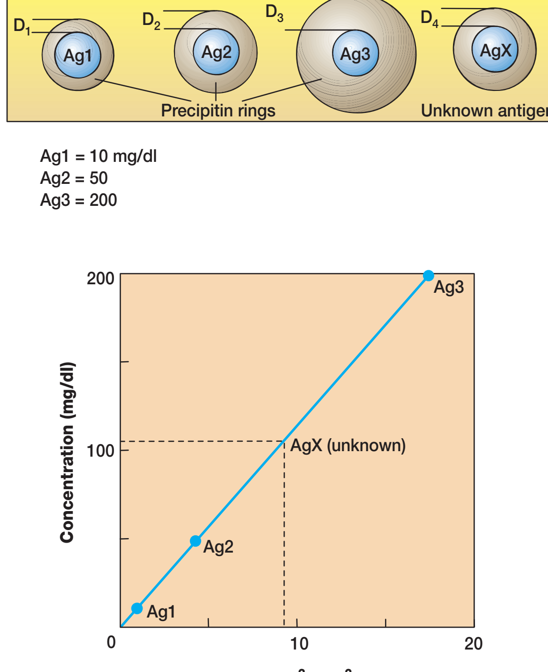
Wells are cut in the agar and known amounts of standard antigen added. The unknown test antigen is added to a separate well (**figure 33.15*a***). The slide is left for 24 hours or until equilibrium has been reached, during which time the antigen diffuses out of the wells to form insoluble complexes. The size of the resulting precipitation ring surrounding various dilutions of antigen selected is proportional to the amount of antigen in the well (the wider the ring, the greater the antigen concentration). This is because the antigen's concentration drops as it diffuses farther out into the agar. The antigen forms a precipitin ring in the agar when its level has decreased sufficiently to reach equivalence and combine with the antibody to produce a large, insoluble network. This method is commonly used to quantitate serum immunoglobulins, complement proteins, and other substances.

The **double diffusion agar assay (Ouchterlony technique)** is based on the principle that diffusion of both antibody and antigen (hence, double diffusion) through agar can form stable and easily observable immune complexes. Test solutions of antigen and antibody are added to the separate wells punched in agar. The solutions diffuse outward, and when antigen and the appropriate antibody meet, they combine and precipitate at the equivalence zone, producing an indicator line (or lines) (figure 33.15*b*). The visible



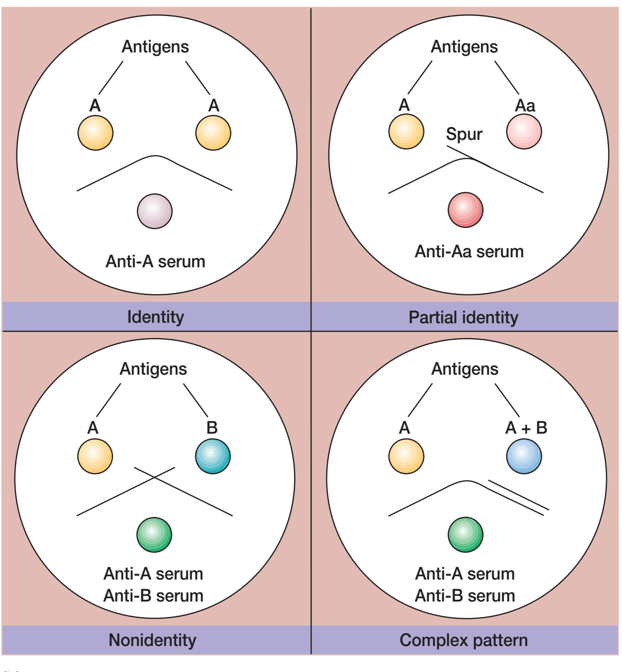


Figure 33.15 Immunodiffusion. (**a**) Single radial immunodiffusion assay. Three standard solutions of different antigen concentrations (Ag1, Ag2, Ag3) and an unknown (AgX) are placed on agar. After equilibration the ring diameters are measured. Usually the square of the diameter of the standard rings is plotted on the x-axis and the antigen concentration on the y-axis. From this standard curve the concentration of an unknown can be determined. (**b**) Double diffusion agar assay showing characteristics of identity (top left), reaction of nonidentity (bottom left), partial identity (top right), and a complex pattern (bottom right).

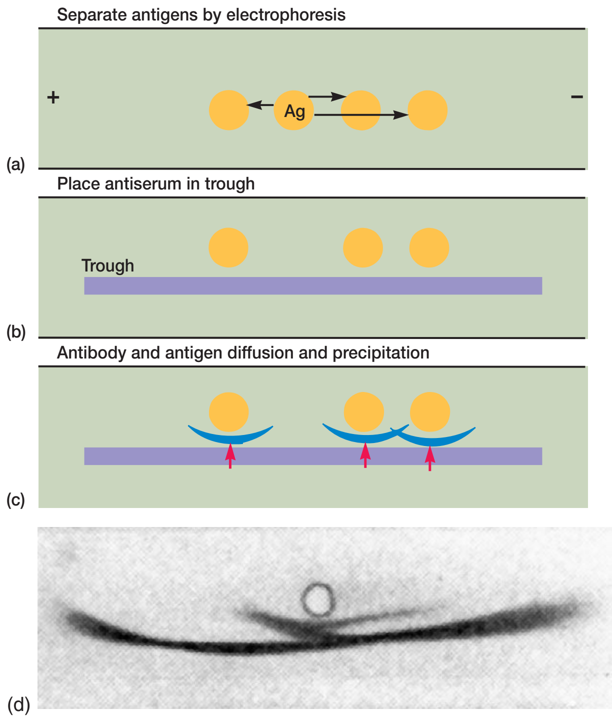

Figure 33.16 Classical Immunoelectrophoresis. (**a**) Antigens are separated in an agar gel by an electrical charge. (**b**) Antibody (antiserum) is then placed in a trough cut parallel to the direction of the antigen migration. (**c**) The antigens and antibodies diffuse through the agar and form precipitin arcs. (**d**) After staining, better visualization is possible.

line of precipitation permits a comparison of antigens for identity (same antigenic determinants), partial identity (cross-reactivity), or nonidentity against a given selected antibody. For example, if a V-shaped line of precipitation forms, this demonstrates that the antibodies bind to the same antigenic determinants in each antigen sample and are identical. If one well is filled with a different antigen that shares some but not all determinants with the first antigen, a Y-shaped line of precipitation forms, demonstrating partial identity. In this reaction the stem of the Y, called a spur, is formed if those antigen or antigenic determinants absent in the first well but present in the second one (antigen a in figure 33.15*b*) react with the diffusing antibodies. If two completely unrelated antigens are added to the wells, either a single straight line of precipitation forms between the two wells, or two separate lines of precipitation form, creating an X-shaped pattern, a reaction of nonidentity.

Immunoelectrophoresis

Some antigen mixtures are too complex to be resolved by simple diffusion and precipitation. Greater resolution is obtained by the technique of classical **immunoelectrophoresis** in which antigens are first separated based on their electrical charge, then visualized by the precipitation reaction. In this procedure antigens are separated by electrophoresis in an agar gel. Positively charged proteins move to the negative electrode, and negatively charged proteins move to the positive electrode (**figure 33.16*a***). A trough is then cut next to the wells (figure 33.16*b*) and filled with antibody. If the plate is incubated, the antibodies and antigens will diffuse and eventually form precipitation bands or arcs (figure 33.16*c*) that can be better visualized by staining (figure 33.16*d*). This assay is used to separate the major blood proteins in serum for certain diagnostic tests. Electrophoresis (p. 327)

Immunofluorescence

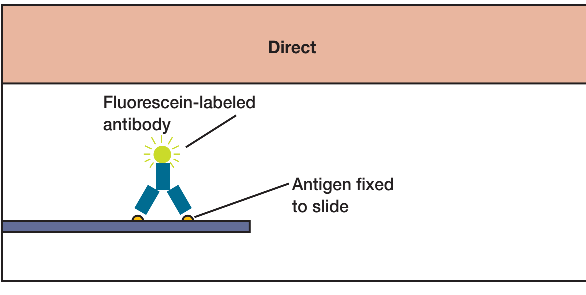
Immunofluorescence is a process in which dyes called fluorochromes are exposed to UV, violet, or blue light to make them fluoresce or emit visible light. Dyes such as rhodamine B or fluorescein isothiocyanate (FITC) can be coupled to antibody molecules without changing the antibody's capacity to bind to a specific antigen. Fluorochromes also can be attached to antigens. There are two main kinds of fluorescent antibody assays: direct and indirect.

Direct immunofluorescence involves fixing the specimen (cell or microorganism) containing the antigen of interest onto a slide (**figure 33.17*a***). Fluorescein-labeled antibodies are then added to the slide and incubated. The slide is washed to remove any unbound antibody and examined with the fluorescence microscope (*see figure 2.12*) for a yellow-green fluorescence. The pattern of fluorescence reveals the antigen's location. Direct immunofluorescence is used to identify antigens such as those found on the surface of group A streptococci and to diagnose enteropathogenic *Escherichia coli, Neisseria meningitidis, Salmonella typhi, Shigella sonnei, Listeria monocytogenes, Haemophilus influenzae* type b, and the rabies virus. The fluorescence microscope (pp. 25–26)

Indirect immunofluorescence (figure 33.17*b*) is used to detect the presence of antibodies in serum following an individual's exposure to microorganisms. In this technique a known antigen is fixed onto a slide. The test antiserum is then added, and if the specific antibody is present, it reacts with antigen to form a complex. When fluorescein-labeled anti-immunoglobulin is added, it reacts with the fixed antibody. After incubation and washing, the slide is examined with the fluorescence microscope. The occurrence of fluorescence shows that antibody specific to the test antigen is present in the serum. Indirect immunofluorescence is used to identify the presence of *Treponema pallidum* antibodies in the diagnosis of syphilis (treponemal antibody absorption, FTA-ABS; *see figure 39.21*) as well as antibodies produced in response to other microorganisms.

Immunoprecipitation

The **immunoprecipitation** technique detects soluble antigens that react with antibodies called precipitins. The precipitin reaction occurs when bivalent or multivalent antibodies and antigens are mixed in the proper proportions. The antibodies link the antigen to form a large antibody-antigen network or lattice that settles out of solution when it becomes sufficiently large (**figure 33.18*a***). Immunoprecipitation reactions occur only at the equivalence zone when there is an optimal ratio of antigen to antibody so that a lattice forms. If the precipitin reaction takes place in a test tube (figure 33.18*b*), a precipitation ring forms in the area in which the optimal ratio or equivalence zone develops. Immune complex formation (p. 756)



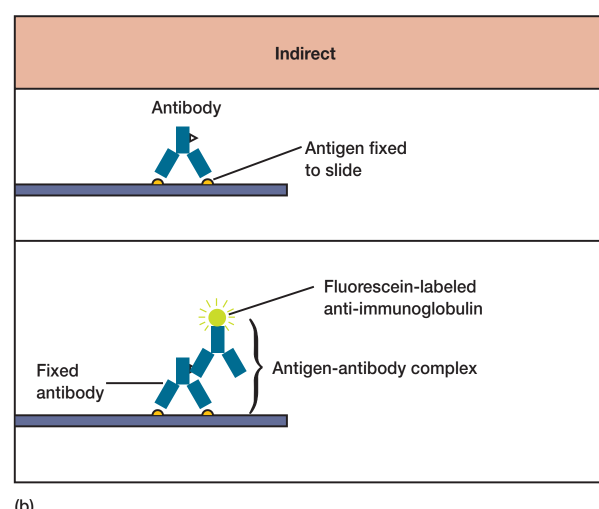


Figure 33.17 Direct and Indirect Immunofluorescence. (**a**) In the direct fluorescent-antibody (FA) technique, the specimen containing antigen is fixed to a slide. Fluorescenated antibodies that recognize the antigen are then added, and the specimen is examined under a UV microscope for yellow-green fluorescence. (**b**) Indirect fluorescent-antibody technique (IFA). The antigen on a slide reacts with an antibody directed against it. The antigen-antibody complex is located with a fluorescent antibody that recognizes immunoglobulins.

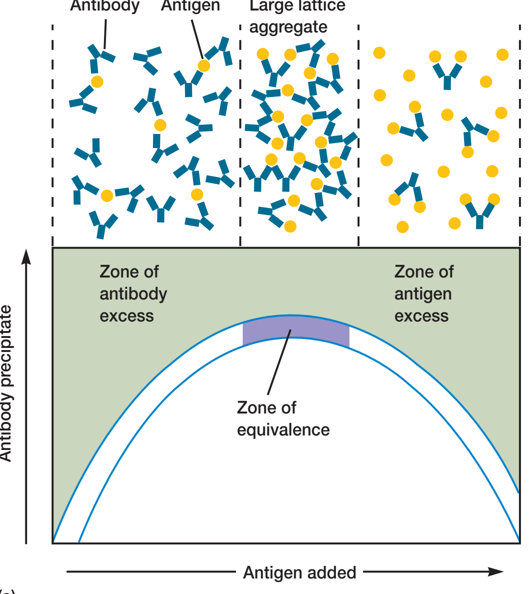

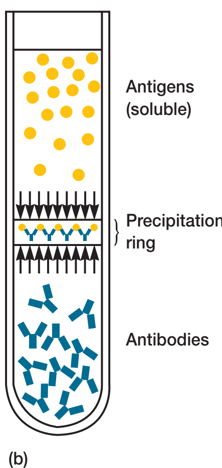

Figure 33.18 Immunoprecipitation. (**a**) Graph showing that a precipitation curve is based on the ratio of antigen to antibody. The zone of equivalence represents the optimal ratio for precipitation. (**b**) A precipitation ring test. Antibodies and antigens diffuse toward each other in a test tube. A precipitation ring is formed at the zone of equivalence.

1. What does a negative complement fixation test show? A positive test?
2. What are the two types of ELISA methods and how do they work? What is a chromogen?
3. What are some advantages of using flow cytometry in comparison to classical microbiological techniques to detect microorganisms?
4. Name two types of immunodiffusion tests and describe how they operate.
5. Describe the classical immunoelectrophoresis technique.
6. What is a fluorochrome?
7. Name and describe the two kinds of fluorescent antibody assays.
8. Specifically, when do immunoprecipitation reactions occur?

Liposomes

Another immunologic technique uses liposomes. A **liposome** [Greek *lipos,* fat, and *soma,* body] is an artificially created microscopic spherical vesicle formed by a lipid bilayer enclosing an aqueous compartment. The aqueous compartment contains a colored dye. The liposome is then sensitized by coupling a specific antibody (or antigen) to the liposome surface. Antibodies specific for the pathogen to be detected are attached to a membrane in a particular shape, such as a triangle. After a patient's sample is added to the test well (**figure 33.19*a***), the substance undergoing analysis instantly binds to the antibodies (or antigen). When the dye-filled sensitized liposomes are added (figure 33.19*b*) and link to the immobilized substance (figure 33.19*c*), a triangle (or other

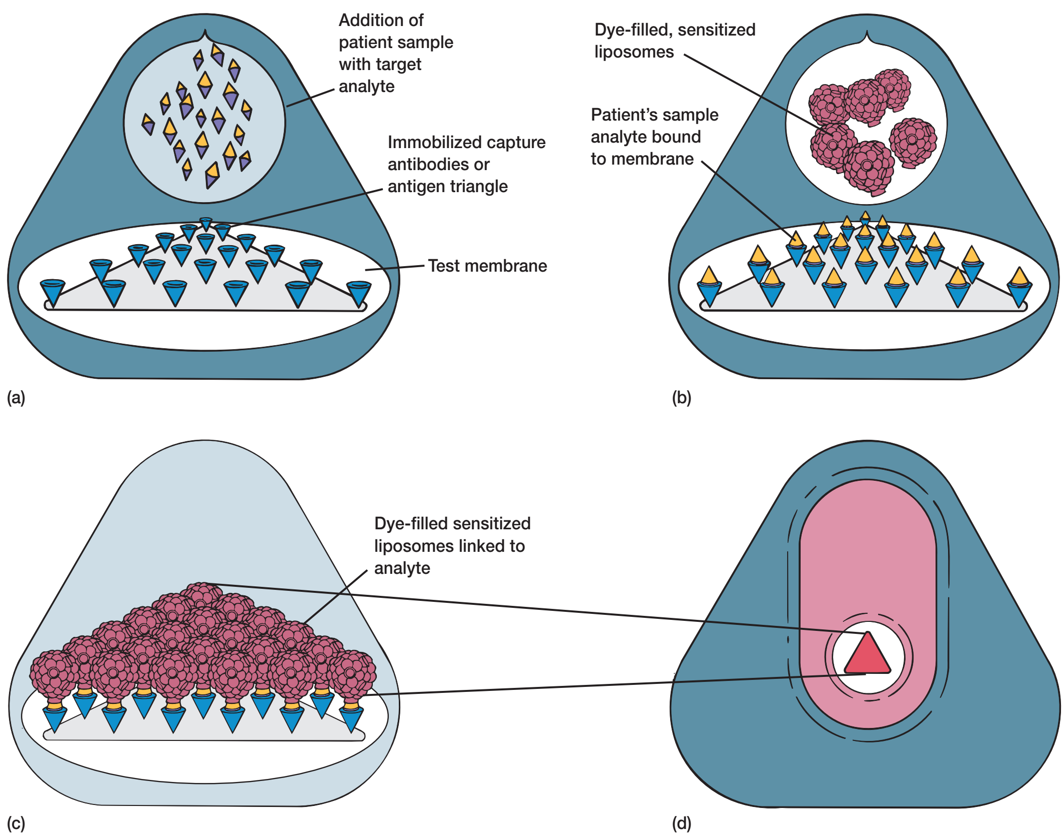

Figure 33.19 The Use of Liposomes in Diagnostic Testing. (**a**) The addition of a patient's sample containing the target analyte. Immobilized capture antibodies or antigen on a test membrane form a geometric design such as a triangle. (**b**) When dye-filled liposomes are added, they bind to the patient's bound analyte (**c**) giving a triangle. (**d**) The triangle indicates a positive reaction.

shape) indicates a positive reaction (figure 33.19*d*). If the sample is negative and contains none of the substance, no binding occurs in the test area when the liposomes are added and either a blank or some other shape appears. Liposome tests are currently available for group A streptococci and the respiratory syncytial virus.

Neutralization

Neutralization tests are antigen-antibody reactions that determine whether the activity of a toxin or virus has been neutralized by antibody. Laboratory animals or tissue culture cells are used as "indicator systems" in these tests. The toxin or virus to be assayed has known effects on the indicator system. The effect in the animal might be death, paralysis, or skin lesions. For example, when the exotoxin of *Clostridium botulinum* is suspected of causing food poisoning in a person (*see section 39.4*), a sample of either the suspect food or the serum, stool, or vomitus of the ill patient is collected. Two groups of indicator mice are used. The control group receives the botulinum antitoxin and the experimental group does not. Filtrates from the source samples are injected into both groups of mice. If toxin is present, all mice except those receiving the antitoxin will die, and the test is positive for food botulism.

Viral neutralization assays are frequently used to detect viral infections. Suspected blood serum containing viral antibodies can be introduced into tissue culture cells or embryonated eggs (*see figure 16.1*). If antibodies are present against the virus, viral neutralization will occur and prevent the virus from infecting the culture cells. No cytopathic effects will be seen.

Radioimmunoassay

The ***radio*i*mmuno*a*ssay* (RIA)** technique has become an extremely important tool in biomedical research and clinical practice (e.g., in cardiology, blood banking, diagnosis of allergies, and endocrinology). Indeed, Rosalyn Yalow won the 1977 Nobel Prize in Physiology or Medicine for its development. RIA uses a purified antigen that is radioisotope-labeled and competes for antibody with unlabeled standard or antigen in experimental samples. The radioactivity associated with the antibody is then detected by means of radioisotope analyzers and autoradiography (photographic emulsions that show areas of radioactivity). If there is much antigen in an experimental sample, it will compete with the radioisotope-labeled antigen for antigen-binding sites on the antibody, and little radioactivity will be bound. A large amount of

Box 33.3

History and Importance of Serotyping

In the early 1930s Rebecca Lancefield (1895–1981) recognized the importance of serological tests. She developed a classification system for the streptococci based on the antigenic nature of cell wall carbohydrates. Her system is now known as the **Lancefield system** in which each different serotype is a Lancefield group and identified by a letter (A through T). This scheme is based on specific antibody agglutination reactions with cell wall carbohydrate antigens (C polysaccharides) extracted from the streptococci. Lancefield also showed that further subdividing of the group A streptococci into specific serological types was possible, based on the presence of type-specific M (protein) antigens.

More recently *Escherichia coli, Salmonella* and other bacteria have been serotyped with specific antigen-antibody reactions involving flagella (H) antigens, capsular (K) antigens, and somatic (cell wall or O) antigens. Within *E. coli* there are over 167 different O antigens.

The current value of serotyping may be seen in the fact that *E. coli* O55, O111, and O127 serotypes are the ones most frequently associated with infantile diarrhea. Thus the serotype of *E. coli* from stool samples of infants with infantile diarrhea is of diagnostic value and aids in identifying the source of the infection.

bound radioactivity indicates that there is little antigen present in the experimental sample.

Serotyping

Serotyping refers to serological procedures used to differentiate strains (serovars or serotypes) of microorganisms that differ in the antigenic composition of a structure or product (**Box 33.3**). The serological identification of a pathogen strain has diagnostic value. Often the symptoms of infections depend on the nature of cell products released by a pathogen. Genes for virulence often occur in the same clone with genes for antigenic cell wall material. Therefore it is possible to identify a pathogen serologically by testing for cell wall antigens. For example, there are 84 strains of *Streptococcus pneumoniae,* each differing in the nature of its capsular material. These differences can be detected by capsular swelling (termed the **Quellung reaction**) if antisera specific for the capsular types are used (**figure 33.20**).

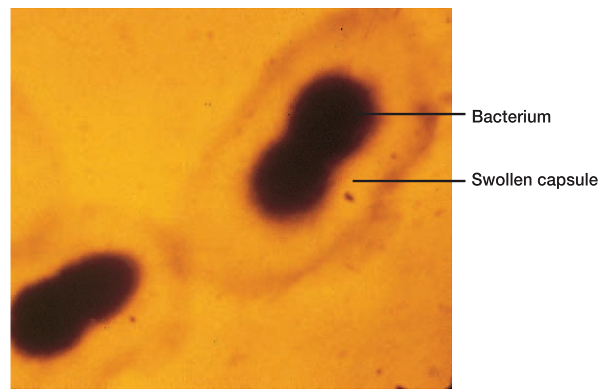

Figure 33.20 Serotyping. *Streptococcus pneumoniae* has reacted with a specific pneumococcal antiserum leading to capsular swelling (the Quelling reaction). The capsules seen around the bacteria indicate potential virulence.

1. What is a neutralization test?
2. Describe the RIA technique. What is serotyping?
3. How are liposomes used to test for the respiratory syncytial virus?

Summary

1. Vaccination is one of the most cost-effective weapons for microbial disease prevention, and vaccines constitute one of the greatest achievements of modern medicine.
2. Artificial immunity to pathogens can be accomplished by either active or passive immunization (**tables 33.1, 33.2** and **figure 33.1**).
3. Many of the current vaccines in use for humans (**table 33.3**) consists of whole organisms that are either inactivated (killed) or attenuated (live but avirulent).
4. Some of the risks associated with whole-organism vaccines can be avoided by using only specific purified macromolecules derived from pathogenic microorganisms (**table 33.4**). Currently, there are three general forms of macromolecule vaccines: capsular polysaccharides, recombinant surface antigens, and inactivated exotoxins (toxoids).
5. Recently a number of microorganisms have been used for recombinant-vector vaccines. The attenuated microorganism serves as a

vector, replicating within the host, and expressing the gene product of the pathogen-encoded antigenic proteins. The proteins can elicit humoral immunity when the proteins escape from the cells and cellular immunity when they are broken down and properly displayed on the cell surface.

6. More complicated genetic vaccines are termed DNA vaccines. DNA vaccines elicit protective immunity against a pathogen by activating both branches of the immune system: humoral and cellular.
7. When the immune response occurs in an exaggerated form and results in tissue damage to the individual, the term hypersensitivity is applied. There are four types of hypersensitivity reactions, designated as types I through IV (**figures 33.2–33.7**).
8. Autoimmune diseases result when self-reactive T and B cells attack the body and cause tissue damage (**table 33.5**). A variety of factors can influence the development of autoimmune disease.
9. The immune system can act detrimentally and reject tissue transplants. There are different types of transplants. Xenografts involve transplants of privileged tissue between different species, and allografts are transplants between genetically different individuals of the same species.
10. Immunodeficiency diseases are a diverse group of conditions in which an individual's susceptibility to various infections is increased; several severe diseases can arise because of one or more defects in the specific or nonspecific immune response.
11. Agglutination reactions in vitro usually form aggregates or clumps (agglutinates) that are visible with the naked eye (**figure 33.9**). Tests have been developed, such as the Widal test, latex microsphere agglutination reaction, hemagglutination, and viral hemagglutination (**figure 33.10**), to detect antigen as well as to determine antibody titer.
12. The complement fixation test can be used to detect a specific antibody for a suspect microorganism in an individual's serum (**figure 33.12**).
13. The enzyme-linked immunosorbent assay (ELISA) involves the linking of various enzymes to either antigens or antibodies. Two basic methods are involved: the double antibody sandwich method and the indirect immunosorbent assay (**figure 33.13**). The first method detects antigens and the latter, antibodies.
14. Flow cytometry and fluorescence allow single- or multiple-microorganism detection based on their peculiar cytometric parameters or by means of certain fluorochromes.
15. Immunoblotting involves polyacrylamide gel electrophoresis of a protein specimen followed by transfer of the separated proteins to nitrocellulose sheets and identification of specific bands.
16. Immunodiffusion refers to a precipitation reaction that occurs between antibody and antigen in an agar gel medium. Two techniques are routinely used: double diffusion in agar and single radial diffusion (**figure 33.15**).
17. In classical immunoelectrophoresis antigens are separated based on their electrical charge, then visualized by precipitation and staining (**figure 33.16**).
18. Immunofluorescence is a process in which certain dyes called fluorochromes are irradiated with UV, violet, or blue light to make them fluoresce. These dyes can be coupled to an antibody. There are two main kinds of fluorescent antibody assays: direct and indirect (**figure 33.17**).
19. Immunoprecipitation reactions occur only when there is an optimal ratio of antigen and antibody to produce a lattice at the zone of equivalence, which is evidenced by a visible precipitate (**figure 33.18**).
20. Liposomes are artificially created microscopic spheres that can be used to detect group A streptococci and the respiratory syncytial virus (**figure 33.19**).
21. Neutralization tests are antigen-antibody reactions that determine whether toxin or virus activity has been neutralized by antibody. Laboratory animals or tissue culture cells are used as indicator systems in these tests.
22. Radioimmunoassays use a purified antigen that is radioisotope-labeled and used to compete with unlabeled standard or antigen in experimental samples for a specific antibody.
23. Serotyping refers to serological procedures used to differentiate strains (serovars or serotypes) of microorganisms that have differences in the antigenic composition of a structure or product (**figure 33.20**).

Questions for Thought and Review

1. Describe how IgE can have both beneficial and detrimental effects in the same host. Why have its detrimental effects persisted? Explain your reasoning.
2. In desensitization procedures, the allergist injects more of the same allergen to which the person is allergic. How can this be beneficial?
3. If excess complement is added in a complement fixation test, how will this affect the results?
4. Specific chemical markers are conjugated to antibodies or antigens in some immunologic tests. What are the advantages of this technique over such tests as agglutination or complement fixation?
5. Of what value are neutralization tests performed in animals or in tissue culture cells?
6. What is the importance of serotyping?
7. What are some features of an in vitro antigen-antibody reaction that makes the reaction so useful for identification and monitoring tests?
8. How are chromogens used as biological markers?
9. Even though *Streptococcus pneumoniae* has over 80 different serotypes, serological reactions are sensitive enough to differentiate one serotype from another. How is this possible?
10. How can electrophoresis be used in immunologic testing procedures?
11. Describe each of the four types of hypersensitivities.
12. Are attenuated vaccines more likely than inactivated vaccines to induce-cell mediated immunity?
13. Do DNA vaccines generate immunological memory? Explain your answer.
14. List the three types of purified molecules that are used as vaccines.
15. Define vaccine immunization.

Critical Thinking Questions

1. How does an inactivated vaccine induce only a humoral response, whereas an attenuated vaccine induces both humoral and cell-mediated responses?
2. Why is a DNA vaccine delivered intramuscularly and not by intravenous or oral routes?
3. ELISA tests usually use a primary and secondary antibody. Why? What are the necessary controls one would need to perform to ensure that the antibody specificity is valid (no false positives or negatives)?

Concepts

1. If a microorganism (symbiont) either harms or lives at the expense of another organism, it is called a parasitic organism and the relationship is termed parasitism. In this relationship the body of an animal is referred to as the host.
2. Those organisms capable of causing disease are called pathogens. Disease is any change in the host from a healthy to an unhealthy, abnormal state in which part or all of the host's body is not capable of carrying on its normal functions.
3. The obligatory steps for the infectious process involving viral diseases are: a virus must enter a host, come into contact with susceptible cells, replicate within the cells, spread to adjacent cells, cause cellular injury, engender a host immune response, be cleared from the body of the host or establish a persistent infection, and be shed back into the environment.
4. The obligatory steps for the infectious process involving bacterial diseases are: the bacterium must be transmitted to a suitable host, attach to and/or colonize the host, grow and multiply within or on the host, and interfere with or impair the normal physiological activities of the host.
5. One important result of the conservation of chromosomal genes is that bacteria are clonal. Only one or a few clonal types of some bacterial pathogens exist in the environment.
6. During coevolution with human hosts, some pathogenic bacteria have evolved complex signal transduction pathways to regulate the genes necessary for virulence.
7. Many bacteria are pathogenic because they have large segments of DNA, called pathogenicity islands, that carry genes responsible for virulence.
8. Two distinct categories of disease can be recognized based on the role bacteria play in the disease causing process: infections (invasions) and intoxications.
9. Toxins produced by pathogenic bacteria are either exotoxins or endotoxins.
10. Viruses and bacteria are continuously evolving and producing unique mechanisms that enable them to escape the host's arsenal of defenses.

Pathogenicity is not the rule. Indeed, it occurs so infrequently and involves such a relatively small number of species, considering the huge population of bacteria on earth, that it has a freakish aspect. Disease usually results from inconclusive negotiations for symbiosis, an overstepping of the line by one side or the other, a biological misinterpretation of borders.

—*Lewis Thomas*

Chapter 28 introduces the concept of symbiosis and deals with two of its subordinate categories: commensalism and mutualism. In this chapter the third category, parasitism, is presented along with one of its possible consequences—pathogenicity. The parasitic way of life is so successful that it has evolved independently in nearly all groups of organisms. In recent years concerted efforts to understand organisms and their relationships with their hosts have developed within the disciplines of virology, rickettsiology, chlamydiology, bacteriology, mycology, parasitology (protozoology and helminthology), entomology, and zoology. This chapter examines the parasitic way of life in terms of health and disease in the animal body and emphasizes viral and bacterial disease mechanisms. The chapter concludes with some viral and bacterial mechanisms used to escape host defenses.

34.1 Host-Parasite Relationships

If a symbiont either harms or lives at the expense of another organism (the **host**), it is a **parasitic organism,** and the relationship is called **parasitism.** In this relationship the body of the host can be viewed as a microenvironment that shelters and supports the growth and multiplication of the parasitic organism. The parasitic organism is usually the smaller of the two partners and is metabolically dependent on the host. There are many parasitic agents or organisms among the viruses, bacteria, fungi, plants, and animals (**table 34.1**). By convention, when the word **parasite** is used without qualification, it refers specifically to a protozoan or helminthic (nematode, trematode, cestode) organism.

Several types of parasitism are recognized. If an organism lives on the surface of its host, it is an **ectoparasite;** if it lives in-

Table 34.1 Categorization of Parasitic Organisms and Agents by Size

Discipline		Parasitic Group		Approximate Size
Virology		Prions	Agents 25–400 nm	350 kDa
		Viroids		130 kDa
		Viruses		
Bacteriology		Chlamydiae	Microorganisms (microbiota)	0.2–1.5 µm
		Mycoplasmas		0.3–0.8 µm
		Rickettsias		0.5–2 µm
		Other bacteria		1–10 µm
Mycology		Fungi		3–15 µm diameter (hyphae)
Protozoology	Parasitology	Protozoa		1–150 µm
Helminthology		Nematodes	Parasites	3 mm–30 cm
		Platyhelminthes (cestodes, trematodes)		1 mm–10 m
Entomology		Ticks and mites	Ectoparasites	0.1–15 mm
Zoology		Horsehair worms		10–20 cm
		Mesozoa		Up to 100 cm
		Leeches		1–5 cm

Table 34.2 Various Types of Infections Associated with Parasitic Organisms

Type	Definition
Abscess	A localized infection with a collection of pus surrounded by an inflamed area
Acute	Short but severe course
Bacteremia	Presence of viable bacteria in the blood
Chronic	Persists over a long time
Covert	Subclinical, no symptoms
Cross	Transmitted between hosts infected with different organisms
Focal	Exists in circumscribed areas
Fulminating	Infectious agent multiplies with great intensity
Iatrogenic	Caused as a result of health care
Latent	Persists in tissues for long periods, during most of which there are no symptoms
Localized	Restricted to a limited region or to one or more anatomical areas
Mixed	More than one organism present simultaneously
Nosocomial	Develops during a stay at a hospital or other clinical care facility
Opportunistic	Due to an agent that does not harm a healthy host but takes advantage of an unhealthy one
Overt	Symptomatic
Phytogenic	Caused by plant pathogens
Primary	First infection that often allows other organisms to appear on the scene
Pyogenic	Results in pus formation
Secondary	Caused by an organism following an initial or primary infection
Sepsis	(1) The condition resulting from the presence of bacteria or their toxins in blood or tissues; the presence of pathogens or their toxins in the blood or other tissues (2) Systemic response to infection; this systemic response is manifested by two or more of the following conditions as a result of infection: temperature, >38 or <36°C; heart rate, >90 beats per min; respiratory rate, >20 breaths per min, or pCO_2, <32 mm Hg; leukocyte count, >12,000 cells per ml^3, or >10% immature (band) forms
Septicemia	Blood poisoning associated with persistence of pathogenic organisms or their toxins in the blood
Septic shock	Sepsis with hypotension despite adequate fluid resuscitation, along with the presence of perfusion abnormalities that may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status
Severe sepsis	Sepsis associated with organ dysfunction, hypoperfusion, or hypotension; hypoperfusion and perfusion abnormalities may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status
Sporadic	Occurs only occasionally
Subclinical (inapparent or covert)	No detectable symptoms or manifestations
Systemic	Spread throughout the body
Toxemia	Condition arising from toxins in the blood
Zoonosis	Caused by a parasitic organism that is normally found in animals other than humans

ternally, it is an **endoparasite.** The host on or in which the parasitic organism either attains sexual maturity or reproduces is the **final host.** A host that serves as a temporary but essential environment for some stages of development is an **intermediate host.** In contrast, a **transfer host** is not necessary for the completion of the organism's life cycle but is used as a vehicle for reaching a final host. A host infected with a parasitic organism that also can infect humans is called a **reservoir host.**

Because, by definition, parasitic organisms are dependent on their hosts, the symbiotic relationship between the host and parasite is a dynamic one (**figure 34.1**). When a parasite is growing and multiplying within or on a host, the host is said to have an **infection.** The nature of an infection can vary widely with respect to severity, location, and number of organisms involved (**table 34.2**). An infection may or may not result in overt disease. An **infectious disease** is any change from a state of health in which part or all of the host body is not capable of carrying on its normal functions due to the presence of an organism or its products. Any organism or agent that produces such a disease is a **pathogen** [Greek *patho,* disease, and *gennan,* to produce]. Its ability to cause disease is called **pathogenicity.** A **primary (frank) pathogen** is any organism that causes disease in a healthy host by a direct interaction. Conversely, an **opportunistic pathogen** is an organism that is either normally free-living, or a part of the host's normal microbiota, but which may adopt a pathogenic role under certain circumstances, such as when the immune system is compromised.

At times an infectious organism can enter a latent state in which there is no shedding of the organism and no symptoms present within the host. This latency can be either intermittent or quiescent. Intermittent latency is exemplified by the herpes virus that causes cold sores (fever blisters). After an initial infection, the symptoms subside. However, the virus remains in nerve tissue and can be activated weeks or years later by factors such as stress or sunlight. In a quiescent latency the organism persists but remains inactive for long periods of time, usually for years. For

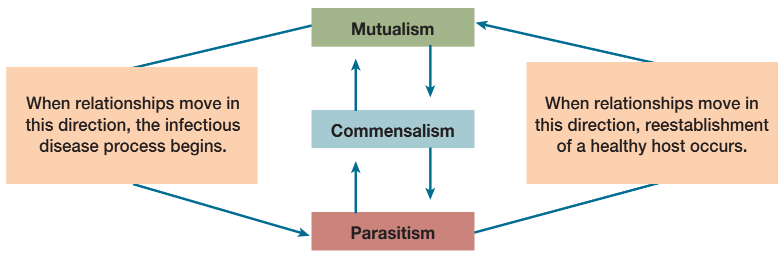

Figure 34.1 Symbiosis. All symbiotic relationships are dynamic, and shifts among them can occur as indicated by the arrows. The most beneficial relationship is mutualism; the most destructive is parasitism. Host susceptibility, virulence of the parasitic organism, and number of parasites are factors that influence these relationships. Disease can result from a shift from either mutualism or commensalism to parasitism. Health may be regained by the reestablishment of mutualism or commensalism.

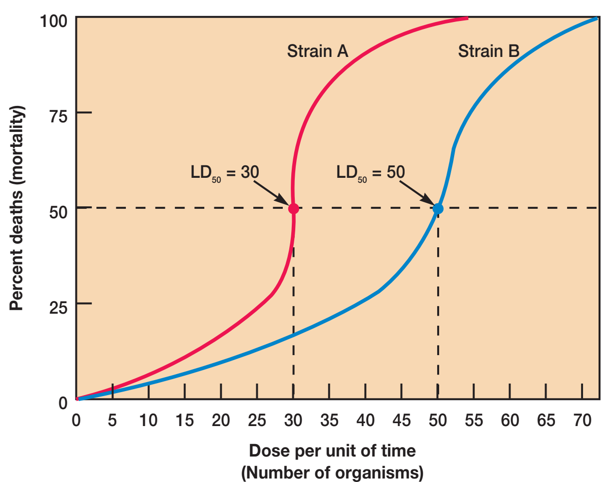

Figure 34.2 Determination of the LD_{50} of a Pathogenic Microorganism. Various doses of a specific pathogen are injected into experimental host animals. Deaths are recorded and a graph constructed. In this example, the graph represents the susceptibility of host animals to two different strains of a pathogen—strain A and strain B. For strain A the LD_{50} is 30, and for strain B it is 50. Hence strain A is more virulent than strain B.

example, the varicella-zoster virus causes chickenpox in children and remains after the disease has subsided. In adulthood, under certain conditions, the same virus may erupt into a disease called shingles. Cold sores (p. 884); Chickenpox (varicella) and shingles (herpes zoster) (pp. 871–72)

The outcome of most host-parasite relationships is dependent on three main factors: (1) the number of organisms present in or on the host, (2) the virulence of the organism, and (3) the host's defenses or degree of resistance. Usually the greater the number of organisms within a given host, the greater the likelihood of disease. However, a few organisms can cause disease if they are extremely virulent or if the host's resistance is low. A host's resistance can drop so much that its own microbiota may cause disease. Such a disease is sometimes called an endogenous disease because the agent originally comes from within the host's own body. Endogenous diseases can be a serious problem among hospitalized patients with very low resistance.

The term **virulence** [Latin *virulentia,* from *virus,* poison] refers to the degree or intensity of pathogenicity. It is determined by three characteristics of the pathogen: invasiveness, infectivity, and pathogenic potential. **Invasiveness** is the ability of the organism to spread to adjacent or other tissues. **Infectivity** is the ability of the organism to establish a focal point of infection. **Pathogenic potential** refers to the degree that the pathogen causes damage. A major aspect of pathogenic potential is toxigenicity. **Toxigenicity** is the pathogen's ability to produce toxins, chemical substances that will damage the host and produce disease. Virulence is often measured experimentally by determining the **lethal dose 50 (LD_{50})** or the **infectious dose 50 (ID_{50}).** These values refer to the dose or number of pathogens that will either kill or infect, respectively, 50% of an experimental group of hosts within a specified period (**figure 34.2**).

It should be noted that disease can result from causes other than toxin production. Sometimes a host will trigger exaggerated immunological responses (**immunopathology**) upon a second exposure or chronic exposure to a microbial antigen. These hypersensitivity reactions damage the host even though the pathogen doesn't produce a toxin. Tuberculosis is a good example of the involvement of hypersensitivity reactions in disease (*see pp. 906–8*). Some diseases also might be due to autoimmune responses. For instance, a viral or bacterial pathogen may stimulate the immune system to attack host tissues because it carries antigens that resembled those of the host, a phenomenon known as molecular mimicry. Streptococcal infections may cause rheumatic fever in this way (*see p. 905*). Hypersensitivity reactions (pp. 768–71)

1. Define parasitic organism, parasitism, infection, infectious disease, pathogenicity, virulence, invasiveness, infectivity, pathogenic potential, and toxigenicity.
2. What factors determine the outcome of most host-parasite relationships?

34.2 Pathogenesis of Viral Diseases

The fundamental process of viral infection is the expression of the viral replicative cycle (*see figures 17.5, 18.4–18.7*) in a host cell. The steps for the infectious process involving viruses are that a virus must

1. Enter a host
2. Contact and enter susceptible cells

3. Replicate within the cells
4. Spread to adjacent cells
5. Cause cellular injury
6. Engender a host immune response
7. Be either cleared from the body of the host, establish a persistent infection, or kill the host
8. Be shed back into the environment

The determinants of pathogenicity are now discussed in more detail.

Entry, Contact, and Primary Replication

The first step in the infectious process is the attachment and entrance of the virus into a susceptible host and the host's cells.

Entrance may be accomplished through one of the body surfaces (skin, respiratory system, gastrointestinal system, urogenital system, or the conjunctiva of the eye). Other viruses enter the host by needle sticks, blood transfusions and organ transplants, or by insect **vectors** (organisms that transmit the pathogen from one host to another). Some viruses replicate at the site of entry, cause disease at the same site (e.g., respiratory and gastrointestinal infections), and do not spread throughout the body. Others spread to sites distant from the point of entry and replicate at these sites. For example, the enteroviruses enter through the gastrointestinal tract but produce disease in the central nervous system. Mucous membranes (pp. 710–12)

Viral Spread and Cell Tropism

Mechanisms of viral spread vary, but the most common routes are the bloodstream and lymphatic system. The presence of viruses in the blood is called **viremia.** In some instances, spread is by way of nerves (e.g., rabies virus, herpes simplex, and varicella-zoster viruses; *see figure 38.2*).

Viruses exhibit cell, tissue, and organ specificities. These specificities are called **tropisms** (Greek *trope,* turning). A tropism by a specific virus usually reflects the presence of specific cell surface receptors on the eucaryotic host cell for that virus (*see figures 18.4 and 38.14*).

Cell Injury and Clinical Illness

Destruction of the virus-infected cells in the target tissues and alterations in host physiology are responsible for the development of viral disease and clinical illness. Some tissue (e.g., intestinal epithelium) can rapidly regenerate after a viral attack and withstand extensive damage. Other tissues, such as nervous system tissues, are not able to regenerate and may never resume normal functioning after damage has occurred.

The potential effects of viruses on individual host cells are the result of a complex series of events. There are four generally accepted patterns of a viral infection. (1) In lytic infections the virus multiplies and kills the host cell immediately and new virions are released. (2) In persistent viral infections the virus lives in the host cell and releases small numbers of virions over a long period of time. This causes little damage to the host cell. (3) In latent infections, the virus resides in the cell but produces no virions. At some later time the virus can be activated and a lytic infection occurs (*see section 18.4*). (4) Some viruses can transform the host cell into a cancer cell that becomes the focal point for a tumor (*see section 18.5*).

Host Immune Response

Both humoral and cellular components of the immune response are involved in the control of viral infections and were discussed in detail in chapters 31 and 32.

Recovery from Infection

The host will either succumb or recover from a viral infection. Recovery mechanisms involve nonspecific defense mechanisms and specific humoral and cellular immunity. The relative importance of each of these factors varies with the virus and the disease, and will be covered in chapter 38.

Virus Shedding

The last step in the infectious process is shedding of the infectious virus back into the environment. This is necessary to maintain a source of viruses in a population of hosts. Shedding often occurs from the same body surface used for entry. During this period, an infected host is infectious and can spread the virus. In some viral infections, such as a rabies infection, humans are dead-end hosts because virus shedding does not occur.

1. For a virus to cause disease, certain steps must be accomplished. Briefly describe each of these steps.
2. What are the four most common patterns of viral infections?

34.3 Pathogenesis of Bacterial Diseases

The steps for infections by pathogenic bacteria include

1. Maintain a reservoir. A **reservoir** is a place to live before and after causing an infection (*see p. 854*).
2. Initially be transported to the host.
3. Adhere to, colonize, and/or invade the host.
4. Multiply (grow) or complete its life cycle on or in the host or the host's cells.
5. Initially evade host defense mechanisms.
6. Possess the ability to damage the host.
7. Leave the host and return to the reservoir or enter a new host.

The first five factors influence the degree of infectivity and invasiveness. Toxigenicity plays a major role in the sixth. The determinants are now discussed in more detail.

Maintaining a Reservoir of the Bacterial Pathogen

All bacterial pathogens must have at least one reservoir. The most common reservoirs for human pathogens are other humans, animals, and the environment. Since the source and/or reservoir of

Table 34.3 Bacterial Adherence Factors (Adhesins) That Play a Role in Infectious Diseases

Adherence Factor	Description
Fimbriae	Filamentous structures that help attach bacteria to other bacteria or to solid surfaces
Glycocalyx or capsule	A layer of exopolysaccharide fibers with a distinct outer margin that surrounds many cells; it inhibits phagocytosis and aids in adherence; when the layer is well organized and not easily washed off it is called a capsule
Pili	Filamentous structures that bind procaryotes together for the transfer of genetic material
S layer	The outermost regularly structured layer of cell envelopes of some archaeobacteria and eubacteria that may promote adherence to surfaces
Slime layer	A bacterial film that is less compact than a capsule and is removed easily
Teichoic and lipoteichoic acids	Cell wall components in gram-positive bacteria that aid in adhesion

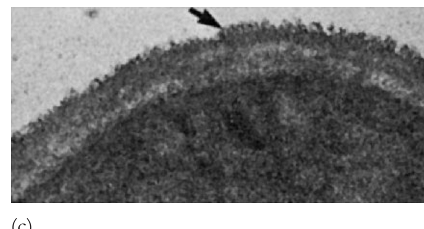
(b)



(c)

Figure 34.3 Microbial Adherence. (**a**) Transmission electron micrograph of fimbriated *Escherichia coli* (×16,625). (**b**) Scanning electron micrograph of epithelial cells with adhering vibrios (×1,200). (**c**) *Candida albicans* fimbriae (arrow) are used to attach the fungus to vaginal epithelial cells.

the pathogen is part of the infectious disease cycle, this aspect of pathogenicity is discussed in detail in chapter 37, which covers the epidemiology of infectious diseases. The infectious disease cycle (pp. 852–58)

Transport of the Bacterial Pathogen to the Host

An essential feature in the development of an infectious disease is the initial transport of the bacterial pathogen to the host. The most obvious means is direct contact—from host to host (coughing, sneezing, body contact). Bacteria also are transmitted indirectly in a variety of ways. Infected hosts shed bacteria into their surroundings. Once in the environment bacteria can be deposited on various surfaces, from which they can be either resuspended into the air or indirectly transmitted to a host later. Soil, water, and food are indirect vehicles that harbor and transmit bacteria to hosts. Vectors and **fomites** (inanimate objects that harbor and transmit pathogens) also are involved in the spread of many bacteria.

Attachment and Colonization by the Bacterial Pathogen

After being transmitted to an appropriate host, the bacterial pathogen must be able to adhere to and colonize host cells and tissues. In this context **colonization** means the establishment of a site of microbial reproduction on or within a host. It does not necessarily result in tissue invasion or damage. Colonization depends on the ability of the bacteria to compete successfully with the host's normal microbiota for essential nutrients. Specialized structures that allow bacteria to compete for surface attachment sites also are necessary for colonization.

Bacterial pathogens and many nonpathogens adhere with a high degree of specificity to particular tissues. Adherence factors called **adhesins** (**table 34.3**) are one reason for this specificity. Adhesins are specialized molecules or structures on the bacteria's cell surface that bind to complementary receptor sites on the host cell surface (**figure 34.3**). They are one type of virulence factor. **Virulence factors** are bacterial products or structural components (e.g., capsules and adhesins) that contribute to virulence or pathogenicity.

Invasion of the Bacterial Pathogen

Entry into host cells and tissues is a specialized strategy used by many bacterial pathogens for survival and multiplication. Pathogens often actively penetrate the host's mucous membranes and epithelium after attachment to the epithelial surface. This may be accomplished through production of lytic substances that alter the host tissue by (1) attacking the ground substance and basement membranes of integuments and intestinal linings, (2) degrading carbohydrate-protein complexes between cells or on the cell surface (the glycocalyx), or (3) disrupting the cell surface.

At times a bacterial pathogen can penetrate the epithelial surface by passive mechanisms not related to the pathogen itself. Examples include (1) small breaks, lesions, or ulcers in a mu-

Table 34.4 Microbial Products (Virulence Factors) Involved in Bacterial Pathogen Dissemination Throughout a Mammalian Host

Product	Organism Involved	Mechanism of Action
Coagulase	*Staphylococcus aureus*	Coagulates (clots) the fibrinogen in plasma. The clot protects the pathogen from phagocytosis and isolates it from other host defenses.
Collagenase	*Clostridium* spp.	Breaks down collagen that forms the framework of connective tissues; allows the pathogen to spread.
Deoxyribonuclease (along with calcium and magnesium)	Group A streptococci, staphylococci, *Clostridium perfringens*	Lowers viscosity of exudates, giving the pathogen more mobility.
Elastase and alkaline protease	*Pseudomonas aeruginosa*	Cleaves laminin associated with basement membranes.
Hemolysins	Staphylococci, streptococci, *Escherichia coli, Clostridium perfringens*	Lyse erythrocytes, causing anemia and weakened host defenses; make iron available for microbial growth.
Hyaluronidase	Groups A, B, C, and G streptococci, staphylococci, clostridia	Hydrolyzes hyaluronic acid, a constituent of the intercellular ground substance that cements cells together and renders the intercellular spaces amenable to passage by the pathogen.
Hydrogen peroxide (H_2O_2) and ammonia (NH_3)	*Mycoplasma* spp., *Ureaplasma* spp.	Are produced as metabolic wastes. These are toxic and damage epithelia in respiratory and urogenital systems.
Immunoglobulin A protease	*Streptococcus pneumoniae*	Cleaves immunoglobulin A into Fab and Fc fragments.
Lecithinase or phospholipase	*Clostridium* spp.	Destroys the lecithin (phosphatidycholine) component of plasma membranes, allowing pathogen to spread.
Leukocidins	Staphylococci, pneumococci, streptococci	Pore-forming exotoxins that kill leukocytes; cause degranulation of lysosomes within leukocytes, which decreases host resistance.
Porins	*Salmonella typhimurium*	Inhibit leukocyte phagocytosis by activating the adenylate cyclase system.
Protein A	*Staphylococcus aureus*	Located on cell wall. Immunoglobulin G (IgG) binds to protein A by its Fc end, thereby preventing complement from interacting with bound IgG.
Pyrogenic Exotoxin B (cysteine protease)	Group A streptococci, *Streptococcus pyogenes*	Degrades proteins.
Streptokinase (fibrinolysin, staphylokinase)	Group A, C, and G streptococci, staphylococci	A protein that binds to plasminogen and activates the production of plasmin, thus digesting fibrin clots; this allows the pathogen to move from the clotted area.

cous membrane that permit initial entry; (2) wounds, abrasions, or burns on the skin's surface; (3) arthropod vectors that create small wounds while feeding; (4) tissue damage caused by other organisms; and (5) existing eucaryotic internalization pathways (e.g., endocytosis and phagocytoses; *see figure 31.16*).

Once under the mucous membrane, the bacterial pathogen may penetrate to deeper tissues and continue disseminating throughout the body of the host. One way the pathogen accomplishes this is by producing specific products and/or enzymes that promote spreading (**table 34.4**). These products are virulence factors. Bacteria may also enter the small terminal lymphatic capillaries that surround epithelial cells. These capillaries merge into large lymphatic vessels that eventually drain into the circulatory system. Once the circulatory system is reached, the bacteria have access to all organs and systems of the host.

Growth and Multiplication of the Bacterial Pathogen

For a bacterial pathogen to be successful in growth and reproduction (colonization), it must find an appropriate environment (nutrients, pH, temperature, redox potential) within the host. Those areas of the host's body that provide the most favorable conditions will harbor the pathogen and allow it to grow and multiply to produce an infection. Some bacteria invade specific cells in which they grow and multiply. Many of these intracellular pathogens have evolved such elaborate nutrient-gathering mechanisms that they have become totally dependent on the host's cells. Finally, some bacteria can actively grow and multiply in the blood plasma. The presence of viable bacteria in the bloodstream is called **bacteremia.** The presence of bacteria or their toxins in the blood often is termed **septicemia** [Greek *septikos,* produced by putrefaction, and *haima,* blood].

Leaving the Host

The last determinant of a successful bacterial pathogen is its ability to leave the host and enter either a new host or a reservoir. Unless a successful escape occurs, the disease cycle will be interrupted and the microorganism will not be perpetuated. Most bacteria employ passive escape mechanisms. Passive escape occurs when a pathogen or its progeny leave the host in feces, urine, droplets, saliva, or desquamated cells.

The Clonal Nature of Bacterial Pathogens

The main mechanism bacteria use to exchange genetic information is the transfer of extrachromosomal genetic elements, plasmids, and phages (*see chapter 13*). Many genes that code for bacterial virulence factors are found on plasmids or phages. These mobile genetic elements can transfer virulence factors between members

© The McGraw–Hill Companies, 2002

of the same species or different species by horizontal gene transfer (*see section 13.1*). At times the genetic elements are part of highly mobile DNA (transposons, *see section 13.3*), and there is a recombination between the extrachromosomal DNA and the chromosome. When this recombination occurs, the genes coding for virulence may become chromosomal.

One important result of the conservation of these chromosomal genes is that the bacteria are clonal. Some bacterial pathogens have only one or a few clonal types existing in the environment. For example, the bacterium that causes typhoid fever (*Salmonella typhi*) has two clonal types, whereas there are over 100 clonal types of *Haemophilus influenzae,* but only a small number are associated with bacterial pneumonia.

Regulation of Bacterial Virulence Factors

As noted in many chapters, some pathogenic bacteria have adapted to both the free-living state and to an environment within a human host. In the adaptive process, these pathogens have evolved complex signal transduction pathways to regulate the genes necessary for virulence. A virulence factor may be present simply because the bacterium has been infected by a phage. Often environmental factors control the expression of the virulence genes. Common signals include temperature, osmolality, available iron, pH, specific ions, and other nutrient factors. Several examples are now presented.

The gene for diphtheria toxin (figure 34.5*b*) from *Corynebacterium diphtheriae* (the pathogen that causes diphtheria) is carried on the temperate bacteriophage β, and its expression is regulated by iron. The toxin is produced only by strains lysogenized by the phages. Expression of the virulence gene of *Bordetella pertussis* (the pathogen that causes whooping cough) is enhanced when the bacteria grow at body temperature (37°C) and suppressed when grown at a lower temperature. Finally, the virulence factors of *Vibrio cholerae* (the pathogen that causes cholera) are regulated at various levels by many environmental factors. Expression of the cholera toxin is higher at pH 6 than at pH 8 and higher at 30 than at 37°C. Osmolality and available amino acids are also important.

Pathogenicity Islands

Many bacteria (*Yersinia* spp., *Pseudomonas aeruginosa, Shigella flexneri, Salmonella typhimurium,* enteropathogenic *E. coli*) are pathogenic because they have large segments of DNA, called **pathogenicity islands,** that carry genes responsible for virulence. These pathogenicity islands have been acquired during evolution by horizontal gene transfer. A pathogen may have more than one pathogenicity island. An excellent example of virulence genes carried in a pathogenicity island are those involved in protein secretion. So far, five pathways of protein secretion (types I to V) have been described in gram-negative bacteria. A set of approximately 20 genes encode a pathogenicity mechanism termed the **type III secretion system** that enables gram-negative bacteria to secrete and inject virulence proteins into the cytoplasm of eucaryotic host cells (**figure 34.4**). Unlike other bacterial secretory systems, the type III system is triggered specifically by contact with host cells, which helps avoid inappropriate activation of host defenses. Secretion of these virulence proteins into a host cell initiates sophisticated "biochemical cross-talk" between the pathogen and the host. The injected proteins resemble eucaryotic factors that signal transduction functions and they are capable of interfering with eucaryotic signaling pathways. Redirection of cellular signaling transduction may disarm host immune responses or reorganize the cytoskeleton, thus establishing subcellular niches for bacterial colonization and facilitating "stealth and interdiction" of host defense communication lines.

Pathogenicity islands generally increase microbial virulence and are not present in nonpathogenic members of the same genus or species. One specific example is found in *E. coli.* The enteropathogenic *E. coli* possesses large DNA fragments, 35 to 170 kilobases in size, that contain several virulence genes absent from commensal *E. coli.* Some of these genes code for proteins that alter actin microfilaments within a host intestinal cell. As a consequence, the host cell surface bulges and develops into a cuplike pedestal to which the bacterium tightly binds.

---

1. What seven steps are involved in the infection process and pathogenesis of bacterial diseases?
2. What are some ways in which bacterial pathogens are transmitted to their hosts? Define vector and fomite.
3. Describe several specific adhesins by which bacterial pathogens attach to host cells.
4. Once under the mucous and epithelial surfaces, what are some mechanisms that bacterial pathogens possess to promote their dissemination throughout the body of a host?
5. What are virulence factors? Pathogenicity islands?
6. What is the significance of the clonal nature of bacterial pathogens? The regulation of virulence factors?

Toxigenicity

Two distinct categories of disease can be recognized based on the role of the bacteria in the disease-causing process: infections and intoxications. An infectious disease results partly from the pathogen's growth and reproduction (or invasiveness) that often produce tissue alterations.

Intoxications are diseases that result from the entrance of a specific preformed toxin (e.g., botulinum toxin) into the body of a host. Toxins can even induce disease in the absence of the organism that produced them. A **toxin** [Latin *toxicum,* poison] is a substance, such as a metabolic product of the organism, that alters the normal metabolism of host cells with deleterious effects on the host. The term **toxemia** refers to the condition caused by toxins that have entered the blood of the host. Toxins produced by bacteria can be divided into two main categories: exotoxins and endotoxins. The primary characteristics of the two groups are compared in **table 34.5.**

Exotoxins

Exotoxins are soluble, heat-labile, proteins (a few are enzymes) that usually are released into the surroundings as the bacterial pathogen grows. Often exotoxins may travel from the site of infection to other body tissues or target cells in which they exert their effects. Exotoxins usually are

1. Synthesized by specific bacteria that often have plasmids or prophages bearing the exotoxin genes

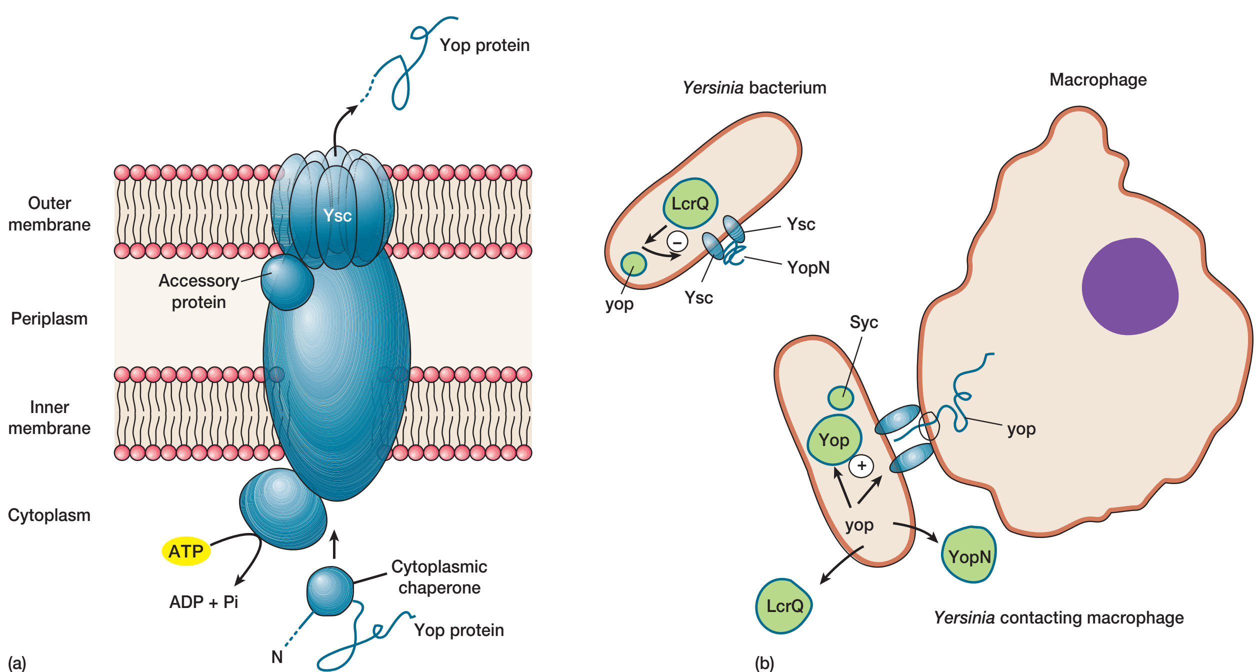


Figure 34.4 Type III Secretion System and Mode of Action of Yop Virulence Protein. (**a**) Schematic drawing of the type III secretion system and Yop (a specific virulence protein) secretion by *Yersinia* spp. (**b**) In this schematic, prior to cell contact, the type III secretion channels (Ysc) are kept shut by YopN, and cytoplasmic accumulation of the negative regulatory factor LcrQ leads to transcription repression of *yop* genes (negative sign in circle). After *Yersinia* contacts the macrophage, YopN is released, allowing rapid secretion of LcrQ, which in turn relieves the block of *yop* gene expression (positive sign in circle). Anti-host Yop proteins, protected by cognate chaperones (Syc), are translocated into the macrophage by the type III secretion machinery (as shown in part *a*). After contact of the *Yersinia* bacterium with a macrophage, Yop is injected into the cytoplasm of the target cell where it catalyzes a rapid and specific dephosphorylation of several macrophage proteins that are required for normal phagocytosis.

Table 34.5 Characteristics of Exotoxins and Endotoxins

Characteristic	Exotoxins	Endotoxins
Chemical composition	Protein, often with two components (A and B)	Lipopolysaccharide complex on outer membrane; lipid A portion is toxic
Disease examples	Botulism, diphtheria, tetanus	Gram-negative infections, meningococcemia
Effect on host	Highly variable between different toxins	Similar for all endotoxins
Fever	Usually do not produce fever	Produce fever by release of interleukin-1
Genetics	Frequently carried by extrachromosomal genes such as plasmids	Synthesized directly by chromosomal genes
Heat stability	Most are heat sensitive and inactivated at 60–80°C	Heat stable
Immune response	Antitoxins provide host immunity; highly antigenic	Limited antibodies produced; weakly immunogenic
Location	Usually excreted outside the living cell	Part of outer membrane of gram-negative bacteria
Production	Produced by both gram-positive and gram-negative bacteria	Found only in gram-negative bacteria; Released on bacterial death and some liberated during growth.
Toxicity	Highly toxic and fatal in microgram quantities	Moderate toxicity
Toxoid production	Converted to antigenic, nontoxic toxoids; toxoids are used to immunize (e.g., tetanus toxoid)	Toxoids cannot be made

2. Heat-labile proteins inactivated at 60 to 80°C
3. Among the most lethal substances known (toxic in very small doses [microgram per kilogram amounts]; e.g., the botulinum toxin)
4. Associated with specific diseases and have specific mechanisms of action
5. Highly immunogenic and stimulate the production of neutralizing antibodies called **antitoxins**
6. Easily inactivated by formaldehyde, iodine, and other chemicals to form immunogenic **toxoids**
7. Unable to produce a fever in the host directly
8. Often given the name of the disease they produce (e.g., the diphtheria toxin)

Exotoxins can be divided into four types based on their structure and physiological activities. (1) One type is the AB toxin, which gets its name from the fact that the portion of the toxin (B) that binds to a host cell receptor is separate from the portion (A) that has the enzyme activity that causes the toxicity. (2) A second type, which also may be an AB toxin, consists of those toxins that affect a specific host site (nervous tissue [neurotoxins], the intestines [enterotoxins], general tissues [cytotoxins]) by acting extracellularly or intracellularly on the host cells. (3) A third type does not have separable A and B portions and acts by disorganizing host cell membranes. Examples include the leukocidins, hemolysins, and phospholipases. (4) A fourth type is the superantigen that acts by stimulating T cells to release cytokines. Examples of the first three types are now discussed. Superantigens are discussed in detail in section 32.2. The general properties of some AB exotoxins are presented in **table 34.6.**

Table 34.6 Properties of Some AB Model Bacterial Exotoxins

Toxin	Organism	Genetic Control	Subunit Structure	Target Cell Receptor	Enzymatic Activity	Biologic Effects
Anthrax toxins	*B. anthracis*	Plasmid	Three separate proteins (EF, LF, PA)[a]	Unknown, probably glycoprotein	EF is a calmodulin-dependent adenylate cyclase; LF enzyme activity is unknown	EF + PA: increase in target cell cAMP level, localized edema; LF + PA: death of target cells and experimental animals
Bordetella adenylate cyclase toxin	*Bordetella* spp.	Chromosomal	A-B[b]	Unknown, probably glycolipid	Calmodulin-activated cyclase	Increase in target cell cAMP level; modified cell function or cell death
Botulinum toxin	*C. botulinum*	Phage	A-B[c]	Possibly ganglioside (GD_{1b})	Zinc-dependent endopeptidase cleavage of synaptobrevin	Decrease in peripheral, presynaptic acetylcholine release; flaccid paralysis
Cholera toxin	*V. cholera*	Chromosomal	A-5B[d]	Ganglioside (GM_1)	ADP ribosylation of adenylate cyclase regulatory protein, G_S	Activation of adenylate cyclase, increase in cAMP level; secretory diarrhea
Diphtheria toxin	*C. diphtheriae*	Phage	A-B[e]	Heparin-binding, EGF-like growth factor precursor	ADP ribosylation of elongation factor 2	Inhibition of protein synthesis; cell death
Heat-labile enterotoxins[f]	*E. coli*	Plasmid	Similar or Identical to Cholera Toxin			
Pertussis toxin	*B. pertussis*	Chromosomal	A-5B[g]	Unknown, probably glycoprotein	ADP ribosylation of signal-transducing G proteins	Block of signal transduction mediated by target G proteins
Pseudomonas exotoxin A	*P. aeruginosa*	Chromosomal	A-B	α_2-Macroglobulin/LDL receptor	Similar or Identical to Diphtheria Toxin	
Shiga toxin	*S. dysenteriae*	Chromosomal	A-5B[h]	Globotriaosylceramide (Gb_3)	RNA *N*-glycosidase	Inhibition of protein synthesis, cell death
Shiga-like toxin 1	*Shigella* spp., *E. coli*	Phage	Similar or Identical to Shiga Toxin			
Tetanus toxin	*C. tetani*	Plasmid	A-B[c]	Ganglioside (GT_1 and/or GD_{1b})	Zinc-dependent endopeptidase cleavage of synaptobrevin	Decrease in neurotransmitter release from inhibitory neurons; spastic paralysis

[a]The binding component (known as protective antigen [PA]) catalyzes/facilitates the entry of either edema factor (EF) or lethal factor (LF).

[b]Apparently synthesized as a single polypeptide with binding and catalytic (adenylate cyclase) domains.

[c]Holotoxin is apparently synthesized as a single polypeptide and cleaved proteolytically as diphtheria toxin; subunits are referred to as L: light chain, A equivalent; H: heavy chain, B equivalent.

[d]The A subunit is proteolytically cleaved into A_1 and A_2, with A_1 possessing the ADP-ribosyl transferase activity; the binding component is made up of five identical B units.

[e]Holotoxin is synthesized as a single polypeptide and cleaved proteolytically into A and B components held together by disulfide bonds.

[f]The heat-labile enterotoxins of *E. coli* are now recognized to be a family of related molecules with identical mechanisms of action.

[g]The binding portion is made up of two dissimilar heterodimers labeled S2-S3 and S2-S4 that are held together by a bridging peptide, SS.

[h]Subunit composition and structure similar to cholera toxin.

AB Exotoxins. **AB toxins** are composed of an enzymatic subunit or fragment (A) that is responsible for the toxic effect once inside the host cell and a binding subunit or fragment (B). Isolated A subunits are enzymatically active but lack binding and cell entry capability, whereas isolated B subunits bind to target cells but are nontoxic and biologically inactive. The B subunit interacts with specific receptors on the target cell or tissue such as the gangliosides GM_1 for cholera toxin, GT_1 and/or GD_1 for tetanus toxin, and GD_1 for botulinum toxin.

Several mechanisms for the entry of A subunits or fragments into target cells have been proposed. In one mechanism the B subunit inserts into the plasma membrane and creates a pore through which the A subunit enters (**figure 34.5*a***). In another mechanism entry is by receptor-mediated endocytosis (figure 34.5*b*).

The mechanism of action of an AB toxin can be quite complex, as shown by the example of diphtheria toxin (figure 34.5*b*). The diphtheria toxin is a protein of about 62,000 mol wt. It binds to cell surface receptors by the B fragment portion and is taken into the cell through the formation of a clathrin-coated vesicle (*see p. 403*). The toxin then enters the vesicle membrane and is cleaved into two parts, one of which, the A fragment, escapes into the cytosol. The A fragment is an enzyme that catalyzes the addition of an ADP-ribose group to the eucaryotic elongation factor EF2 that aids in translocation during protein synthesis (*see pp. 270–71*). The substrate for this reaction is the coenzyme NAD^+.

$$NAD^+ + EF2 \rightarrow \text{ADP-ribosyl-EF2} + \text{nicotinamide}$$

The modified EF2 protein cannot participate in the elongation cycle of protein synthesis, and the cell dies because it can no longer synthesize proteins.

AB exotoxins vary widely in their relative contribution to the disease process with which they are associated.

Specific Host Site Exotoxins. The second type of exotoxin is categorized on the basis of the site affected: **neurotoxins** (nerve tissue), **enterotoxins** (intestinal mucosa), and **cytotoxins** (general tissues). Some of the bacterial pathogens that produce these exotoxins are presented in table 34.6: neurotoxins (botulinum toxin and tetanus toxin), enterotoxins (cholera toxin, *E. coli* heat-labile toxins), and cytoxins (diphtheria toxin, Shiga toxin).

Neurotoxins usually are ingested as preformed toxins that affect the nervous system and indirectly cause enteric (pertaining to the small intestine) symptoms. Examples include staphylococcal enterotoxin B, *Bacillus cereus* emetic toxin [Greek *emetos,* vomiting], and botulinum toxin.

True enterotoxins [Greek *enter,* intestine] have a direct effect on the intestinal mucosa and elicit profuse fluid secretion. The classic enterotoxin, cholera toxin (choleragen), has been studied extensively. It is an AB toxin. The B subunit is made of five parts arranged as a donut-shaped ring. The B subunit ring anchors itself to the epithelial cell's plasma membrane and then inserts the smaller A subunit into the cell. The A subunit activates tissue adenylate cyclase to increase intestinal cyclic AMP (cAMP) concentrations. High concentrations of cAMP provoke the movement of massive quantities of water and electrolytes across the intestinal cells into the lumen of the gut. The genes for this enterotoxigenicity reside on the *Vibrio cholera* chromosome. Toxins in food (pp. 926–33, 975–76); Toxins as superantigens (p. 732)

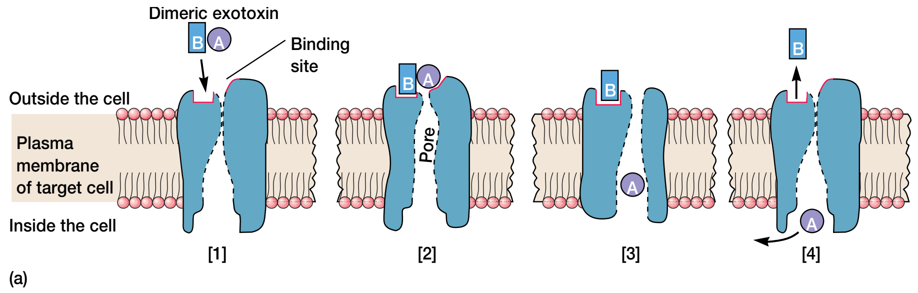
Cytotoxins have a specific toxic action upon cells/tissues of special organs and are named according to the type of cell/tissue or organ for which they are specific. Examples include nephrotoxin (kidney), hepatotoxin (liver), and cardiotoxin (heart).

Membrane-Disrupting Exotoxins. The third type of exotoxin lyses host cells by disrupting the integrity of the plasma membrane. There are two subtypes of **membrane-disrupting exotoxins.** The first (**figure 34.6*a***), is a protein that binds to the cholesterol portion of the host cell plasma membrane, inserts itself into the membrane, and forms a channel (pore). This causes the cytoplasmic contents to leak out. Also, because the osmolality of the cytoplasm is higher than the extracellular fluid, this causes a sudden influx of water into the cell, causing it to swell and rupture. Two specific examples of this type of membrane-disrupting exotoxin are now presented.

Some pathogens produce membrane-disrupting toxins that kill phagocytic leukocytes. These are termed **leukocidins** [*leuko*cyte and Latin *caedere,* to kill]. Most leukocidins are produced by pneumonococci, streptococci, and staphylococci. Since the pore-forming exotoxin produced by these bacteria destroys leukocytes, this in turn decreases host resistance. Other toxins, called **hemolysins** [*haima,* blood, and Greek *lysis,* dissolution], also can be secreted by pathogenic bacteria. Many hemolysins probably form pores in the plasma membrane of erythrocytes through which hemoglobin and/or ions are released (the erythrocytes lyse or, more specifically, hemolyze). **Streptolysin-O (SLO)** is a hemolysin, produced by *Streptococcus pyogenes,* that is inactivated by O_2 (hence the "O" in its name). SLO causes beta hemolysis of erythrocytes on agar plates incubated anaerobically (*see figure 23.17*). A complete zone of clearing around the bacterial colony growing on blood agar is called **beta hemolysis,** and a partial clearing of the blood is called **alpha hemolysis. Streptolysin-S (SLS)** is also produced by *S. pyogenes* but is insoluble and bound to the bacterial cell. It is O_2 stable (hence the "S" in its name) and causes beta hemolysis on aerobically incubated blood-agar plates. SLO and SLS act as leukocidins and kill leukocytes. It should also be noted that hemolysins attack the plasma membranes of many cells, not just erythrocytes and leukocytes.

The second sub-type of membrane-disrupting toxins are the **phospholipase** enzymes. Phospholipases remove the charged head group (figure 34.6*b*) from the lipid portion of the phospholipids in the host-cell plasma membrane. This destabilizes the membrane and the cell lyses and dies. One example of the pathogenesis caused by phospholipases is the disease gas gangrene. In this disease, the *Clostridium perfringens* α-toxin almost totally destroys the local population of white blood cells.

Roles of Exotoxins in Disease. Bacterial exotoxins affect a human host three main ways: (1) ingestion of preformed exotoxin, (2) colonization of a mucosal surface followed by exotoxin production, and (3) colonization of a wound or abscess followed by local exotoxin production. Each of these is now briefly discussed.



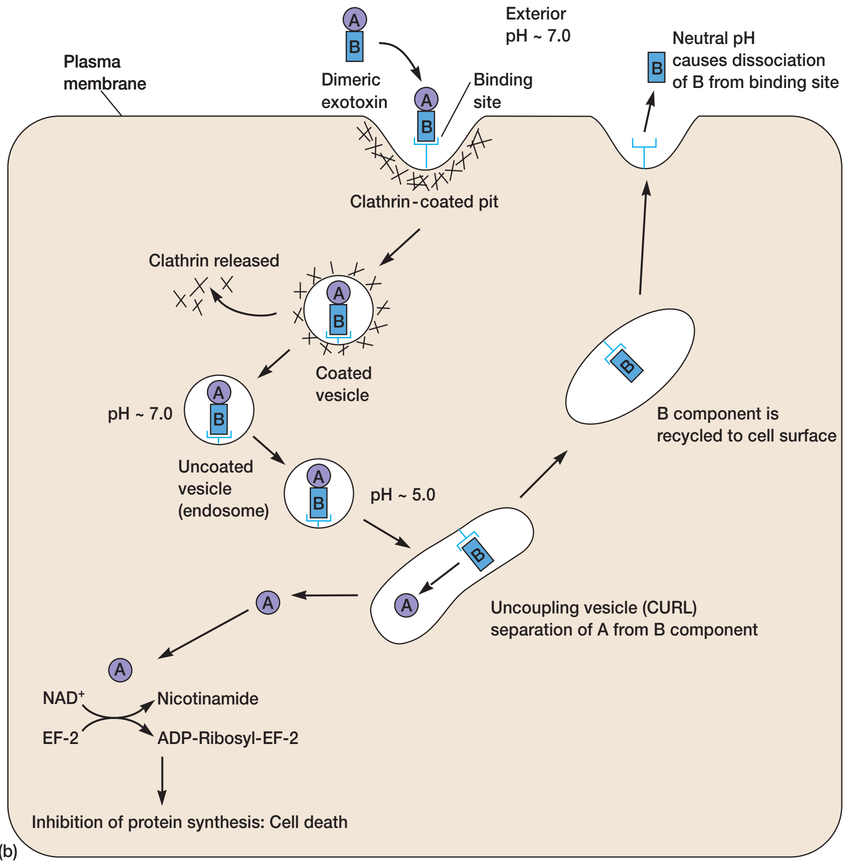


Figure 34.5 Diagrammatic Representation of Two AB Exotoxin Transport Mechanisms. (**a**) Domain B of the dimeric exotoxin (AB) binds to a specific membrane receptor of a target cell [*1*]. A conformational change [*2*] generates a pore [*3*] through which the A domain crosses the membrane and enters the cytosol, followed by recreation [*4*] of the binding site. (**b**) Receptor-mediated endocytosis of the diphtheria toxin involves the dimeric exotoxin binding to a receptor-ligand complex that is internalized in a clathrin-coated pit that pinches off to become a coated vesicle. The clathrin coat depolymerizes resulting in an uncoated endosome vesicle. The pH in the endosome decreases due to the H^+-ATPase activity. The low pH causes A and B components to separate. An endosome in which this separation occurs is sometimes called a CURL (compartment of *u*ncoupling of *r*eceptor and *l*igand). The B domain is then recycled to the cell surface. The A domain moves through the cytosol, catalyzes the ADP-ribosylation of EF-2 (elongation factor 2) and inhibits protein synthesis, leading to cell death.

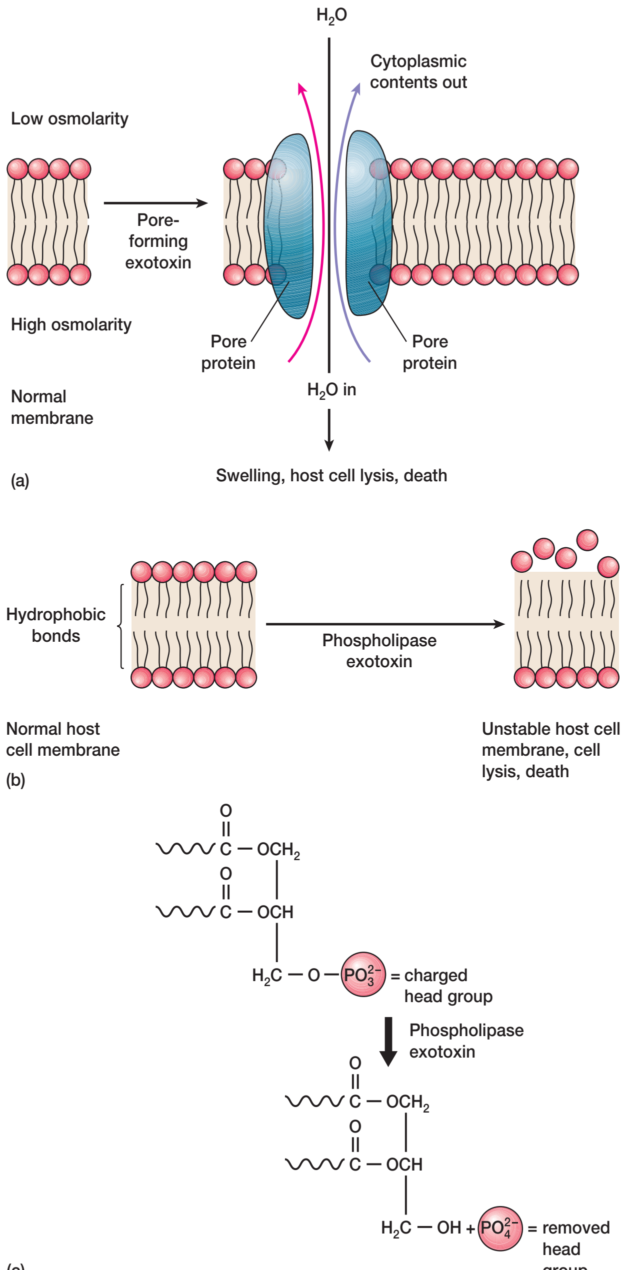

Figure 34.6 Two Subtypes of Membrane-Disrupting Exotoxins. (**a**) A channel-forming (pore-forming) type of exotoxin that inserts itself into the normal host cell membrane and makes an open channel (pore). Formation of multiple pores causes cytoplasmic contents to leave the cell and water to move in, leading to cellular lysis and death of the host cell. (**b**) A phospholipid-hydrolyzing phospholipase exotoxin destroys membrane integrity. (**c**) The exotoxin removes the charged polar head groups from the phospholipid part of the host cell membrane. This destabilizes the membrane and causes the host cell to lyse.

In the first example (**figure 34.7*a***), the exotoxin is produced by bacteria growing in food. When food is consumed, the preformed exotoxin is also consumed. The classical example is staphylococcal food poisoning (*see section 39.4*) caused solely by the ingestion of preformed enterotoxin. Since the bacteria (*Staphylococcus aureus*) cannot colonize the gut, they pass through the body without producing any more exotoxin; thus, this type of bacterial disease is self-limiting.

In the second example (figure 34.7*b*), bacteria colonize a mucosal surface but do not invade underlying tissue or enter the bloodstream. The toxin either causes disease locally or enters the bloodstream and is distributed systemically where it can cause disease at distant sites. The classical example here is the disease cholera caused by *Vibrio cholerae* (*see section 39.4*). Once the bacteria enter the body, they adhere to the intestinal mucosa where they are not invasive but secrete the cholera toxin, which is an AB exotoxin that catalyzes an ADP– ribosylation similar to that of diphtheria exotoxin (figure 34.5*b*). As a result, cholera toxin stimulates hypersecretion of water and chloride ions and the patient loses massive quantities of water.

The third example of exotoxins in disease pathogenesis occurs when bacteria grow in a wound or abscess (figure 34.7*c*). The exotoxin causes local tissue damage or kills phagocytes that enter the infected area. A disease of this type is gas gangrene (*see section 39.3*) in which the exotoxin (α-toxin) of *Clostridium perfringens* causes the tissue destruction in the wound.

1. What is the difference between an infectious disease and an intoxication? Define toxemia.
2. Describe some general characteristics of exotoxins.
3. How do exotoxins get into host cells?
4. Describe the biological effects of several bacterial exotoxins.
5. Discuss the mechanisms by which exotoxins can damage cells.
6. What are the four types of exotoxins?
7. What is the mode of action of a leukocidin? Of a hemolysin?
8. Name two specific hemolysins.
9. What are the three main roles exotoxins have in human disease pathogenesis?

Endotoxins

Gram-negative bacteria have lipopolysaccharide (LPS) in the outer membrane of their cell wall that, under certain circumstances, is toxic to specific hosts. This LPS (*see figures 3.23–3.25*) is called an **endotoxin** because it is bound to the bacterium and is released when the microorganism lyses (**Box 34.1**). Some is also released during bacterial multiplication. The toxic component of the LPS is the lipid portion, called lipid A. Lipid A is not a single macromolecular structure but appears to be a complex array of lipid residues. The lipid A component exhibits all the properties (see characteristic 5 on p. 801) associated with endotoxicity and gram-negative bacteremia. Gram-negative cell wall (pp. 58–60)

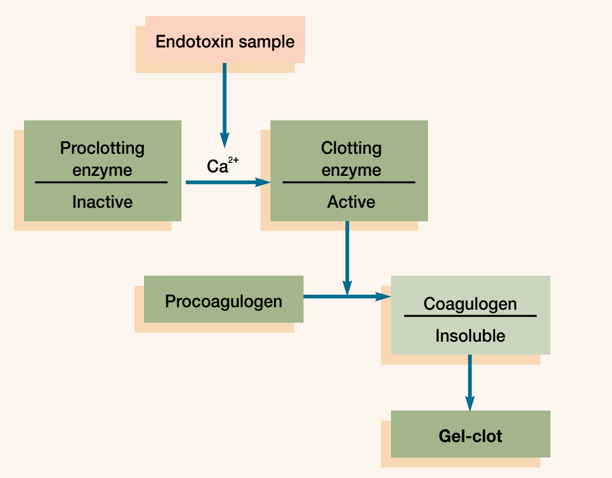
Box 34.1

Detection and Removal of Endotoxins

Bacterial endotoxins have plagued the pharmaceutical industry and medical device producers for years. For example, administration of drugs contaminated with endotoxins can result in complications—even death—to patients. Recently endotoxins have become a problem for individuals and firms working with cell cultures and genetic engineering. The result has been the development of sensitive tests and methods to identify and remove these endotoxins. The procedures must be very sensitive to trace amounts of endotoxins. Most firms have set a limit of 0.25 **endotoxin units** (E.U.), 0.025 ng/ml, or less as a release standard for their drugs, media, or products.

One of the most accurate tests for endotoxins is the in vitro *Limulus* amoebocyte lysate (LAL) assay. The assay is based on the observation that when an endotoxin contacts the clot protein from circulating amoebocytes of *Limulus,* a gel-clot forms. The assay kits available today contain calcium, proclotting enzyme, and procoagulogen. The proclotting enzyme is activated by bacterial endotoxin lipopolysaccharide and calcium to form active clotting enzyme (see **Box figure**). Active clotting enzyme then catalyzes the cleavage of procoagulogen into polypeptide subunits (coagulogen). The subunits join by disulfide bonds to form a gel-clot. Spectrophotometry is then used to measure the protein precipitated by the lysate. The LAL test is sensitive at the nanogram level but must be standardized against Food and Drug Administration Bureau of Biologics endotoxin reference standards. Results are reported in endotoxin units per milliliter and reference made to the particular reference standards used.

Removal of endotoxins presents more of a problem than their detection. Those present on glassware or medical devices can be inactivated if the equipment is heated at 250°C for 30 minutes. Soluble endotoxins range in size from 20 kDa to large aggregates with diameters up to 0.1µm. Thus they cannot be removed by conventional filtration systems. Manufacturers are currently developing special filtration systems and filtration cartridges that retain these endotoxins and help alleviate contamination problems.



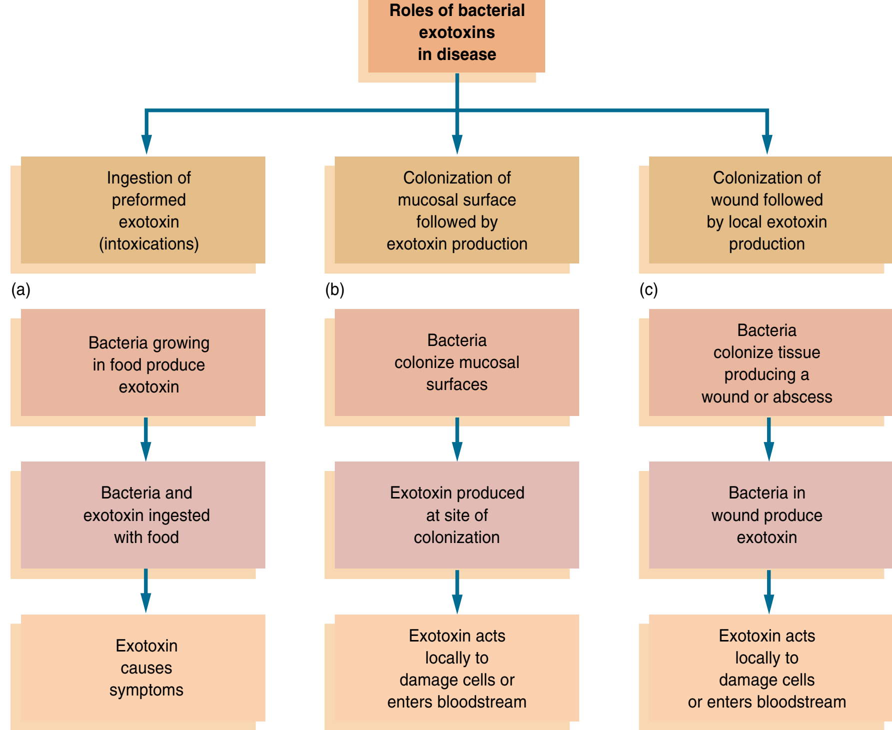


Figure 34.7 Roles of Exotoxins in Disease Pathogenesis. Three ways (**a**, **b**, **c**) in which bacterial exotoxins can contribute to the progression of disease in a human.

Besides the preceding characteristics, bacterial endotoxins are

1. Heat stable
2. Toxic only at high doses (milligram per kilogram amounts)
3. Weakly immunogenic
4. Generally similar, despite source
5. Usually capable of producing general systematic effects: fever (are pyrogenic), shock, blood coagulation, weakness, diarrhea, inflammation, intestinal hemorrhage, and fibrinolysis (enzymatic breakdown of fibrin, the major protein component of blood clots)

The characteristics of endotoxins and exotoxins are contrasted in table 34.5.

The main biological effect of LPS is an indirect one, being mediated by host molecules and systems rather than by LPS directly. For example, endotoxins can initially activate Hageman Factor (blood clotting factor XII), which in turn activates up to four humoral systems: coagulation, complement, fibrinolytic, and kininogen systems.

Gram-negative endotoxins also indirectly induce a fever in the host by causing macrophages to release **endogenous pyrogens** that reset the hypothalamic thermostat. One important endogenous pyrogen is the cytokine interleukin-1 (*see figure 31.19*). Other cytokines released by macrophages, such as the tumor necrosis factor, also produce fever.

Recent evidence indicates that LPS affects macrophages and monocytes by binding to special plasma proteins called **LPS-binding proteins.** The LPS-LPS-binding protein complex then attaches to receptors on monocytes, macrophages, and other cells. This triggers several events, including the production of cytokines IL-1, IL-6, and tumor necrosis factor. As mentioned previously, IL-1 and tumor necrosis factor induce fever. These cytokines also promote other endotoxin effects: complement activation, coagulation, prostaglandin formation, and so forth.

1. Describe the chemical structure of the LPS endotoxin.
2. List some general characteristics of endotoxins.
3. How do gram-negative endotoxins induce fever in a mammalian host?

34.4 Microbial Mechanisms for Escaping Host Defenses

So far, we have discussed some of the ways viral and bacterial pathogens cause disease in a host. During the course of microbe and human evolution, these same pathogens have evolved ways for escaping host defenses. Many of these mechanisms are found throughout the microbial world and several are now discussed.

Evasion of Host Defenses by Viruses

As noted earlier in this chapter, the pathology arising from a viral infection is due to either (1) the host's immune response, which attacks virus-infected cells or produces hypersensitivity reactions (*see section 33.2*), or (2) the direct consequence of viral multiplication within host cells. Viruses have evolved a variety of ways to suppress or evade the host's immune response. These mechanisms are just now becoming recognized through genomics and the functional analysis of specific gene products. Several examples follow.

Some viruses may mutate and change antigenic sites (antigenic drift, *see section 37.5*) on the virion proteins (the influenza virus) or may down-regulate the level of expression of viral cell surface proteins (the herpesvirus). Other viruses (HIV) may infect cells (T cells) of the immune system and diminish their function. HIV as well as the measles virus and cytomegalovirus cause the fusion of host cells. This allows these viruses to move from an infected cell to an uninfected cell without exposure to the antibody-containing fluids of the host. The herpesvirus may infect neurons that express little or no major histocompatibility complex molecules (*see section 32.4*). The adenovirus produces proteins that inhibit major histocompatibility complex function. Finally, hepatitis B virus infected cells produce large amounts of antigens not associated with the complete virus. These antigens bind the available neutralizing antibody (*see section 32.6*) so that there is insufficient free antibody to bind with the complete viral particle.

Evasion of Host Defenses by Bacteria

Bacteria also have evolved many mechanisms to evade host defenses. Because bacteria would not be well served either by the death of their host or their own death, their survival strategy is protection against host defenses rather than host destruction. Several of these evasive mechanisms are now discussed.

Evading the Complement System

To evade the activity of complement, some bacteria have capsules (see chapter opening figure) that prevent complement activation. Some gram-negative bacteria can lengthen the O chains in their lipopolysaccharide to prevent complement activation. Others such as *Neisseria gonorrhoeae* generate **serum resistance.** These bacteria have modified lipooligosaccharides on their surface that interfere with proper formation of the membrane attack complex (*see figure 31.14*) during the complement cascade. The virulent forms of *N. gonorrhoeae* that possess serum resistance are able to spread throughout the body of the host and cause systemic disease, whereas those *N. gonorrhoeae* that lack serum resistance remain localized in the genital tract. Complement activation (pp. 714–18, 758–59)

Resisting Phagocytosis

As noted several times previously, before a phagocytic cell can phagocytose a bacterium, it must first directly contact the bacterium's surface. Some bacteria such as *Streptococcus pneumoniae, Neisseria meningitidis,* and *Haemophilus influenzae* can produce a slippery mucoid capsule that prevents the phagocyte from effectively contacting the bacterium. Other bacteria evade phagocytosis by producing specialized surface proteins such as the M protein on *S. pyogenes.* Like capsules, these proteins interfere with adherence between a phagocytic cell and the bacterium.

Bacterial pathogens can resist phagocytosis in quite different ways. For example, *Staphylococcus* produces leukocidins

that destroy phagocytes before phagocytosis can occur. *Streptococcus pyogenes* releases a protease that cleaves the C5a complement factor and thus inhibits complement's ability to attract phagocytes to the infected area.

Survival Inside Phagocytic Cells

Some bacteria have evolved the ability to survive inside neutrophils, monocytes, and macrophages. Such pathogens are very pathogenic because they are impervious to a most important host protective mechanism. One evading mechanism is to escape from the phagosome before it merges with the lysosome, as seen with *Listeria monocytogenes, Shigella,* and *Rickettsia.* Another approach is to resist the toxic products released into the phagolysosome after fusion occurs. A good example of a bacterium that is resistant to the lysosomal enzymes is *Mycobacterium tuberculosis,* probably at least partly because of its waxy external layer. Still other bacteria prevent fusion of phagosomes with lysosomes (*Chlamydia*). Phagocytosis (pp. 718–20)

Evading the Specific Immune Response

To evade the specific immune response, some bacteria (*Streptococcus pyogenes*) produce capsules that are not antigenic since they resemble host tissue components. *N. gonorrhoeae* can also evade the specific immune response by two mechanisms: (1) it makes genetic variations in its pili (phase variation) so that specific antibodies are useless against the new pili and adherence to host tissue occurs, and (2) it produces IgA proteases that destroy secretory IgA and allow adherence. Finally, some bacteria produce proteins (such as staphylococcal protein A and protein G of *Streptococcus pyogenes*) that interfere with antibody-mediated opsonization (*see figure 31.15*) by binding to the Fc portion of immunoglobulins.

1. What are some mechanisms viruses use to evade host defenses?
2. How do bacteria evade each of the following host defenses: the complement system, phagocytosis, and the specific immune response?

Summary

1. Parasitism is a type of symbiosis between two species in which the smaller organism is physiologically dependent on the larger one, termed the host. The parasitic organism usually harms its host in some way.
2. An infection is the colonization of the host by a parasitic organism. An infectious disease is the result of the interaction (**figure 34.1**) between the parasitic organism and its host, causing the host to change from a state of health to a diseased state. Any organism that produces such a disease is a pathogen.
3. Pathogenicity refers to the quality or ability of an organism to produce pathological changes or disease. Virulence refers to the degree or intensity of pathogenicity of an organism and is measured experimentally by the LD_{50} or ID_{50} (**figure 34.2**).
4. The fundamental process of viral infection is the expression of the viral replicative cycle in a host cell. To produce disease a virus must enter a host; come into contact with susceptible cells; reproduce; spread to adjacent cells; cause cellular injury; engender a host immune response; be either cleared from the body of the host, establish a persistent infection, or kill the host; and be shed back into the environment.
5. Pathogens or their products can be transmitted to a host by either direct or indirect means. Transmissibility is the initial requisite in the establishment of an infectious disease.
6. Special adherence factors (**table 34.3**) allow pathogens to bind to specific receptor sites on host cells and colonize the host (**figure 34.3**).
7. Pathogens can enter host cells by both active and passive mechanisms. Once inside, they can produce specific products and/or enzymes that promote dissemination throughout the body of the host. These are termed virulence factors (**table 34.4**).
8. The pathogen generally is found in the area of the host's body that provides the most favorable conditions for its growth and multiplication.
9. In bacteria, one important result of the conservation of chromosomal genes is that bacteria are clonal. For most pathogenic bacteria, there are only a few clonal types that exist in the environment.
10. During coevolution with human hosts, some pathogenic bacteria have evolved complex signal transduction pathways to regulate the genes necessary for virulence.
11. Many bacteria are pathogenic because they have large segments of DNA called pathogenicity islands that carry genes responsible for virulence.
12. Intoxications are diseases that result from the entrance of a specific toxin into a host. The toxin can induce the disease in the absence of the toxin-producing organism. Toxins produced by pathogens can be divided into two main categories: exotoxins and endotoxins (**table 34.5**).
13. Exotoxins are soluble, heat-labile, potent, toxic proteins produced by the pathogen as a result of its normal metabolism. They have very specific effects and can be categorized as neurotoxins, cytotoxins, or enterotoxins. Most exotoxins conform to the AB model in which the A subunit or fragment is enzymatic and the B subunit or fragment, the binding portion (**table 34.6**). Several mechanisms exist by which the A component enters target cells (**figure 34.5**).
14. Exotoxins can be divided into four types: (a) the AB toxins, (b) specific host site toxins (neurotoxins, enterotoxins, cytotoxins), (c) toxins that disrupt plasma membranes of host cells (leukocidins, hemolysins, and phospholipases), and (d) superantigens.
15. Bacterial exotoxins cause disease in a human host in three main ways: (a) ingestion of preformed exotoxin, (b) colonization of a mucosal surface followed by exotoxin production, and (c) colonization of a wound followed by local exotoxin production.
16. Endotoxins are heat-stable, toxic substances that are part of the cell wall lipopolysaccharide of some gram-negative bacteria. Most endotoxins function by initially activating Hageman Factor, which in turn activates one to four humoral systems. These include the intrinsic blood clotting cascade, complement activation, fibrinolytic system, and kininogen system. Endotoxins also stimulate macrophages to release cytokines such as IL-1, IL-6, and TNF-α.
17. During the course of microbe and human evolution, some pathogens have evolved ways for escaping host defenses. Viruses have mechanisms that either suppress or evade the host's immune response. Bacteria have evolved mechanisms to evade the complement system, phagocytosis, and the specific immune response.

Questions for Thought and Review

1. Why does a parasitic organism not have to be a parasite?
2. In general, infectious diseases that are commonly fatal are newly evolved relationships between the parasitic organism and the host. Why is this so?
3. What does an organism require to be parasitic?
4. What are some bacterial determinants that provide the organism with the ability to colonize and invade the host?
5. What is the significance of the clonal nature of bacterial pathogens?
6. How do some bacteria regulate their virulence factors?
7. Describe a pathogenicity island.
8. What are four types of exotoxins based on their structural and physiological activities?
9. What is the difference between the general properties of endotoxins and exotoxins?
10. How do some viruses evade the defenses of a human host? How do some bacteria evade the defenses of a human host?

Critical Thinking Questions

1. Explain the observation that different pathogens infect different parts of the host.
2. Intracellular bacterial infections present a particular difficulty for the host. Why is it harder to defend against these infections than against viral infections and extracellular bacterial infections?

Concepts

1. Many diseases are treated with chemotherapeutic agents, such as antibiotics, that inhibit or kill the pathogen while harming the host as little as possible.
2. Ideally, antimicrobial agents disrupt microbial processes or structures that differ from those of the host. They may damage pathogens by hampering cell wall synthesis, inhibiting microbial protein and nucleic acid synthesis, disrupting microbial membrane structure and function, or blocking metabolic pathways through inhibition of key enzymes.
3. The effectiveness of chemotherapeutic agents depends on many factors: the route of administration and location of the infection, the presence of interfering substances, the concentration of the drug in the body, the nature of the pathogen, the presence of drug allergies, and the resistance of microorganisms to the drug.
4. The increasing number and variety of drug-resistant pathogens is a serious public health problem.
5. Although antibacterial chemotherapy is more advanced, drugs for the treatment of fungal and viral infections are also becoming increasingly available.

It was the knowledge of the great abundance and wide distribution of actinomycetes, which dated back nearly three decades, and the recognition of the marked activity of this group of organisms against other organisms that led me in 1939 to undertake a systematic study of their ability to produce antibiotics.

—*Selman A. Waksman*

The control of microorganisms is critical for the prevention and treatment of disease. Chapter 7 is concerned principally with the chemical and physical agents used to treat inanimate objects in order to destroy microorganisms or inhibit their growth. In addition, the use of antiseptics is briefly reviewed. Microorganisms also grow on and within other organisms, and microbial colonization can lead to disease, disability, and death. Thus the control or destruction of microorganisms residing within the bodies of humans and other animals is of great importance.

When disinfecting or sterilizing an inanimate object, one naturally must use procedures that do not damage the object itself. The same is true for the treatment of living hosts. The most successful drugs interfere with processes that differ between the pathogen and host, and seriously damage the target microorganism while harming its host as little as possible. This chapter introduces the principles of chemotherapy and briefly reviews the characteristics of selected antibacterial, antifungal, and antiviral drugs.

Modern medicine is dependent on **chemotherapeutic agents,** chemical agents that are used to treat disease. Chemotherapeutic agents destroy pathogenic microorganisms or inhibit their growth at concentrations low enough to avoid undesirable damage to the host. Most of these agents are **antibiotics** [Greek *anti,* against, and *bios,* life], microbial products or their derivatives that can kill susceptible microorganisms or inhibit their growth. Drugs such as the sulfonamides are sometimes called antibiotics although they are synthetic chemotherapeutic agents, not microbially synthesized.

35.1 The Development of Chemotherapy

The modern era of chemotherapy began with the work of the German physician Paul Ehrlich (1854–1915). Ehrlich reasoned that a chemical with selective toxicity that would kill pathogens and not human cells might be effective in treating disease. He hoped to find a toxic dye molecule, a "magic bullet," that would specifically bind to pathogens and destroy them; therefore he began experimenting with dyes. By 1904 Ehrlich found that the dye trypan red was active against the trypanosome that causes African sleeping sickness (*see figure 27.3*) and could be used therapeutically. Subsequently Ehrlich and a young Japanese scientist named Sahachiro Hata tested a variety of arsenicals on syphilis-infected rabbits and found that compound number 606, arsphenamine, was active against the syphilis spirochete (*see figure 21.15*b). Arsphenamine was made available in 1910 under the trade name Salvarsan. Ehrlich's successes in the chemotherapy of sleeping sickness and syphilis established his concept of selective toxicity and led to the testing of hundreds of compounds for their therapeutic potential.

In 1927 the German chemical industry giant, I. G. Farbenindustrie, began a long-term search for chemotherapeutic agents under the direction of Gerhard Domagk. The company provided vast numbers of dyes and other chemicals that Domagk tested for activity against pathogenic bacteria and for toxicity in animals. During this screening program Domagk discovered that Prontosil Red, a new dye for staining leather, was nontoxic for animals and completely protected mice against pathogenic streptococci and staphylococci. These results were published in 1935, and in the same year the French scientists Jacques and Therese Trefouel showed that Prontosil Red was converted in the body to sulfanilamide, the true active factor. Domagk had actually discovered sulfonamides or sulfa drugs and for this discovery he received the Nobel Prize in 1939.

The story of the discovery and development of penicillin, the first antibiotic to be used therapeutically, is complex and fascinating. Although penicillin was actually discovered in 1896 by a 21-year-old French medical student named Ernest Duchesne, his work was forgotten, and penicillin was rediscovered and brought to the attention of scientists by the Scottish physician Alexander Fleming. Fleming had been interested in finding something that would kill pathogens ever since working on wound infections during the First World War. One day in September 1928, a *Penicillium notatum* spore accidentally landed on the surface of an exposed petri dish before it had been inoculated with staphylococci, and a new medical era was born. Although the precise events are still unclear, Ronald Hare has suggested that Fleming left the contaminated plate on a laboratory bench while he was on vacation. Because the first few days of the vacation were cool, the fungus grew more rapidly than the bacteria and produced penicillin. When the weather then turned warm, the bacteria began to grow and were lysed. On his return, Fleming noticed that a *Penicillium* colony was growing at one edge and that the staphylococci surrounding it had been destroyed. Rather than discarding the contaminated plate, he correctly deduced that his mold contaminant was producing a diffusible substance lethal to staphylococci. He began efforts to characterize what he called penicillin. He found that broth from a *Penicillium* culture contained peni-

Box 35.1

The Use of Antibiotics in Microbiological Research

Although the use of antibiotics in the treatment of disease is emphasized in this chapter, it should be noted that antibiotics are extremely important research tools. For example, they aid the cultivation of viruses by preventing bacterial contamination. When eggs are inoculated with a virus sample, antibiotics often are included in the inoculum to maintain sterility. Usually a mixture of antibiotics (e.g., penicillin, amphotericin, and streptomycin) also is added to tissue cultures used for virus cultivation and other purposes.

Researchers often use antibiotics as instruments to dissect metabolic processes by inhibiting or blocking specific steps and observing the consequences. Although selective toxicity is critical when antibiotics are employed therapeutically, specific toxicity is more important in this context: the antibiotic must act by a specific and precisely understood mechanism. A clinically useful antimicrobial agent such as penicillin sometimes may be employed in research, but often an agent with specific toxicity and excellent research potential is too toxic for therapeutic use. The actinomycins, discovered in 1940 by Selman Waksman, are a case in point. They are so toxic to higher organisms that it was suggested they be used as rat poison. Today actinomycin D is a standard research tool specifically used to block RNA synthesis. Other examples of antibiotics useful in research, with the process inhibited, are the following: chloramphenicol (bacterial protein synthesis), cycloserine (peptidoglycan synthesis), nalidixic acid and novobiocin (bacterial DNA synthesis), rifampin (bacterial RNA synthesis), cycloheximide (eucaryotic protein synthesis), daunomycin (fungal RNA synthesis), mitomycin C (DNA synthesis), polyoxin D (fungal cell wall chitin synthesis), and cerulenin (fatty acid synthesis).

In practice, the antibiotic is administered and changes in cell function are monitored. If one desired to study the dependence of bacterial flagella synthesis on RNA transcription, the flagella could be removed by high-speed mixing in a blender, followed by actinomycin D addition to the incubation mixture. The bacterial culture would then be observed for flagella regeneration in the absence of RNA synthesis. The results of such experiments must be interpreted with caution. Flagella synthesis may have been blocked because actinomycin D inhibited some other process, thus affecting flagella regeneration indirectly rather than simply inhibiting transcription of a gene required for flagella synthesis. Furthermore, not all microorganisms respond in the same way to a particular drug.

cillin and that the antibiotic could destroy several pathogenic bacteria. Unfortunately Fleming's next experiments convinced him that penicillin would not remain active in the body long enough after injection to destroy pathogens. After giving a talk on penicillin and publishing several papers on the subject between 1929 and 1931, he dropped the research.

In 1939 Howard Florey, a professor of pathology at Oxford University, was in the midst of testing the bactericidal activity of many substances, including lysozyme and the sulfonamides. After reading Fleming's paper on penicillin, one of Florey's coworkers, Ernst Chain, obtained the *Penicillium* culture from Fleming and set about culturing it and purifying penicillin. Florey and Chain were greatly aided in this by the biochemist Norman Heatley. Heatley devised the original assay, culture, and purification techniques needed to produce crude penicillin for further experimentation. When the purified penicillin was injected into mice infected with streptococci or staphylococci, practically all the mice survived. Florey and Chain's success was reported in 1940, and subsequent human trials were equally successful. Fleming, Florey, and Chain received the Nobel Prize in 1945 for the discovery and production of penicillin.

The discovery of penicillin stimulated the search for other antibiotics. Selman Waksman announced in 1944 that he had found a new antibiotic, streptomycin, produced by the actinomycete *Streptomyces griseus.* This discovery arose from the patient screening of about 10,000 strains of soil bacteria and fungi. Waksman received the Nobel Prize in 1952, and his success led to a worldwide search for other antibiotic-producing soil microorganisms. Microorganisms producing chloramphenicol, neomycin, terramycin, and tetracycline were isolated by 1953.

The discovery of chemotherapeutic agents and the development of newer, more powerful drugs has transformed modern medicine and greatly alleviated human suffering. Furthermore, antibiotics have proven exceptionally useful in microbiological research (**Box 35.1**).

1. What are chemotherapeutic agents? Antibiotics?
2. What contributions to chemotherapy were made by Ehrlich, Domagk, Fleming, Florey and Chain, and Waksman?

35.2 General Characteristics of Antimicrobial Drugs

As Ehrlich so clearly saw, to be successful a chemotherapeutic agent must have **selective toxicity:** it must kill or inhibit the microbial pathogen while damaging the host as little as possible. The degree of selective toxicity may be expressed in terms of (1) the therapeutic dose, the drug level required for clinical treatment of a particular infection, and (2) the toxic dose, the drug level at which the agent becomes too toxic for the host. The **therapeutic index** is the ratio of the toxic dose to the therapeutic dose. The larger the therapeutic index, the better the chemotherapeutic agent (all other things being equal).

A drug that disrupts a microbial function not found in eucaryotic animal cells often has a greater selective toxicity and a higher therapeutic index. For example, penicillin inhibits bacterial cell wall peptidoglycan synthesis but has little effect on host cells because they lack cell walls; therefore penicillin's therapeutic index

Table 35.1 Properties of Some Common Antibacterial Drugs

Drug	Primary Effect	Spectrum	Side Effects[a]
Ampicillin	Cidal	Broad (gram +, some –)	Allergic responses (diarrhea, anemia)
Bacitracin	Cidal	Narrow (gram +)	Renal injury if injected
Carbenicillin	Cidal	Broad (gram +, many –)	Allergic responses (nausea, anemia)
Cephalosporins	Cidal	Broad (gram +, some –)	(Allergic responses, thrombophlebitis, renal injury)
Chloramphenicol	Static	Broad (gram +, –; rickettsia and chlamydia)	Depressed bone marrow function, allergic reactions
Ciprofloxacin	Cidal	Broad (gram +, –)	Gastrointestinal upset, allergic responses
Clindamycin	Static	Narrow (gram +, anaerobes)	Diarrhea
Dapsone	Static	Narrow (mycobacteria)	(Anemia, allergic responses)
Erythromycin	Static	Narrow (gram +, mycoplasma)	(Gastrointestinal upset, hepatic injury)
Gentamicin	Cidal	Narrow (gram –)	(Allergic responses, nausea, loss of hearing, renal damage)
Isoniazid	Static or cidal	Narrow (mycobacteria)	(Allergic reactions, gastrointestinal upset, hepatic injury)
Methicillin	Cidal	Narrow (gram +)	Allergic responses (renal toxicity, anemia)
Penicillin	Cidal	Narrow (gram +)	Allergic responses (nausea, anemia)
Polymyxin B	Cidal	Narrow (gram –)	(Renal damage, neurotoxic reactions)
Rifampin	Static	Broad (gram +, mycobacteria)	(Hepatic injury, nausea, allergic responses)
Streptomycin	Cidal	Broad (gram +, –; mycobacteria)	(Allergic responses, nausea, loss of hearing, renal damage)
Sulfonamides	Static	Broad (gram +, –)	Allergic responses (renal and hepatic injury, anemia)
Tetracyclines	Static	Broad (gram +, –; rickettsia and chlamydia)	Gastrointestinal upset, teeth discoloration (renal and hepatic injury)
Trimethoprim	Cidal	Broad (gram +, –)	(Allergic responses, rash, nausea, leukopenia)
Vancomycin	Cidal	Narrow (gram +)	Hypotension, neutropenia, kidney damage, allergic reactions

[a]Occasional side effects are in parentheses. Other side effects not listed may also arise.

is high. A drug may have a low therapeutic index because it inhibits the same process in host cells or damages the host in other ways. These undesirable effects on the host, called **side effects,** are of many kinds and may involve almost any organ system (**table 35.1**). Because side effects can be severe, chemotherapeutic agents should be administered with great care.

Drugs vary considerably in their range of effectiveness. Many are **narrow-spectrum drugs**—that is, they are effective only against a limited variety of pathogens (table 35.1). Others are **broad-spectrum drugs** and attack many different kinds of pathogens. Drugs may also be classified based on the general microbial group they act against: antibacterial, antifungal, antiprotozoan, and antiviral. Some agents can be used against more than one group; for example, sulfonamides are active against bacteria and some protozoa.

Chemotherapeutic agents can be synthesized by microorganisms or manufactured by chemical procedures independent of microbial activity. A number of the most commonly employed antibiotics are natural—that is, totally synthesized by one of a few bacteria or fungi (**table 35.2**). In contrast, several important chemotherapeutic agents are completely synthetic. The synthetic antibacterial drugs in table 35.1 are the sulfonamides, trimethoprim, chloramphenicol, ciprofloxacin, isoniazid, and dapsone. Many antiviral and antiprotozoan drugs are synthetic. An increasing number of antibiotics are semisynthetic. Semisynthetic antibiotics are natural antibiotics that have been chemically modified by the addition of extra chemical groups to make them less susceptible to inactivation by pathogens. Ampicillin, carbenicillin, and methicillin (table 35.1) are good examples.

Table 35.2 Microbial Sources of Some Antibiotics

Microorganism	Antibiotic
Bacteria	
Streptomyces spp.	Amphotericin B
	Chloramphenicol (also synthetic)
	Erythromycin
	Kanamycin
	Neomycin
	Nystatin
	Rifampin
	Streptomycin
	Tetracyclines
	Vancomycin
Micromonospora spp.	Gentamicin
Bacillus spp.	Bacitracin
	Polymyxins
Fungi	
Penicillium spp.	Griseofulvin
	Penicillin
Cephalosporium spp.	Cephalosporins

Chemotherapeutic agents, like disinfectants, can be either **cidal** or **static.** As mentioned earlier (*see section 7.1*), static agents reversibly inhibit growth; if the agent is removed, the microorganisms will recover and grow again.

Although a cidal agent kills the target pathogen, its activity is concentration dependent and the agent may be only static at low

levels. The effect of an agent also varies with the target species: an agent may be cidal for one species and static for another. Because static agents do not directly destroy the pathogen, elimination of the infection depends on the host's own resistance mechanisms. A static agent may not be effective if the host's resistance is too low.
Host resistance and the immune response (chapters 31–33)

Some idea of the effectiveness of a chemotherapeutic agent against a pathogen can be obtained from the **minimal inhibitory concentration (MIC).** The MIC is the lowest concentration of a drug that prevents growth of a particular pathogen. The **minimal lethal concentration (MLC)** is the lowest drug concentration that kills the pathogen. A cidal drug kills pathogens at levels only two to four times the MIC, whereas a static agent kills at much higher concentrations (if at all).

1. Define the following terms: selective toxicity, therapeutic index, side effect, narrow-spectrum drug, broad-spectrum drug, synthetic and semisynthetic antibiotics, cidal and static agents, minimal inhibitory concentration (MIC), and minimal lethal concentration (MLC).

35.3 Determining the Level of Antimicrobial Activity

Determination of antimicrobial effectiveness against specific pathogens is essential to proper therapy. Testing can show which agents are most effective against a pathogen and give an estimate of the proper therapeutic dose.

Dilution Susceptibility Tests

Dilution susceptibility tests can be used to determine MIC and MLC values. In the broth dilution test, a series of broth tubes (usually Mueller-Hinton broth) containing antibiotic concentrations in the range of 0.1 to 128 μg/ml is prepared and inoculated with standard numbers of the test organism. The lowest concentration of the antibiotic resulting in no growth after 16 to 20 hours of incubation is the MIC. The MLC can be ascertained if the tubes showing no growth are subcultured into fresh medium lacking antibiotic. The lowest antibiotic concentration from which the microorganisms do not recover and grow when transferred to fresh medium is the MLC. The agar dilution test is very similar to the broth dilution test. Plates containing Mueller-Hinton agar and various amounts of antibiotic are inoculated and examined for growth. Recently several automated systems for susceptibility testing and MIC determination with broth or agar cultures have been developed.

Disk Diffusion Tests

If a rapidly growing aerobic or facultative pathogen like *Staphylococcus* or *Pseudomonas* is being tested, a disk diffusion technique may be used to save time and media. The principle behind the assay technique is fairly simple. When an antibiotic-impregnated disk is placed on agar previously inoculated with the test bacterium, the disk picks up moisture and the antibiotic diffuses radially outward through the agar, producing an antibiotic concentration gradient. The antibiotic is present at high concentrations near the disk and affects even minimally susceptible microorganisms (resistant organisms will grow up to the disk). As the distance from the disk increases, the antibiotic concentration drops and only more susceptible pathogens are harmed. A clear zone or ring is present around an antibiotic disk after incubation if the agent inhibits bacterial growth. The wider the zone surrounding a disk, the more susceptible the pathogen is. Zone width also is a function of the antibiotic's initial concentration, its solubility, and its diffusion rate through agar. Thus zone width cannot be used to compare directly the effectiveness of two different antibiotics.

Currently the disk diffusion test most often used is the **Kirby-Bauer method,** which was developed in the early 1960s at the University of Washington Medical School by William Kirby, A. W. Bauer, and their colleagues. An inoculating loop or needle is touched to four or five isolated colonies of the pathogen growing on agar and then used to inoculate a tube of culture broth. The culture is incubated for a few hours at 35°C until it becomes slightly turbid and is diluted to match a turbidity standard. A sterile cotton swab is dipped into the standardized bacterial test suspension and used to evenly inoculate the entire surface of a Mueller-Hinton agar plate. After the agar surface has dried for about 5 minutes, the appropriate antibiotic test disks are placed on it, either with sterilized forceps or with a multiple applicator device (**figure 35.1**). The plate is immediately placed in a 35°C incubator. After 16 to 18 hours of incubation, the diameters of the zones of inhibition are measured to the nearest mm.

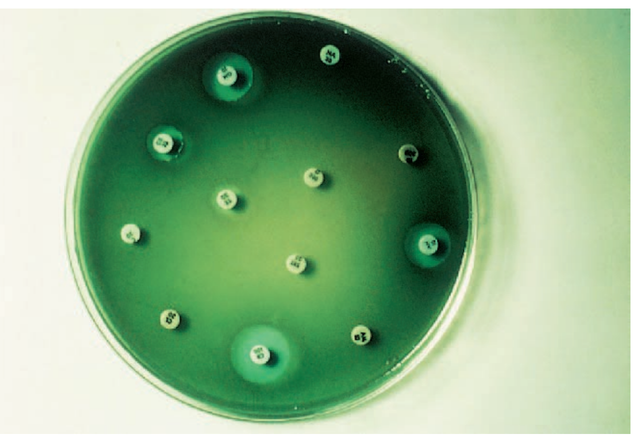
Kirby-Bauer test results are interpreted using a table that relates zone diameter to the degree of microbial resistance (table 35.3). The values in **table 35.3** were derived by finding the MIC values and zone diameters for many different microbial strains. A plot of MIC (on a logarithmic scale) versus zone inhibition diameter (arithmetic scale) is prepared for each antibiotic (**figure 35.2**). These plots are then used to find the zone diameters corresponding to the drug concentrations actually reached in the body. If the zone diameter for the lowest level reached in the body is smaller than that seen with the test pathogen, the pathogen should have an MIC value low enough to be destroyed by the drug. A pathogen with too high an MIC value (too small a zone diameter) is resistant to the agent at normal body concentrations.

Measurement of Drug Concentrations in the Blood

A drug must reach a concentration at the site of infection above the pathogen's MIC to be effective. In cases of severe, life-threatening disease, it often is necessary to monitor the concentration of drugs in the blood and other body fluids. This may be achieved by microbiological, chemical, immunologic, enzymatic, or chromatographic assays.

1. How can dilution susceptibility tests and disk diffusion tests be used to determine microbial drug sensitivity?
2. Briefly describe the Kirby-Bauer test and its purpose.

(a)



(b)

Figure 35.1 The Kirby-Bauer Method. (**a**) A multiple antibiotic disk dispenser and (**b**) disk diffusion test results.

Table 35.3 Inhibition Zone Diameter of Selected Chemotherapeutic Drugs

		Zone Diameter (Nearest mm)		
Chemotherapeutic Drug	**Disk Content**	**Resistant**	**Intermediate**	**Susceptible**
Carbenicillin (with *Proteus* spp. and *E. coli*)	100 µg	≤17	18–22	≥23
Carbenicillin (with *Pseudomonas aeruginosa*)	100 µg	≤13	14–16	≥17
Ceftriaxone	30 µg	≤13	14–20	≥21
Chloramphenicol	30 µg	≤12	13–17	≥18
Erythromycin	15 µg	≤13	14–17	≥18
Penicillin G (with staphylococci)	10 U[a]	≤20	21–28	≥29
Penicillin G (with other microorganisms)	10 U	≤11	12–21	≥22
Streptomycin	10 µg	≤11	12–14	≥15
Sulfonamides	250 or 300 µg	≤12	13–16	≥17
Tetracycline	30 µg	≤14	15–18	≥19

[a]One milligram of penicillin G sodium = 1,600 units.

35.4 Mechanisms of Action of Antimicrobial Agents

The mechanisms of action of specific chemotherapeutic agents are taken up in more detail when individual drugs and groups of drugs are discussed later in this chapter. A few general observations are offered at this point. It is important to know something about the mechanisms of drug action because such knowledge helps explain the nature and degree of selective toxicity of individual drugs and sometimes aids in the design of new chemotherapeutic agents.

Antimicrobial drugs can damage pathogens in several ways, as can be seen in **table 35.4,** which summarizes the mechanisms of the antibacterial drugs listed in table 35.1. The most selective antibiotics are those that interfere with the synthesis of bacterial cell walls (e.g., penicillins, cephalosporins, vancomycin, and bacitracin). These drugs have a high therapeutic index because bacterial cell walls have a unique structure (*see section 3.5*) not found in eucaryotic cells.

Streptomycin, gentamicin, spectinomycin, clindamycin, chloramphenicol, tetracyclines, erythromycin, and many other

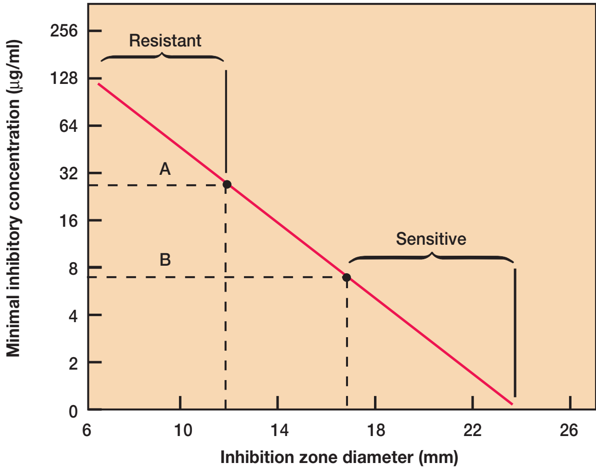


Figure 35.2 Interpretation of Kirby-Bauer Test Results. The relationship between the minimal inhibitory concentrations with a hypothetical drug and the size of the zone around a disk in which microbial growth is inhibited. As the sensitivity of microorganisms to the drug increases, the MIC value decreases and the inhibition zone grows larger. Suppose that this drug varies from 7–28 µg/ml in the body during treatment. Dashed line A shows that any pathogen with a zone of inhibition less than 12 mm in diameter will have an MIC value greater than 28 µg/ml and will be resistant to drug treatment. A pathogen with a zone diameter greater than 17 mm will have an MIC less than 7 µg/ml and will be sensitive to the drug (see line B). Zone diameters between 12 and 17 mm indicate intermediate sensitivity and usually signify resistance.

Table 35.4 Mechanisms of Antibacterial Drug Action

Drug	Mechanism of Action
Cell Wall Synthesis Inhibition	
Penicillin Ampicillin Carbenicillin Methicillin Cephalosporins	Inhibit transpeptidation enzymes involved in the cross-linking of the polysaccharide chains of the bacterial cell wall peptidoglycan. Activate cell wall lytic enzymes.
Vancomycin	Binds directly to the D-Ala-D-Ala terminus and inhibits transpeptidation.
Bacitracin	Inhibits cell wall synthesis by interfering with action of the lipid carrier that transports wall precursors across the plasma membrane.
Protein Synthesis Inhibition	
Streptomycin Gentamicin	Binds with the 30S subunit of the bacterial ribosome to inhibit protein synthesis and causes misreading of mRNA.
Chloramphenicol	Binds to the 50S ribosomal subunit and blocks peptide bond formation through inhibition of peptidyl transferase.
Tetracyclines	Bind to the 30S ribosomal subunit and interfere with aminoacyl-tRNA binding.
Erythromycin and clindamycin	Bind to the 50S ribosomal subunit and inhibit peptide chain elongation.
Fusidic acid	Binds to EF-G and blocks translocation.
Nucleic Acid Synthesis Inhibition	
Ciprofloxacin and other quinolones	Inhibit bacterial DNA gyrase and thus interfere with DNA replication, transcription, and other activities involving DNA.
Rifampin	Blocks RNA synthesis by binding to and inhibiting the DNA-dependent RNA polymerase.
Cell Membrane Disruption	
Polymyxin B	Binds to the plasma membrane and disrupts its structure and permeability properties.
Metabolic Antagonism	
Sulfonamides	Inhibit folic acid synthesis by competition with *p*-aminobenzoic acid.
Trimethoprim	Blocks tetrahydrofolate synthesis through inhibition of the enzyme dihydrofolate reductase.
Dapsone	Interferes with folic acid synthesis.
Isoniazid	May disrupt pyridoxal or NAD metabolism and functioning. Inhibits the synthesis of the mycolic acid "cord factor."

antibiotics inhibit protein synthesis by binding with the procaryotic ribosome. Because these drugs discriminate between procaryotic and eucaryotic ribosomes, their therapeutic index is fairly high, but not as favorable as that of cell wall synthesis inhibitors. Some drugs bind to the 30S (small) subunit, while others attach to the 50S (large) ribosomal subunit. Several different steps in the protein synthesis mechanism can be affected: aminoacyl-tRNA binding, peptide bond formation, mRNA reading, and translocation. For example, fusidic acid binds to EF-G and blocks translocation, whereas mucopirocin inhibits isoleucyl-tRNA synthetase (*see section 12.2*).

The antibacterial drugs that inhibit nucleic acid synthesis or damage cell membranes often are not as selectively toxic as other antibiotics. This is because procaryotes and eucaryotes do not differ

as greatly with respect to nucleic acid synthetic mechanisms or cell membrane structure. Good examples of drugs that affect nucleic acid synthesis or membrane structure are quinolones and polymyxins. Quinolones inhibit the DNA gyrase and thus interfere with DNA replication, repair, and transcription. Polymyxins act as detergents or surfactants and disrupt the bacterial plasma membrane.

Several valuable drugs act as **antimetabolites:** they block the functioning of metabolic pathways by competitively inhibiting the use of metabolites by key enzymes. Sulfonamides and several other drugs inhibit folic acid metabolism. Sulfonamides (e.g., sulfanilamide, sulfamethoxazole, and sulfacetamide) have a high therapeutic index because humans cannot synthesize folic acid and must obtain it in their diet. Most bacterial pathogens synthesize their own folic acid and are therefore susceptible to inhibitors of folate metabolism. Antimetabolite drugs also can inhibit other pathways. For example, isoniazid interferes with either pyridoxal or NAD metabolism.

1. Give five ways in which chemotherapeutic agents kill or damage bacterial pathogens.
2. What are antimetabolites?

35.5 Factors Influencing the Effectiveness of Antimicrobial Drugs

It is crucial to recognize that drug therapy is not a simple matter. Drugs may be administered in several different ways, and they do not always spread rapidly throughout the body or immediately kill all invading pathogens. A complex array of factors influence the effectiveness of drugs.

First, the drug must actually be able to reach the site of infection. The mode of administration plays an important role. A drug such as penicillin G is not suitable for oral administration because it is relatively unstable in stomach acid. Some antibiotics—for example, gentamicin and other aminoglycosides—are not well absorbed from the intestinal tract and must be injected intramuscularly or given intravenously. Other antibiotics (neomycin, bacitracin) are applied topically to skin lesions. Nonoral routes of administration often are called **parenteral routes.** Even when an agent is administered properly, it may be excluded from the site of infection. For example, blood clots or necrotic tissue can protect bacteria from a drug, either because body fluids containing the agent may not easily reach the pathogens or because the agent is absorbed by materials surrounding it.

Second, the pathogen must be susceptible to the drug. Bacteria in abscesses may be dormant and therefore resistant to chemotherapy, because penicillins and many other agents affect pathogens only if they are actively growing and dividing. A pathogen, even though growing, may simply not be susceptible to a particular agent. For example, penicillins and cephalosporins, which inhibit cell wall synthesis (table 35.4), do not harm mycoplasmas, which lack cell walls.

Third, the chemotherapeutic agent must exceed the pathogen's MIC value if it is going to be effective. The concentration reached will depend on the amount of drug administered, the route of administration and speed of uptake, and the rate at which the drug is cleared or eliminated from the body. It makes sense that a drug will remain at high concentrations longer if it is absorbed over a long period and excreted slowly.

Finally, chemotherapy has been rendered a less effective and much more complex matter by the spread of drug resistance plasmids. The nature of drug resistance is dealt with later in this chapter.

1. Briefly discuss the factors that influence the effectiveness of antimicrobial drugs.
2. What is parenteral administration of a drug?

35.6 Antibacterial Drugs

With the background provided by the preceding introduction to chemotherapy, a few of the more important chemotherapeutic agents can be briefly described. Tables 35.1 and 35.4 summarize the properties and mechanism of action of a variety of drugs.

Sulfonamides or Sulfa Drugs

A good way to inhibit or kill pathogens is by use of compounds that are **structural analogues,** molecules structurally similar to metabolic intermediates. These analogues compete with metabolites in metabolic processes because of their similarity, but are just different enough so that they cannot function normally in cellular metabolism. The first antimetabolites to be used successfully as chemotherapeutic agents were the sulfonamides, discovered by G. Domagk. **Sulfonamides** or sulfa drugs are structurally related to sulfanilamide, an analogue of *p*-aminobenzoic acid (**figures 35.3** and **35.4**). The latter substance is used in the synthesis of the cofactor folic acid.

When sulfanilamide or another sulfonamide enters a bacterial cell, it competes with *p*-aminobenzoic acid for the active site of an enzyme involved in folic acid synthesis, and the folate concentration decreases. The decline in folic acid is detrimental to the bacterium because folic acid is essential to the synthesis of purines and pyrimidines, the bases used in the construction of DNA, RNA, and other important cell constituents. The resulting inhibition of purine and pyrimidine synthesis leads to cessation of bacterial growth or death of the pathogen. Sulfonamides are selectively toxic for many pathogens because these bacteria manufacture their own folate and cannot effectively take up the cofactor. In contrast, humans cannot synthesize folate and must obtain it in the diet; therefore sulfonamides will not affect the host. Sulfonamides and the competitive inhibition of enzymes (p. 164); Purine and pyrimidine structure and synthesis (pp. 216–18)

The effectiveness of sulfonamides is limited by the increasing sulfonamide resistance of many bacteria. Furthermore, as many as 5% of the patients receiving sulfa drugs experience adverse side effects, chiefly in the form of allergic responses (fever, hives, and rashes).

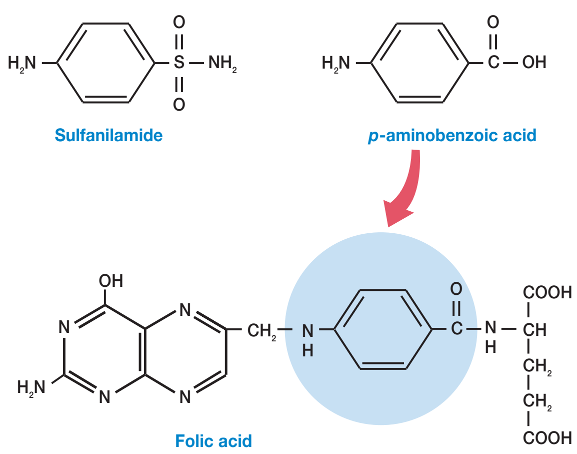

Figure 35.3 Sulfanilamide. Sulfanilamide and its relationship to the structure of folic acid.

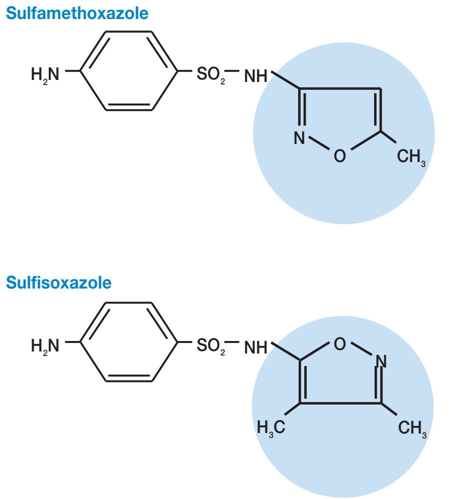

Figure 35.4 Two Modern Sulfonamide Drugs. The shaded areas are side chains substituted for a hydrogen in sulfanilamide (figure 35.3).

Nalidixic acid

Norfloxacin

Ciprofloxacin

Figure 35.5 Quinolone Antimicrobial Agents. Ciprofloxacin and norfloxacin are newer generation fluoroquinolones. The 4-quinolone ring in nalidixic acid has been numbered.

Quinolones

A second group of synthetic antimicrobial agents are increasingly used to treat a wide variety of infections. The **quinolones** are synthetic drugs that contain the 4-quinolone ring. The first quinolone, nalidixic acid (**figure 35.5**), was synthesized in 1962. More recently a family of fluoroquinolones has been produced. Three of these—ciprofloxacin, norfloxacin, and ofloxacin—are currently used in the United States, and more fluoroquinolones are being synthesized and tested. Quinolones are effective when administered orally. They sometimes cause adverse side effects, particularly gastrointestinal upset.

Quinolones act by inhibiting the bacterial DNA gyrase or topoisomerase II, probably by binding to the DNA gyrase complex. This enzyme introduces negative twists in DNA and helps separate its strands (**figure 35.6**). DNA gyrase inhibition disrupts DNA replication and repair, transcription, bacterial chromosome separation during division, and other cell processes involving DNA. Fluoroquinolones also inhibit topoisomerase IV, another enzyme that untangles DNA during replication. It is not surprising that quinolones are bactericidal. The mechanism of DNA replication (pp. 236–39)

The quinolones are broad-spectrum drugs. They are highly effective against enteric bacteria such as *E. coli* and *Klebsiella pneumoniae.* They can be used with *Haemophilus, Neisseria, Pseudomonas aeruginosa,* and other gram-negative pathogens. The quinolones also are active against gram-positive bacteria such as *Staphylococcus aureus, Streptococcus pyogenes,* and *Mycobacterium tuberculosis.* Currently they are used in treating urinary tract infections, sexually transmitted diseases caused by *Neisseria* and *Chlamydia,* gastrointestinal infections, respiratory tract infections, skin infections, and osteomyelitis.

Penicillins

Penicillin G or benzylpenicillin, the first antibiotic to be widely used in medicine, has the structural properties characteristic of

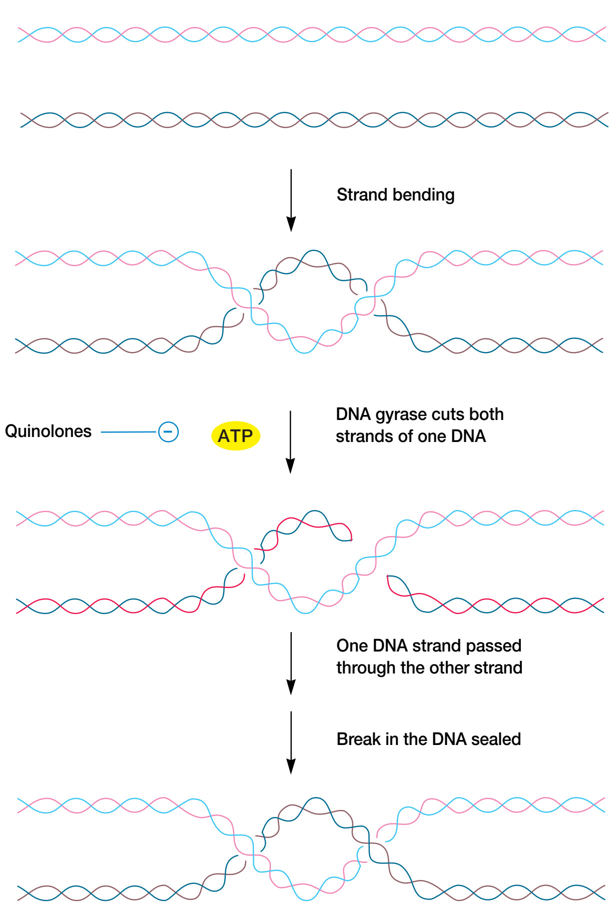

Figure 35.6 DNA Gyrase Action and Quinolone Inhibition.

the penicillin family (**figure 35.7**). Most **penicillins** are derivatives of 6-aminopenicillanic acid and differ from one another only with respect to the side chain attached to its amino group. The most crucial feature of the molecule is the β-lactam ring, which appears to be essential for activity. **Penicillinase,** the enzyme synthesized by many penicillin-resistant bacteria, destroys penicillin activity by hydrolyzing a bond in this ring (figure 35.7).

The mechanism of action of penicillins is still not completely known. Their structures do resemble that of the terminal D-alanyl-D-alanine found on the peptide side chain of the peptidoglycan subunit. It has been proposed that penicillins inhibit the enzyme catalyzing the transpeptidation reaction because of their structural similarity, which would block the synthesis of a complete, fully cross-linked peptidoglycan and lead to osmotic lysis. The mechanism is consistent with the observation that penicillins act only on growing bacteria that are synthesizing new peptidoglycan. However, more recently it has been discovered that penicillins bind to several penicillin-binding proteins and may destroy bacteria by activating their own autolytic enzymes. There now is some evidence that penicillin kills bacteria even in the absence of autolysins or murein hydrolases. Lysis could occur after bacterial viability has already been lost. Penicillin may stimulate special proteins called bacterial holins to form holes or lesions in the plasma membrane. This would directly lead to membrane leakage and death; murein hydrolases also could move through the holes, disrupt the peptidoglycan, and lyse the cell. Apparently the mechanism of penicillin action is more complex than previously imagined. Bacterial peptidoglycan structure (pp. 56–57); Peptidoglycan synthesis (pp. 221–22)

Penicillins differ from each other in several ways. Penicillin G is effective against gonococci, meningococci, and several gram-positive pathogens such as streptococci and staphylococci (**table 35.5**), but it must be administered parenterally because it is destroyed by stomach acid. Penicillin V is similar to penicillin G, but it is more acid resistant and can be given orally. Ampicillin can be administered orally and has a broader spectrum of activity as it is effective against gram-negative bacteria such as *Haemophilus, Salmonella,* and *Shigella.* Carbenicillin and ticarcillin also are broad spectrum and particularly potent against *Pseudomonas* and *Proteus.*

An increasing number of bacteria are penicillin resistant. Penicillinase-resistant penicillins such as methicillin (figure 35.7), nafcillin, and oxacillin are frequently employed against these bacterial pathogens.

Although penicillins are the least toxic of the antibiotics, about 1 to 5% of the adults in the United States are allergic to them. Occasionally a person will die of a violent allergic response; therefore patients should be questioned about penicillin allergies before treatment is begun.

Cephalosporins

Cephalosporins are a family of antibiotics originally isolated in 1948 from the fungus *Cephalosporium,* and their β-lactam structure is very similar to that of the penicillins (**figure 35.8**). As might be expected from their structural similarities, cephalosporins resemble penicillins in inhibiting the transpeptidation reaction during peptidoglycan synthesis. They are broad-spectrum drugs frequently given to patients with penicillin allergies.

Many cephalosporins are in use. There are three groups or generations of these drugs that differ in their spectrum of activity (figure 35.8). First-generation cephalosporins are more effective against gram-positive than gram-negative pathogens. Second-generation drugs act against many gram-negative as well as gram-positive pathogens. Third-generation drugs are particularly effective against gram-negative pathogens, and often also reach the central nervous system.

Most cephalosporins (including cephalothin, cefoxitin, ceftriaxone, and cefoperazone) are administered parenterally. Cefoperazone is resistant to destruction by β-lactamases and effective against many gram-negative bacteria, including *Pseudomonas aeruginosa.* Cephalexine and cefixime are given orally rather than by injection.

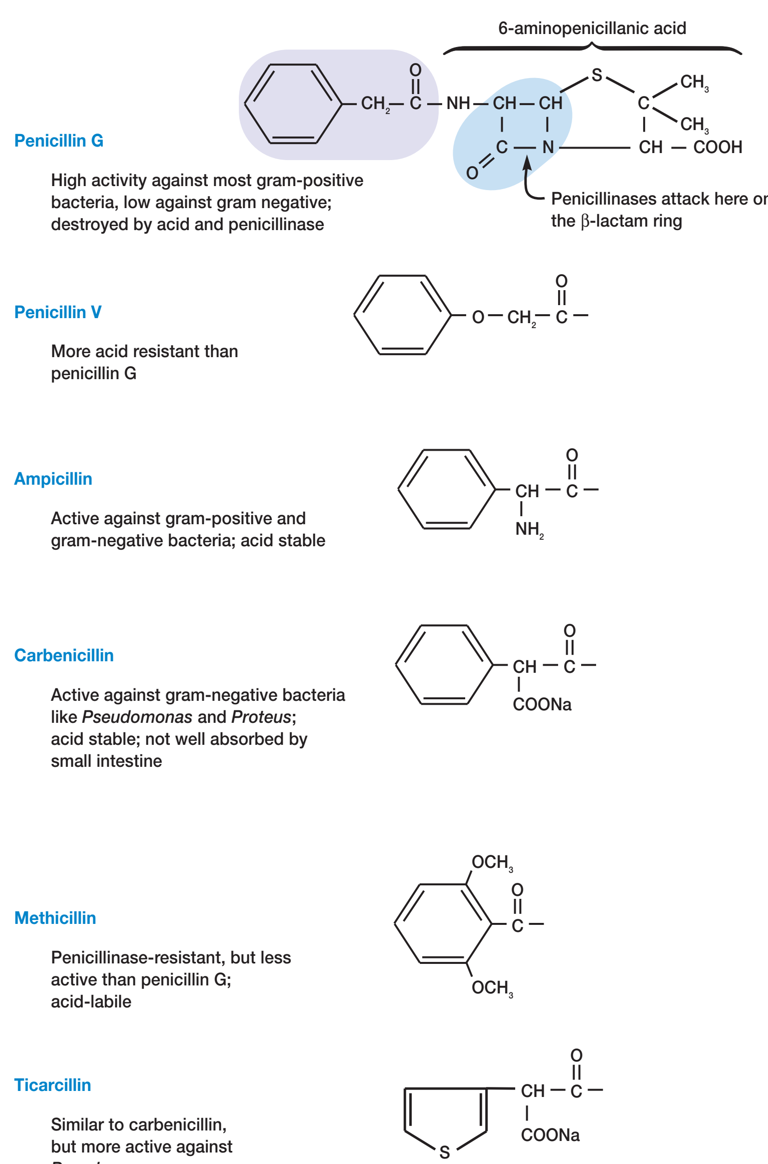

Figure 35.7 Penicillins. The structures and characteristics of representative penicillins. All are derivatives of 6-aminopenicillanic acid; in each case the purple shaded portion of penicillin G is replaced by the side chain indicated. The β-lactam ring is also shaded (blue), and an arrow points to the bond that is hydrolyzed by penicillinase.

The Tetracyclines

The **tetracyclines** are a family of antibiotics with a common four-ring structure to which a variety of side chains are attached (**figure 35.9**). Oxytetracycline and chlortetracycline are naturally produced by some species of the actinomycete genus *Streptomyces;* others are semisynthetic drugs. These antibiotics inhibit protein synthesis by combining with the small (30S) subunit of the ribosome and inhibiting the binding of aminoacyl-tRNA molecules to the ribosomal A site. Because their action is only bacteriostatic, the effectiveness of treatment depends on active host resistance to the pathogen. The mechanism of protein synthesis (pp. 265–72)

Figure 35.8 Cephalosporin Antibiotics. These drugs are derivatives of 7-aminocephalosporanic acid and contain a β-lactam ring.

Tetracycline (chlortetracycline, doxycycline)

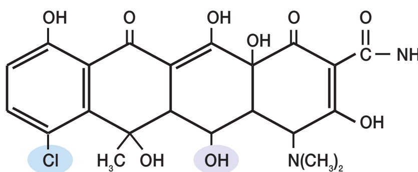

Figure 35.9 Tetracyclines. Three members of the tetracycline family. Tetracycline lacks both of the groups that are shaded. Chlortetracycline (aureomycin) differs from tetracycline in having a chlorine atom (blue); doxycycline consists of tetracycline with an extra hydroxyl (purple).

Tetracyclines are broad-spectrum antibiotics active against gram-negative bacteria, gram-positive bacteria, rickettsias, chlamydiae, and mycoplasmas. High doses may result in nausea, diarrhea, yellowing of teeth in children, and damage to the liver and kidneys.

Aminoglycoside Antibiotics

There are several important **aminoglycoside antibiotics. Streptomycin,** kanamycin, neomycin, and tobramycin are synthesized by *Streptomyces,* whereas gentamicin comes from a related bacterium, *Micromonospora purpurea.* Although there is considerable variation in structure among the different aminoglycosides, all contain a cyclohexane ring and amino sugars (**figure 35.10**). Aminoglycosides bind to the small ribosomal subunit and interfere with protein synthesis in at least two ways. They directly inhibit protein synthesis and also cause misreading of the genetic message carried by mRNA.

The aminoglycosides are bactericidal and tend to be most active against gram-negative pathogens. Streptomycin's usefulness has decreased greatly due to widespread drug resistance, but it is still effective against tuberculosis and plague. Gentamicin is used to treat *Proteus, Escherichia, Klebsiella,* and *Serratia* infections. Aminoglycosides are quite toxic and can cause deafness, renal damage, loss of balance, nausea, and allergic responses.

Streptomycin

Gentamicin C_{1a}

Figure 35.10 Representative Aminoglycoside Antibiotics.

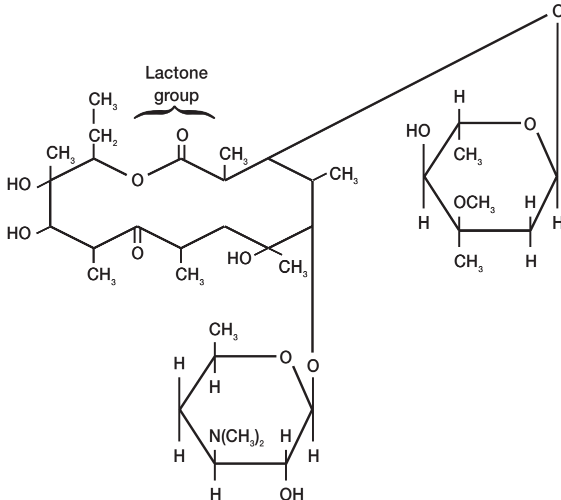

Figure 35.11 Erythromycin, a Macrolide Antibiotic. The 14-member lactone ring is connected to two sugars.

Erythromycin and Other Macrolides

Erythromycin, the most frequently used **macrolide antibiotic,** is synthesized by *Streptomyces erythraeus.* The macrolides contain a 12- to 22-carbon lactone ring linked to one or more sugars (**figure 35.11**). Erythromycin is usually bacteriostatic and binds with the 23S rRNA of the 50S ribosomal subunit to inhibit peptide chain elongation during protein synthesis.

Erythromycin is a relatively broad-spectrum antibiotic effective against gram-positive bacteria, mycoplasmas, and a few gram-negative bacteria. It is used with patients allergic to penicillins and in the treatment of whooping cough, diphtheria, diarrhea caused by *Campylobacter,* and pneumonia from *Legionella* or *Mycoplasma* infections.

Newer macrolides are now in use. Clindamycin is effective against a variety of bacteria including staphylococci and anaerobes such as *Bacteroides.* Azithromycin is particularly effective against *Chlamydia trachomatis.*

Vancomycin and Teicoplanin

Vancomycin is a glycopeptide antibiotic produced by *Streptomyces orientalis.* It is a cup-shaped molecule composed of a peptide linked to a disaccharide. The antibiotic blocks peptidoglycan synthesis by inhibiting the transpeptidation step that cross-links adjacent peptidoglycan strands. The resulting peptidoglycan is mechanically weak and the cells osmotically lyse. Vancomycin's peptide portion binds specifically to the D-alanine-D-alanine terminal sequence on the pentapeptide portion of peptidoglycan. This complex blocks transpeptidase action.

The antibiotic is bactericidal for *Staphylococcus* and some members of the genera *Clostridium, Bacillus, Streptococcus,* and *Enterococcus.* It is given both orally and intravenously, and has been particularly important in the treatment of antibiotic resistant staphylococcal and enterococcal infections. Vancomycin-resistant strains of *Enterococcus* have become widespread and recently a few cases of resistant *Staphylococcus aureus* have appeared.

Figure 35.12 Chloramphenicol.

Teicoplanin is a glycopeptide antibiotic from *Actinoplanes teichomyceticus* that is similar in structure and mechanism of action to vancomycin. It is active against staphylococci, enterococci, streptococci, clostridia, *Listeria,* and many other gram-positive pathogens. This antibiotic presently is used in Europe and elsewhere, but not in the United States.

Chloramphenicol

Although **chloramphenicol** (**figure 35.12**) was first produced from cultures of *Streptomyces venezuelae,* it is now made through chemical synthesis. Like erythromycin, chloramphenicol binds to 23S rRNA on the 50S ribosomal subunit. It inhibits the peptidyl transferase and is bacteriostatic.

This antibiotic has a very broad spectrum of activity but unfortunately is quite toxic. One may see allergic responses or neurotoxic reactions. The most common side effect is a temporary or permanent depression of bone marrow function, leading to aplastic anemia and a decreased number of blood leukocytes. Chloramphenicol is used only in life-threatening situations when no other drug is adequate.

Box 35.2

Antibiotic Misuse and Drug Resistance

The sale of antimicrobial drugs is big business. In the United States millions of pounds of antibiotics valued at billions of dollars are produced annually. Approximately 40 to 50% of these antibiotics are added to livestock feed.

Because of the massive quantities of antibiotics being prepared and used, an increasing number of diseases are resisting treatment due to the spread of drug resistance. A good example is *Neisseria gonorrhoeae,* the causative agent of gonorrhea. Gonorrhea was first treated successfully with sulfonamides in 1936, but by 1942 most strains were resistant and physicians turned to penicillin. Within 16 years a penicillin-resistant strain had emerged in the Far East. A penicillinase-producing gonococcus reached the United States in 1976 and is still spreading in this country.

In late 1968 an epidemic of dysentery caused by *Shigella* broke out in Guatemala and affected at least 112,000 persons; 12,500 deaths resulted. The strains responsible for this devastation carried an R plasmid giving them resistance to chloramphenicol, tetracycline, streptomycin, and sulfonamide. In 1972 a typhoid epidemic swept through Mexico producing 100,000 infections and 14,000 deaths. It was due to a *Salmonella typhi* strain with the same multiple drug-resistance pattern seen in the previous *Shigella* outbreak.

Haemophilus influenzae type b is responsible for many cases of childhood pneumonia and middle ear infections, as well as respiratory infections and meningitis. It is now becoming increasingly resistant to tetracyclines, ampicillin, and chloramphenicol. The same situation is occurring with *Streptococcus pneumoniae.*

In 1946 almost all strains of *Staphylococcus* were penicillin sensitive. Today most hospital strains are resistant to penicillin G, and some are now also resistant to methicillin and/or gentamicin and only can be treated with vancomycin. Some strains of *Enterococcus* have become resistant to most antibiotics, including vancomycin. Recently a few cases of vancomycin-resistant *S. aureus* have been reported in the United States and Japan. At present these strains are only intermediately resistant to vancomycin. If full vancomycin resistance develops and spreads, *S. aureus* may become untreatable.

It is clear from these and other examples (e.g., multiresistant *Mycobacterium tuberculosis*) that drug resistance is an extremely serious public health problem. Much of the difficulty arises from drug misuse. Drugs frequently have been overused in the past. It has been estimated that over 50% of the antibiotic prescriptions in hospitals are given without clear evidence of infection or adequate medical indication. Many physicians have administered antibacterial drugs to patients with colds, influenza, viral pneumonia, and other viral diseases. A recent study showed that over 50% of the patients diagnosed with colds and upper respiratory infections and 66% of those with chest colds (bronchitis) are given antibiotics, even though over 90% of these cases are caused by viruses. Frequently antibiotics are prescribed without culturing and identifying the pathogen or without determining bacterial sensitivity to the drug. Toxic, broad-spectrum antibiotics are sometimes given in place of narrow-spectrum drugs as a substitute for culture and sensitivity testing, with the consequent risk of dangerous side effects, superinfections, and the selection of drug-resistant mutants. The situation is made worse by patients not completing their course of medication. When antibiotic treatment is ended too early, drug-resistant mutants may survive. Drugs are available to the public in many countries; people may practice self-administration of antibiotics and further increase the prevalence of drug-resistant strains.

The use of antibiotics in animal feeds is undoubtedly another contributing factor to increasing drug resistance. The addition of low levels of antibiotics to livestock feeds does raise the efficiency and rate of weight gain in cattle, pigs, and chickens (partially because of infection control in overcrowded animal populations). However, this also increases the number of drug-resistant bacteria in animal intestinal tracts. There is evidence for the spread of bacteria such as *Salmonella* from animals to human populations. In 1983, 18 people in four midwestern states were infected with a multiple-drug-resistant strain of *Salmonella newport.* Eleven were hospitalized for salmonellosis and one died. All 18 patients had recently been infected by eating hamburger from beef cattle fed subtherapeutic doses of chlortetracycline for growth promotion. Resistance to some antibiotics has been traced to the use of specific farmyard antibiotics. Avoparcin resembles vancomycin in structure, and virginiamycin resembles Synercid. There is good circumstantial evidence that extensive use of these two antibiotics in animal feed has led to an increase in vancomycin and Synercid resistance among enterococci. The use of the quinolone antibiotic enrofloxacin in swine herds appears to have promoted ciprofloxacin resistance in pathogenic strains of *Salmonella.* Elimination of antibiotic food supplements might well aid in slowing the spread of drug resistance.

The spread of antibiotic resistance can be due to quite subtle factors. For example, products such as soap and deodorants often now contain triclosan and other germicides. There is increasing evidence that the widespread use of triclosan actually favors an increase in antibiotic resistance (*see section 7.5*).

1. For each class of antibacterial drugs presented, give the following information: general chemical composition or structure, mechanism of action, behavioral properties (cidal or static, broad spectrum or narrow spectrum), route of administration and therapeutic uses, significant problems with side effects, and drug resistance.
2. Define structural analogue, 6-aminopenicillanic acid, penicillinase, aminoglycoside, and macrolide.

35.7 Drug Resistance

The spread of drug-resistant pathogens is one of the most serious threats to the successful treatment of microbial disease (**Box 35.2**). This section describes the ways in which bacteria acquire drug resistance and how resistance spreads within a bacterial population.

Mechanisms of Drug Resistance

Bacteria become drug resistant in several different ways. It should be noted at the beginning that a particular type of resistance mechanism

is not confined to a single class of drugs. Two bacteria may use different resistance mechanisms to withstand the same chemotherapeutic agent. Furthermore, resistant mutants arise spontaneously and are then selected. Mutants are not created directly by exposure to a drug.

Pathogens often become resistant simply by preventing entrance of the drug. Many gram-negative bacteria are unaffected by penicillin G because it cannot penetrate the envelope's outer membrane. Changes in penicillin binding proteins also render a cell resistant. A decrease in permeability can lead to sulfonamide resistance. Mycobacteria resist many drugs because of the high content of mycolic acids (*see p. 543*) in a complex lipid layer outside their peptidoglycan. This layer is impermeable to most drugs.

A second resistance strategy is to pump the drug out of the cell after it has entered. Some pathogens have plasma membrane translocases, often called efflux pumps, that expel drugs. Because they are relatively nonspecific and can pump many different drugs, these transport proteins often are called multidrug-resistance pumps. Many are drug/proton antiporters—that is, protons enter the cell as the drug leaves. Such systems are present in *E. coli, Pseudomonas aeruginosa, Mycobacterium smegmatis,* and *Staphylococcus aureus.*

Many bacterial pathogens resist attack by inactivating drugs through chemical modification. The best-known example is the hydrolysis of the β-lactam ring of many penicillins by the enzyme penicillinase. Drugs also are inactivated by the addition of groups. Resistant organisms may phosphorylate or acetylate aminoglycosides and acetylate chloramphenicol.

Because each chemotherapeutic agent acts on a specific target, resistance arises when the target enzyme or organelle is modified so that it is no longer susceptible to the drug. For example, the affinity of ribosomes for erythromycin and chloramphenicol can be decreased by a change in the 23S rRNA to which they bind. Enterococci become resistant to vancomycin by changing the terminal D-alanine-D-alanine in their peptidoglycan to a D-alanine-D-lactate. This drastically reduces antibiotic binding. The effects of antimetabolites may be resisted through alteration of susceptible enzymes. In sulfonamide-resistant bacteria the enzyme that uses *p*-aminobenzoic acid during folic acid synthesis (the tetrahydropteroic acid synthetase) often has a much lower affinity for sulfonamides. *Mycobacterium tuberculosis* becomes resistant to the drug rifampin due to mutations that alter the β subunit of its RNA polymerase. Rifampin cannot bind to the mutant RNA polymerase and block the initiation of transcription.

Resistant bacteria may either use an alternate pathway to bypass the sequence inhibited by the agent or increase the production of the target metabolite. For example, some bacteria are resistant to sulfonamides simply because they use preformed folic acid from their surroundings rather than synthesize it themselves. Other strains increase their rate of folic acid production and thus counteract sulfonamide inhibition.

The Origin and Transmission of Drug Resistance

The genes for drug resistance are present on both the bacterial chromosome and **plasmids,** small DNA molecules that can exist separate from the chromosome or be integrated in it. Plasmids (pp. 294–97)

Spontaneous mutations in the bacterial chromosome, although they do not occur very often, will make bacteria drug resistant. Usually such mutations result in a change in the drug receptor; therefore the antibiotic cannot bind and inhibit (e.g., the streptomycin receptor protein on bacterial ribosomes). Many mutants are probably destroyed by natural host resistance mechanisms. However, when a patient is being treated extensively with antibiotics, some resistant mutants may survive and flourish because of their competitive advantage over nonresistant strains.

Frequently a bacterial pathogen is drug resistant because it has a plasmid bearing one or more resistance genes; such plasmids are called **R plasmids** (*r*esistance plasmids). Plasmid resistance genes often code for enzymes that destroy or modify drugs; for example, the hydrolysis of penicillin or the acetylation of chloramphenicol and aminoglycoside drugs. Plasmid-associated genes have been implicated in resistance to the aminoglycosides, choramphenicol, penicillins and cephalosporins, erythromycin, tetracyclines, sulfonamides, and others. Once a bacterial cell possesses an R plasmid, the plasmid may be transferred to other cells quite rapidly through normal gene exchange processes such as conjugation, transduction, and transformation. Because a single plasmid may carry genes for resistance to several drugs, a pathogen population can become resistant to several antibiotics simultaneously, even though the infected patient is being treated with only one drug. Conjugation (pp. 302–5); Transduction (pp. 307–9); Transformation (pp. 305–7)

Extensive drug treatment favors the development and spread of antibiotic-resistant strains because the antibiotic destroys normal, susceptible bacteria that would usually compete with drug-resistant strains. The result may be the emergence of drug-resistant pathogens leading to a **superinfection.** Superinfections are a significant problem because of the existence of multiple-drug-resistant bacteria that often produce drug-resistant respiratory and urinary tract infections. A classic example of a superinfection resulting from antibiotic administration is the disease pseudomembranous enterocolitis caused by *Clostridium difficile.* When a patient is treated with clindamycin, ampicillin, or cephalosporin, many intestinal bacteria are killed, but *C. difficile* is not. This intestinal inhabitant, which is normally a minor constituent of the population, flourishes in the absence of competition and produces a toxin that stimulates the secretion of a pseudomembrane by intestinal cells. If the superinfection is not treated early with vancomycin, the pseudomembrane must be surgically removed or the patient will die. Fungi, such as the yeast *Candida albicans,* also produce superinfections when bacterial competition is eliminated by antibiotics.

Several strategies can be employed to discourage the emergence of drug resistance. The drug can be given in a high enough concentration to destroy susceptible bacteria and most spontaneous mutants that might arise during treatment. Sometimes two different drugs can be administered simultaneously with the hope that each drug will prevent the emergence of resistance to the other. Finally, chemotherapeutic drugs, particularly broad-spectrum drugs, should be used only when definitely necessary. If possible, the pathogen should be identified, drug sensitivity tests run, and the proper narrow-spectrum drug employed.

Despite efforts to control the emergence and spread of drug resistance, the situation continues to worsen. Of course, as mentioned previously, antibiotics should be used in ways that reduce the development of resistance. Another approach is to search for new antibiotics that microorganisms have never encountered (*see Box 29.1*). Pharmaceutical companies collect and analyze samples from around the world in a search for completely new antimicrobial agents. Structure-based or rational drug design is a third option. If the three-dimensional structure of a susceptible target molecule such as an enzyme essential to microbial function is known, computer programs can be used to design drugs that precisely fit the target molecule. These drugs might be able to bind to the target and disrupt its function sufficiently to destroy the pathogen. Pharmaceutical companies are using this approach to attempt to develop drugs for the treatment of AIDS, cancer, and the common cold. At least one company is developing "enhancers." These are cationic peptides that disrupt bacterial membranes by displacing their magnesium ions. Antibiotics then penetrate and rapidly exert their effects. Other pharmaceutical companies are developing efflux-pump inhibitors to administer with antibiotics and prevent their expulsion by the resistant pathogen.

There has been some recent progress in developing new antibiotics that are effective against drug-resistant pathogens. Two new drugs are fairly effective against vancomycin-resistant enterococci. Synercid is a mixture of the streptogramin antibiotics quinupristin and dalfopristin that inhibits protein synthesis. A second drug, linezolid (Zyvox), is the first drug in a new family of antibiotics, the oxazolidinones. It inhibits protein synthesis and is active against both vancomycin-resistant enterococci and methicillin-resistant *Staphylococcus aureus.*

A most interesting response to the current crisis is the renewed interest in an idea first proposed early in the twentieth century by Felix d'Herelle, one of the discoverers of bacterial viruses or bacteriophages (*see p. 363*). d'Herelle proposed that bacteriophages could be used to treat bacterial diseases. Although most microbiologists did not pursue his proposal actively due to technical difficulties and the advent of antibiotics, Russian scientists developed the medical use of bacteriophages. Currently Russian physicians use bacteriophages to treat many bacterial infections. Bandages are saturated with phage solutions, phage mixtures are administered orally, and phage preparations are given intravenously to treat *Staphylococcus* infections. Three American companies are actively conducting research on phage therapy and preparing to carry out clinical trials. Bacteriophages (chapter 17)

1. Briefly describe the five major ways in which bacteria become resistant to drugs and give an example of each.
2. Define plasmid, R plasmid, and superinfection. How are R plasmids involved in the spread of drug resistance?

35.8 Antifungal Drugs

Treatment of fungal infections generally has been less successful than that of bacterial infections largely because eucaryotic fungal cells are much more similar to human cells than are bacteria. Many drugs that inhibit or kill fungi are therefore quite toxic for humans. In addition, most fungi have a detoxification system that modifies many antibiotics, probably by hydroxylation. As a result the added antibiotics are fungistatic only as long as repeated application maintains high levels of unmodified antibiotic. Despite their relatively low therapeutic index, a few drugs are useful in treating many major fungal diseases. Effective antifungal agents frequently either extract membrane sterols or prevent their synthesis. Similarly, because animal cells do not have cell walls, the enzyme chitin synthase is the target for fungal-active antibiotics such as polyoxin D and nikkomycin.

Fungal infections are often subdivided into infections of superficial tissues or superficial mycoses and systemic mycoses. Treatment for these two types of disease is very different. Several drugs are used to treat superficial mycoses. Three drugs containing imidazole—miconazole, ketoconazole (**figure 35.13**), and clotrimazole—are broad-spectrum agents available as creams and solutions for the treatment of dermatophyte infections such as athlete's foot, and oral and vaginal candidiasis (*see chapter 40*). They are thought to disrupt fungal membrane permeability and inhibit sterol synthesis. Tolnaftate is used topically for the treatment of cutaneous infections, but is not as effective against infections of the skin and hair. **Nystatin** (figure 35.13), a polyene antibiotic from *Streptomyces,* is used to control *Candida* infections of the skin, vagina, or alimentary tract. **Griseofulvin** (figure 35.13), an antibiotic formed by *Penicillium,* is given orally to treat chronic dermatophyte infections. It is thought to disrupt the mitotic spindle and inhibit cell division; it also may inhibit protein and nucleic acid synthesis. Side effects of griseofulvin include headaches, gastrointestinal upset, and allergic reactions. Superficial and systemic mycoses (pp. 942–44, 945–48)

Systemic infections are very difficult to control and can be fatal. Three drugs commonly used against systemic mycoses are **amphotericin B,** 5-flucytosine, and fluconazole (figure 35.13). Amphotericin B from *Streptomyces* spp. binds to the sterols in fungal membranes, disrupting membrane permeability and causing leakage of cell constituents. It is quite toxic and used only for serious, life-threatening infections. The synthetic oral antimycotic agent 5-flucytosine (5-fluorocytosine) is effective against most systemic fungi, although drug resistance often develops rapidly. The drug is converted to 5-fluorouracil by the fungi, incorporated into RNA in place of uracil, and disrupts RNA function. Its side effects include skin rashes, diarrhea, nausea, aplastic anemia, and liver damage. Fluconazole is used in the treatment of candidiasis, cryptococcal meningitis, and coccidioidal meningitis. Adverse effects are relatively uncommon.

Just as with antibacterial drugs, overuse of antifungal agents leads to an increase in drug resistance. For example, *Candida* infections are becoming more frequent and drug resistant.

1. Summarize the mechanism of action and the therapeutic use of the following antifungal drugs: miconazole, nystatin, griseofulvin, amphotericin B, and 5-flucytosine.

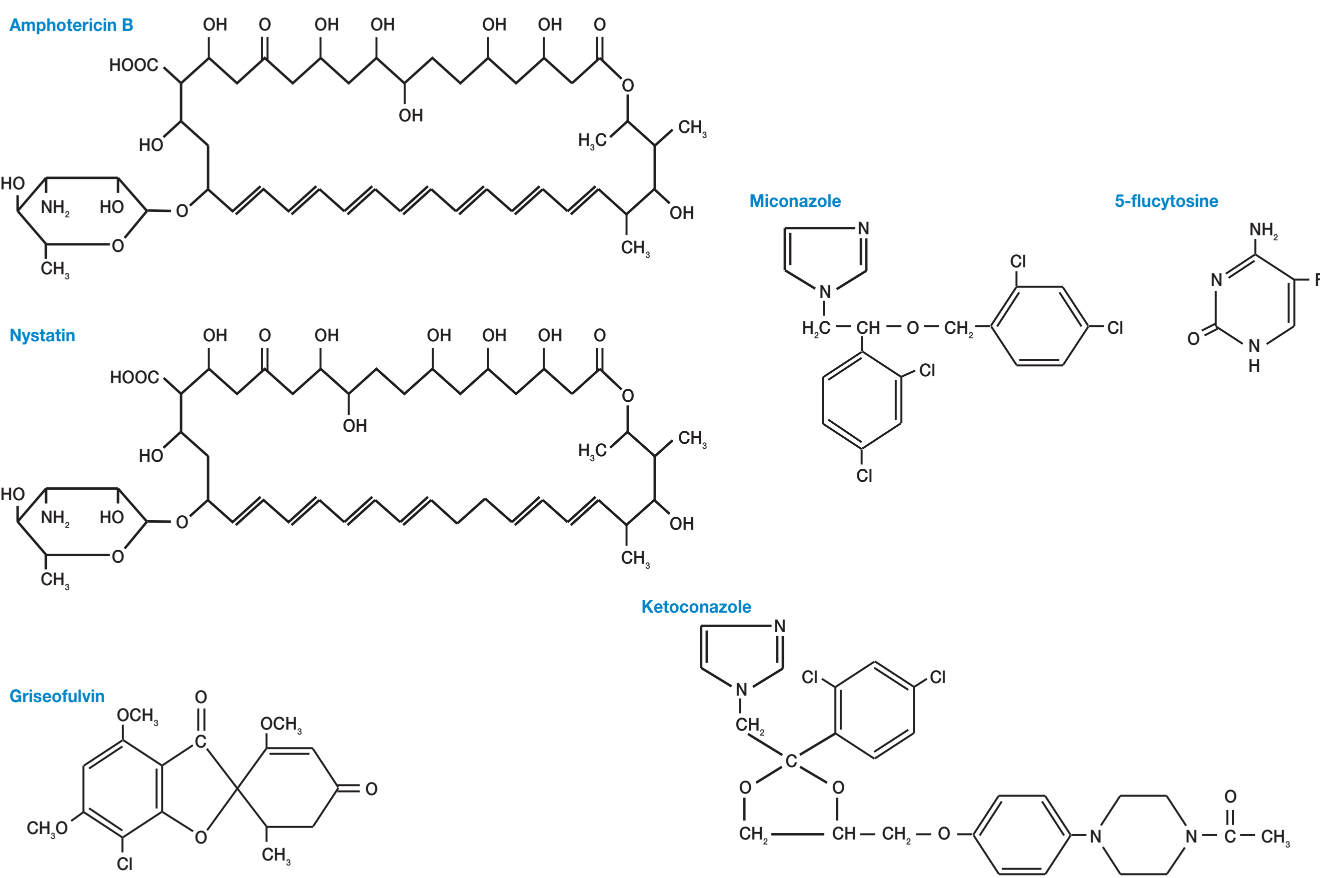

Figure 35.13 Antifungal Drugs. Six commonly used drugs are shown here.

35.9 Antiviral Drugs

For many years the possibility of treating viral infections with drugs appeared remote because viruses enter host cells and make use of host cell enzymes and constituents to a large extent. A drug that would block virus reproduction also was thought to be toxic for the host. Inhibitors of virus-specific enzymes and life cycle processes have now been discovered, and several drugs are used therapeutically. Some important examples are shown in **figure 35.14.** Animal virus life cycles (pp. 399–409)

Most antiviral drugs disrupt either critical stages in the virus life cycle or the synthesis of virus-specific nucleic acids. **Amantadine** and rimantadine can be used to prevent influenza A infections. When given in time, it will reduce the incidence of influenza by 50 to 70% in an exposed population. Amantadine blocks the penetration and uncoating of influenza virus particles (*see section 18.2*). **Adenine arabinoside** or **vidarabine** disrupts the activity of DNA polymerase and several other enzymes involved in DNA and RNA synthesis and function. It is given intravenously or applied as an ointment to treat herpes infections. A third drug, **acyclovir,** is also used in the treatment of herpes infections. Upon phosphorylation, acyclovir resembles deoxy-GTP and inhibits the virus DNA polymerase. Unfortunately acyclovir-resistant strains of herpes are already developing. Effective acyclovir derivatives and relatives are now available. Valacyclovir is an orally administered prodrug form of acyclovir. Ganciclovir, penciclovir, and its oral form famciclovir are effective in treatment of herpesviruses. Another kind of drug, foscarnet, inhibits the virus DNA polymerase in a different way. Foscarnet is an organic analogue of pyrophosphate (figure 35.14) that binds to the polymerase active site and blocks the cleavage of pyrophosphate from nucleoside triphosphate substrates. It is used in treating herpes and cytomegalovirus infections.

Several broad-spectrum anti-DNA virus drugs have been developed. A good example is the drug HPMPC or cidofovir (figure 35.14). It is effective against papovaviruses, adenoviruses, herpesviruses, iridoviruses, and poxviruses. The drug acts on the viral DNA polymerase as a competitive inhibitor and alternative substrate of dCTP. It has been used primarily against cytomegalovirus but also against herpes simplex and human papillomavirus infections.

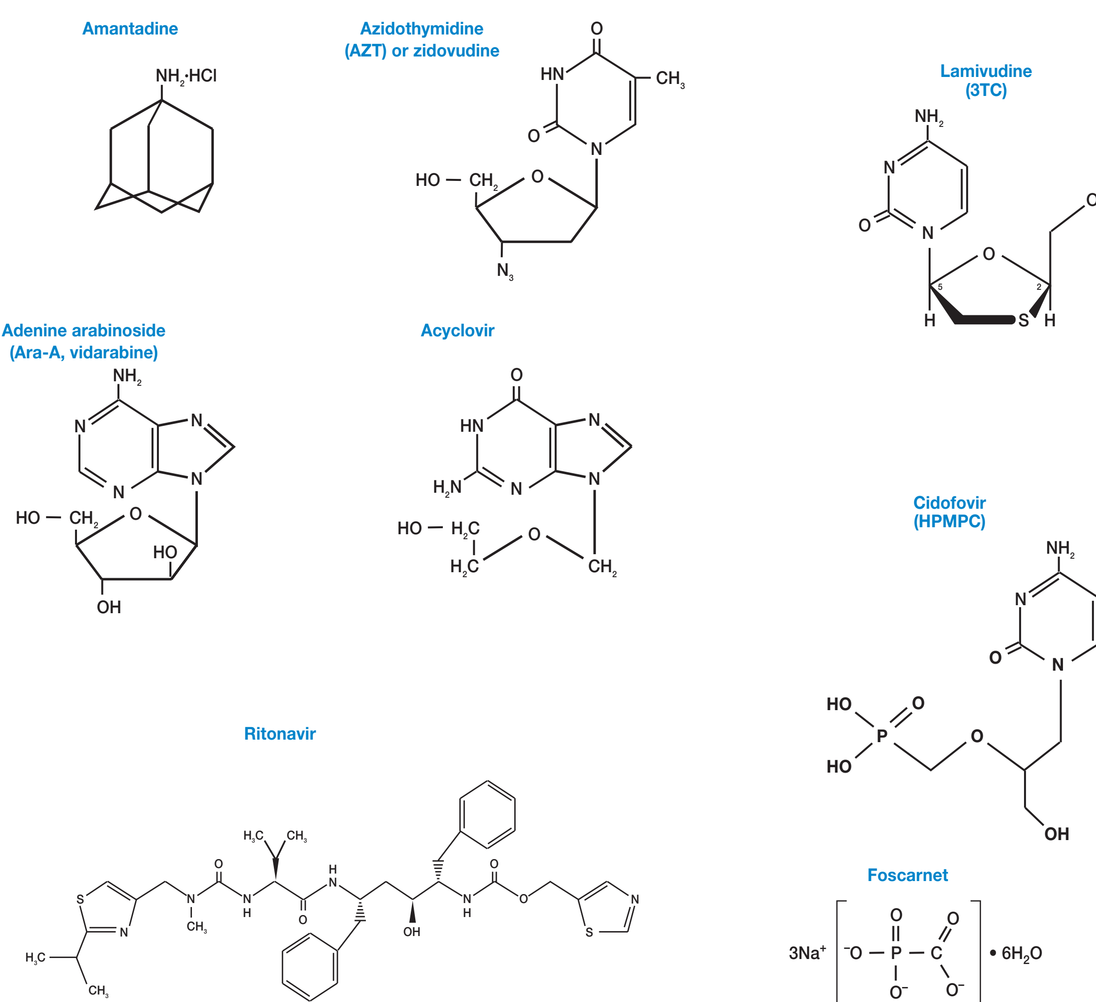

Figure 35.14 Representative Antiviral Drugs.

Research on anti-HIV drugs has been particularly active. Many of the first drugs to be developed were reverse transcriptase inhibitors such as **azidothymidine (AZT)** or **zidovudine,** lamivudine (3TC), didanosine (ddI), zalcitabine (ddC), and stavudine (d4T) (figure 35.14). These interfere with reverse transcriptase activity and therefore block HIV reproduction. More recently **HIV protease inhibitors** have been developed. Three of the most used are saquinvir, indinavir, and ritonavir (figure 35.14). These mimic the peptide bond that is normally attacked by the protease. The most successful treatment regimen involves a cocktail of agents given at high dosages to prevent the development of drug resistance. For example, the combination of AZT, 3TC, and ritonavir is very effective in reducing HIV plasma concentrations almost to zero. However, the treatment does not seem able to eliminate latent proviral HIV DNA that still resides in memory T cells, and possibly elsewhere. The biology and reproduction of HIV (pp. 407, 878–84)

Probably the most publicized antiviral agents are **interferons.** These small proteins, produced by the host, inhibit virus replication and may be clinically useful in the treatment of influenza, hepatitis, herpes, and colds. The mechanism of interferon action is discussed in more detail in *section 31.9.*

1. Describe two different ways in which antiviral drugs disrupt virus reproduction and give an example of each.
2. Briefly summarize the way in which HIV is currently treated and how the two general classes of anti-HIV drugs act.

Summary

1. Chemotherapeutic agents are compounds that destroy pathogenic microorganisms or inhibit their growth and are used in the treatment of disease. Most are antibiotics: microbial products or their derivatives that can kill susceptible microorganisms or inhibit their growth.
2. The modern era of chemotherapy began with Paul Ehrlich's work on drugs against African sleeping sickness and syphilis. Other early pioneers were Gerhard Domagk, Alexander Fleming, Howard Florey, Ernst Chain, Norman Heatley, and Selman Waksman.
3. An effective chemotherapeutic agent must have selective toxicity. A drug with great selective toxicity has a high therapeutic index and usually disrupts a structure or process unique to the pathogen. It has fewer side effects.
4. Antibiotics can be classified in terms of the range of target microorganisms (narrow spectrum versus broad spectrum); their source (natural, semisynthetic, or synthetic); and their general effect (static versus cidal) (**table 35.1**).
5. Antibiotic effectiveness can be estimated through the determination of the minimal inhibitory concentration and the minimal lethal concentration with dilution susceptibility tests. Disk diffusion tests like the Kirby-Bauer test are often used to estimate a pathogen's susceptibility to drugs quickly (**figure 35.2**).
6. Chemotherapeutic agents can damage bacterial pathogens in several ways: inhibition of cell wall synthesis, protein synthesis, or nucleic acid synthesis; disruption of membrane structure; and inhibition of key enzymes (**table 35.4**).
7. A variety of factors can greatly influence the effectiveness of antimicrobial drugs during actual use.
8. Sulfonamides or sulfa drugs resemble *p*-aminobenzoic acid and competitively inhibit folic acid synthesis (**figure 35.3**).
9. Quinolones are a family of bactericidal synthetic drugs that inhibit DNA gyrase and thus inhibit such processes as DNA replication (**figure 35.6**).
10. Members of the penicillin family contain a β-lactam ring and disrupt bacterial cell wall synthesis, resulting in cell lysis (**figure 35.7**). Some, like penicillin G, are usually administered by injection and are most effective against gram-positive bacteria. Others can be given orally (penicillin V), are broad spectrum (ampicillin, carbenicillin), or are penicillinase resistant (methicillin).
11. Cephalosporins are similar to penicillins, and are given to patients with penicillin allergies (**figure 35.8**).
12. Tetracyclines are broad-spectrum antibiotics having a four-ring nucleus with attached groups (**figure 35.9**). They bind to the small ribosomal subunit and inhibit protein synthesis.
13. Aminoglycoside antibiotics like streptomycin and gentamicin bind to the small ribosomal subunit, inhibit protein synthesis, and are bactericidal (**figure 35.10**).
14. Erythromycin is a bacteriostatic macrolide antibiotic that binds to the large ribosomal subunit and inhibits protein synthesis (**figure 35.11**).
15. Vancomycin is a glycopeptide antibiotic that inhibits the transpeptidation reaction during peptidoglycan synthesis. It is used against drug-resistant staphylococci, enterococci, and clostridia.
16. Chloramphenicol is a broad-spectrum, bacteriostatic antibiotic that inhibits protein synthesis (**figure 35.12**). It is quite toxic and used only for very serious infections.
17. Bacteria can become resistant to a drug by excluding it from the cell, pumping the drug out of the cell, enzymatically altering it, modifying the target enzyme or organelle to make it less drug sensitive, and so forth. The genes for drug resistance may be found either on the bacterial chromosome or on a plasmid called an R plasmid.
18. Chemotherapeutic agent misuse fosters the increase and spread of drug resistance, and may lead to superinfections.
19. Because fungi are more similar to human cells than bacteria, antifungal drugs generally have a lower therapeutic index than antibacterial agents and produce more side effects.
20. Superficial mycoses can be treated with miconazole, ketoconazole, clotrimazole, tolnaftate, nystatin, and griseofulvin (**figure 35.13**). Amphotericin B, 5-flucytosine, and fluconazole are used for systemic mycoses.
21. Antiviral drugs interfere with critical stages in the virus life cycle (amantadine, rimantadine, and ritonavir) or inhibit the synthesis of virus-specific nucleic acids (zidovudine, adenine arabinoside, acyclovir) (**figure 35.14**). Interferon proteins inhibit virus replication and may be therapeutically useful in the future.

Key Terms

acyclovir *821*
adenine arabinoside or vidarabine *821*
amantadine *821*
aminoglycoside antibiotic *816*
amphotericin B *820*
antibiotic *806*
antimetabolites *812*
azidothymidine (AZT) *822*
broad-spectrum drugs *808*
cephalosporin *814*
chemotherapeutic agent *806*
chloramphenicol *817*
cidal *808*
dilution susceptibility tests *809*
erythromycin *817*
griseofulvin *820*
HIV protease inhibitors *822*
interferon *822*
Kirby-Bauer method *809*
macrolide antibiotic *817*
minimal inhibitory concentration (MIC) *809*
minimal lethal concentration (MLC) *809*
narrow-spectrum drugs *808*
nystatin *820*
parenteral route *812*
penicillinase *814*
penicillins *814*
plasmids *819*
quinolones *813*
R plasmids *819*
selective toxicity *807*
side effects *808*
static *808*
streptomycin *816*
structural analogues *812*
sulfonamide *812*
superinfection *819*
tetracycline *815*
therapeutic index *807*
vancomycin *817*
zidovudine *822*

Questions for Thought and Review

1. Why do penicillins and cephalosporins have a much higher therapeutic index than most other antibiotics? What are antimetabolites?
2. Would there be any advantage to administering a bacteriostatic agent along with penicillin? Any disadvantage?
3. Why do antifungal drugs have a much lower therapeutic index than do most antibacterial drugs? Why does one often have to apply antifungal medications frequently?
4. What advantages would there be from administering two chemotherapeutic agents simultaneously?
5. Give several ways in which the development of antibiotic-resistant pathogens can be slowed or prevented.

Critical Thinking Questions

1. What advantage might soil bacteria and fungi gain from the synthesis of antibiotics?
2. Why might it be desirable to prepare a variety of semisynthetic antibiotics?
3. Why is it so difficult to find or synthesize effective antiviral drugs?

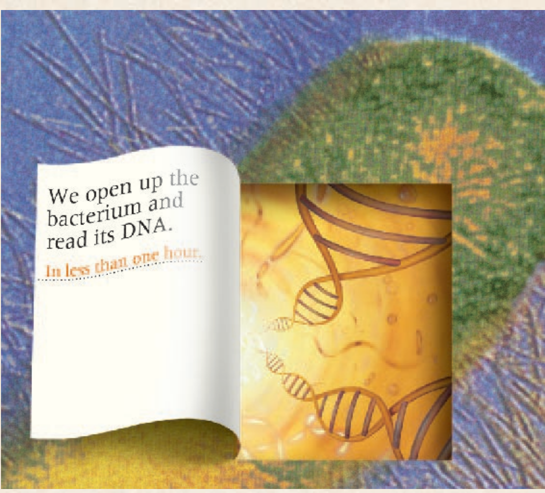
CHAPTER 36

Clinical Microbiology



With microbial infections, time and accuracy in diagnosis are critically important. In clinical microbiology laboratories, new technologies (such as PCR and nucleic acid–based detection methods as shown in this illustration) are now being used with greater frequency to replace older methods of microbial diagnosis due to their increased accuracy and reduced time requirement.

36.4 Computers in Clinical Microbiology 844

Concepts

1. Clinical microbiologists and clinical microbiology laboratories perform many services, all related to the identification and control of microorganisms.
2. Success in clinical microbiology depends on (1) using the proper aseptic technique; (2) correctly obtaining the clinical specimen from the infected patient by swabs, needle aspiration, intubation, or catheters; (3) correctly handling the specimen; and (4) quickly transporting the specimen to the laboratory.
3. Once the clinical specimen reaches the laboratory, it is cultured and identified. Identification measures include microscopy; growth on enrichment, selective, differential, or characteristic media; specific biochemical tests; rapid test methods; immunologic techniques; bacteriophage typing; and molecular methods such as nucleic acid-based detection methods, gas-liquid chromatography, and plasmid fingerprinting.
4. After the microorganism has been isolated, cultured, and/or identified, samples are used in susceptibility tests to find which method of control will be most effective. The results are provided to the physician as quickly as possible.
5. Computer systems in clinical microbiology are designed to speed identification of the pathogen and communication of results back to the physician.

The specimen is the beginning. All diagnostic information from the laboratory depends upon the knowledge by which specimens are chosen and the care with which they are collected and transported.

—*Cynthia A. Needham*

Pathogens, particularly bacteria and yeasts, coexist with harmless microorganisms on or in the host. These pathogens must be properly identified as the actual cause of infectious diseases. This is the purpose of clinical microbiology. The clinical microbiologist identifies agents and organisms (hereafter referred to as microorganisms) based on morphological, biochemical, immunologic, and molecular procedures. Time is a significant factor in the identification process, especially in life-threatening situations. Computers and advances in technology for rapid identification, some commercially available, have greatly aided the clinical microbiologist. Molecular methods allow identification of microorganisms based on highly specific genomic and biochemical properties. Once isolated and identified, the microorganism can then be subjected to antimicrobial sensitivity tests. In the final analysis the patient's well-being and health can benefit significantly from information provided by the clinical microbiology laboratory—the subject of this chapter.

36.1 Specimens

The major focus of the **clinical microbiologist** is to isolate and identify microorganisms from clinical specimens rapidly. The purpose of the clinical microbiology laboratory is to provide the physician with information concerning the presence or absence of microorganisms that may be involved in the infectious disease process (**figure 36.1**). These individuals and facilities also determine the susceptibility of microorganisms to antimicrobial agents. Clinical microbiology makes use of information obtained from research on such diverse topics as microbial biochemistry and physiology, immunology, molecular biology, genomics, and the host-parasite relationships involved in the infectious disease process.

In clinical microbiology a clinical specimen (hereafter, specimen) represents a portion or quantity of human material that is tested, examined, or studied to determine the presence or absence of particular microorganisms. Safety for the patients, hospital, and laboratory staff is very important. The guidelines presented in **Box 36.1** (Universal Precautions for Health-Care Professionals) were established by the Centers for Disease Control and Prevention (CDC) to address areas of specimen handling. Other important concerns regarding specimens need emphasis:

1. The specimen selected should adequately represent the diseased area and also may include additional sites (e.g., liver and blood specimens) in order to isolate and identify potential agents of the particular disease process.
2. A quantity of specimen adequate in amount to allow a variety of diagnostic testing should be obtained.
3. Attention must be given to specimen collection in order to avoid contamination from the many varieties of microorganisms indigenous to the skin and mucous membranes (*see figure 31.2*).
4. The specimen should be forwarded promptly to the clinical laboratory.
5. If possible, the specimen should be obtained before antimicrobial agents have been administered to the patient.

Collection

Overall, the results obtained in the clinical laboratory are only as good as the quality of the specimen collected for analysis. Specimens may be collected by several methods using aseptic technique. Aseptic technique refers to specific procedures used to prevent unwanted microorganisms from contaminating the clinical specimen. Each method is designed to ensure that only the proper material will be sent to the clinical laboratory.

The most common method used to collect specimens from the anterior nares or throat is the sterile **swab.** A sterile swab is a rayon-, calcium alginate, or dacron-tipped polystyrene applicator. Manufacturers of swabs have their own unique container design and instructions for proper use. For example, many commercially manufactured swabs contain a transport medium designed to preserve a variety of microorganisms and to prevent multiplication of rapidly growing members of the population (**figure 36.2*a***). However, with the exception of the nares or throat, the use of swabs for the collection of specimens is of little value and should be discouraged for two major reasons: swabs are associated with a greater risk of contamination with surface and subsurface microorganisms, and they have a limited volume capacity (<0.1 ml).

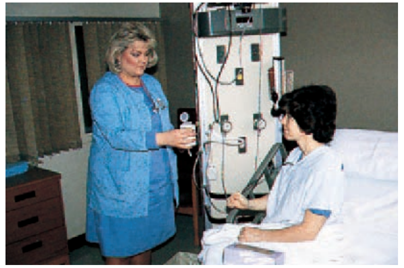
Needle aspiration is used to collect specimens aseptically (e.g., anaerobic bacteria) from cerebrospinal fluid, pus, and blood. For both samples stringent antiseptic techniques are used to avoid skin contamination. To prevent blood from clotting and entrapping microorganisms, various anticoagulants (e.g., heparin, sodium citrate) are included within the specimen bottle or tube (figure 36.2*b*).

Intubation [Latin *in,* into, and *tuba,* tube] is the inserting of a tube into a body canal or hollow organ. For example, intubation can be used to collect specimens from the stomach. In this procedure a long sterile tube is attached to a syringe, and the tube is either swallowed by the patient or passed through a nostril (figure 36.2*c*) into the patient's stomach. Specimens are then withdrawn periodically into the sterile syringe. The most common intubation tube is the Levin tube.

A **catheter** is a tubular instrument used for withdrawing or introducing fluids from or into a body cavity. For example, urine specimens may be collected with catheters to detect urinary tract infections caused by bacteria and from newborns and neonates who cannot give a voluntary urinary specimen. Three types are commonly used for urine. The hard catheter is used when the urethra is very narrow or has strictures. The French catheter is a soft tube used to obtain a single specimen sample. If multiple samples are required over a prolonged period, a Foley catheter is used (figure 36.2*d*).

The most common method used for the collection of urine is the clean-catch method. After the patient has cleansed the urethral

© The McGraw−Hill Companies, 2002



(**a**) The identification of the microorganism begins at the patient's bedside. The nurse is giving instructions to the patient on how to obtain a sputum specimen.

(**b**) The specimen is sent to the laboratory to be processed. Notice that the specimen and worksheet are in different Ziplock bags.

(**c**) Specimens such as sputum are plated on various types of media under a laminar airflow hood. This is to prevent specimen aerosols from coming in contact with the microbiologist.

(**d**) Sputum and other specimens are usually Gram stained to determine whether or not bacteria are present and to obtain preliminary results on the nature of any bacteria found.

(**e**) After incubation, the plates are examined for significant isolates. The Gram stain may be reexamined for correlation.

(**f**) Suspect colonies are picked for biochemical, immunologic, or molecular testing.

(**g**) Colonies are prepared for identification by rapid test systems.

(**h**) In a short period of time, sometimes 4 hours, computer-generated information is obtained that will consist of biochemical identification and antibiotic susceptibility results.

(**i**) All information about the specimen is now entered into a computer and the data are transmitted directly to the hospital ward.

Figure 36.1 Isolation and Identification of Microorganisms in a Clinical Laboratory.

Box 36.1

Universal Precautions for Health-Care Professionals

Since medical history and examination cannot reliably identify all patients infected with HIV or other blood-borne pathogens, blood and body-fluid precautions should be consistently used for all patients. Workers in microbiological research laboratories also are exposed to health hazards and need to employ universal precautions (*see Box 7.2, p. 145*).

1. All health-care workers should routinely use appropriate barrier precautions to prevent skin and mucous-membrane exposure when contact with blood or other body fluids of any patient is anticipated. Gloves should be worn for touching blood and body fluids, mucous membranes, or non-intact skin of all patients, for handling items or surfaces soiled with blood or body fluids, and for performing venipuncture and other vascular access procedures. Gloves should be changed after contact with each patient. Masks and protective eyewear or face shields should be worn during procedures that are likely to generate droplets of blood or other body fluids to prevent exposure of mucous membranes of the mouth, nose, and eyes. Gowns, aprons, or lab coats should be worn during procedures that are likely to generate splashes of blood or other body fluids.
2. Hands and other skin surfaces should be washed immediately and thoroughly if contaminated with blood or other body fluids. Hands should be washed immediately after gloves are removed.
3. All health-care workers should take precautions to prevent injuries caused by needles, scalpels, and other sharp instruments or devices during procedures; when cleaning used instruments; during disposal of used needles; and when handling sharp instruments after procedures. To prevent needlestick injuries, needles should not be recapped, purposely bent or broken by hand, removed from disposable syringes, or otherwise manipulated by hand. After they are used, disposable syringes and needles, scalpel blades, and other sharp items should be placed in puncture-resistant containers for disposal.
4. Although saliva has not been implicated in HIV transmission, to minimize the need for emergency mouth-to-mouth resuscitation, mouthpieces, resuscitation bags, or other ventilation devices should be available for use in areas in which the need for resuscitation is predictable.
5. Health-care workers who have exudative lesions or weeping dermatitis should refrain from all direct patient care and from handling patient-care equipment.
6. The following procedure should be used to clean up spills of blood or blood-containing fluids. (1) Put on gloves and any other necessary barriers. (2) Wipe up excess material with disposable towels and place the towels in a container for sterilization. (3) Disinfect the area with either a commercial EPA-approved germicide or household bleach (sodium hypochlorite). The latter should be diluted from 1/100 (smooth surfaces) to 1/10 (porous or dirty surfaces); the dilution should be no more than 24 hours old. When dealing with large spills or those containing sharp objects such as broken glass, first cover the spill with disposable toweling. Then saturate the toweling with commercial germicide or a 1/10 bleach solution and allow it to stand for at least 10 minutes. Finally clean as described above.

Source: Adapted from Morbidity and Mortality Weekly Report, 36 (Suppl. 2S) 5S–10S. Centers for Disease Control and Prevention Guidelines, Atlanta, GA.

meatus (opening), a small container is used to collect the urine. The optimal time to use the clean-catch method is early morning because the urine contains more microorganisms as a result of being in the bladder overnight. In the clean-catch midstream method, the first urine voided is not collected because it will be contaminated with those transient microorganisms normally occurring in the lower portion of the urethra. Only the midstream portion is collected since it most likely will contain those microorganisms found in the urinary bladder. If warranted for some patients, needle aspirations also are done directly into the urinary bladder.

Sputum is the most common specimen collected in suspected cases of lower respiratory tract infections. Specifically, **sputum** is the mucous secretion expectorated from the lungs, bronchi, and trachea through the mouth, in contrast to saliva, which is the secretion of the salivary glands. Sputum is collected in specially designed sputum cups (figure 36.2*e*).

Handling

Immediately after collection the specimen must be properly labeled and handled. The person collecting the specimen is responsible for ensuring that the name, hospital, registration number, location in the hospital, diagnosis, current antimicrobial therapy, name of attending physician, admission date, and type of specimen are correctly and legibly written or imprinted on the culture request form. This information must correspond to that written or imprinted on a label affixed to the specimen container. The type or source of the sample and the choice of tests to be performed also must be specified on the request form.

Transport

Speed in transporting the specimen to the clinical laboratory after it has been obtained from the patient is of prime importance. Some laboratories refuse to accept specimens if they have been in transit too long.

Microbiological specimens may be transported to the laboratory by various means (figure 36.1*b*). For example, certain specimens should be transported in a medium that preserves the microorganisms and helps maintain the ratio of one organism to another. This is especially important for specimens in which normal microorganisms may be mixed with microorganisms foreign to the body location.

Special treatment is required for specimens when the microorganism is thought to be anaerobic. The material is aspirated

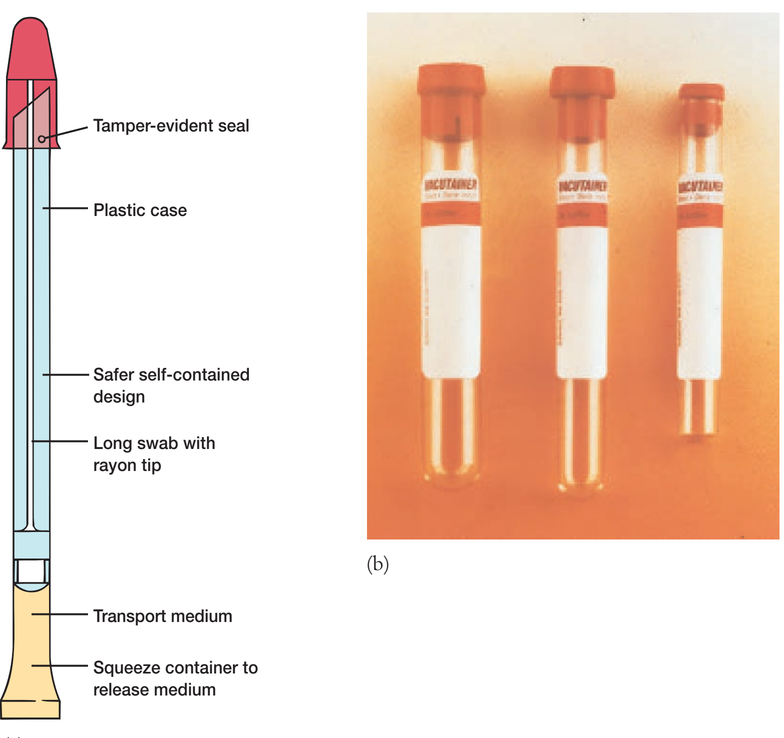

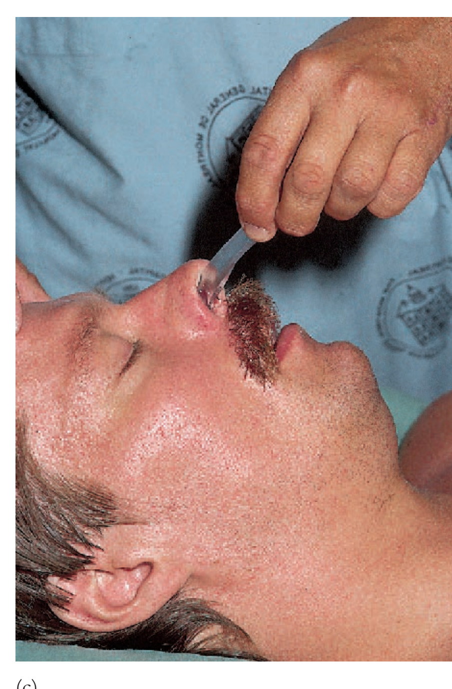

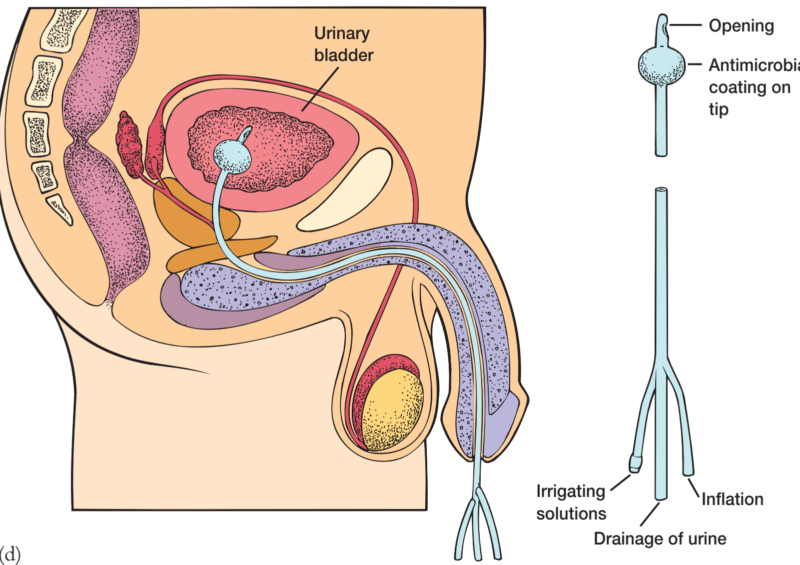

Figure 36.2 Collection of Clinical Specimens. (**a**) A drawing of a sterile swab with a specific transport medium. (**b**) Sterile Vacutainer tubes for the collection of blood. (**c**) Nasotracheal intubation. (**d**) A drawing of a Foley catheter. Notice that three separate lumens are incorporated within the round shaft of the catheter for drainage of urine, inflation, and introducing irrigating solutions into the urinary bladder. After the Foley catheter has been introduced into the urinary bladder, the tip is inflated to prevent it from being expelled. (**e**) This specially designed sputum cup allows the patient to expectorate a clinical specimen directly into the cup. In the laboratory, the cup can be opened from the bottom to reduce the chance of contamination from extraneous pathogens.

Figure 36.3 Some Anaerobic Transport Systems. A vial and syringe. These systems contain a nonnutritive transport medium that retards diffusion of oxygen after specimen addition and helps maintain microorganism viability up to 72 hours. A built-in color indicator system is clear and turns lavender in the presence of oxygen.

with a needle and syringe. Most of the time it is practical to remove the needle, cap the syringe with its original seal, and bring the specimen directly to the clinical laboratory. Transport of these specimens should take no more than 10 minutes; otherwise, the specimen must be injected immediately into an anaerobic transport vial (**figure 36.3**). Vials should contain a transport medium with an indicator, such as resazurin, to show that the interior of the vial is anaerobic at the time the specimen is introduced. Swabs for anaerobic culture usually are less satisfactory than aspirates or tissues, even if they are transported in an anaerobic vial.

Many clinical laboratories insist that stool specimens (the fecal discharge from the bowels) for culture be transported in various buffered preservatives. Preparation of these transport media is described in various manuals (see Additional Reading).

Transport of urine specimens to the clinical laboratory must be done as soon as possible. No more than 1 hour should elapse between the time the specimen is obtained and the time it is examined. If this time schedule cannot be followed, the urine sample must be refrigerated immediately.

Cerebrospinal fluid (CSF) from patients suspected of having meningitis should be examined immediately by skilled personnel in the clinical microbiology laboratory. CSF is obtained by lumbar puncture under conditions of strict asepsis, and the sample is transported to the laboratory within 15 minutes. Specimens for the isolation of viruses are iced before transport, and can be kept at 4°C for up to 72 hours; if the sample will be stored longer than 72 hours, it should be frozen at −72°C.

1. What is the function of the clinical microbiologist? The clinical microbiology laboratory?
2. What general guidelines should be followed in collecting and handling clinical specimens?
3. Define the following terms: specimen, swab, catheter, and sputum.
4. What are some transport problems associated with stool specimens? Anaerobic cultures? Urine specimens?

36.2 Identification of Microorganisms from Specimens

The clinical microbiology laboratory can provide preliminary or definitive identification of microorganisms based on (1) microscopic examination of specimens, (2) study of the growth and biochemical characteristics of isolated microorganisms (pure cultures), (3) immunologic tests that detect antibodies or microbial antigens, (4) bacteriophage typing (restricted to research settings and the CDC), and (5) molecular methods.

Microscopy

Wet-mount, heat-fixed, or chemically fixed specimens can be examined with an ordinary bright-field microscope. These preparations can be enhanced with either phase-contrast or dark-field microscopy. The latter is the procedure of choice for the detection of spirochetes in skin lesions associated with early syphilis or in blood specimens of people with early leptospirosis. The fluorescence microscope can be used to identify certain acid-fast microorganisms (*Mycobacterium tuberculosis*) after they are stained with fluorochromes such as auramine-rhodamine (*see section 2.2*). (Some morphological features used in classification and identification of microorganisms are presented in section 19.5 and in table 19.3.) The light microscope (pp. 19–27).

Many stains that can be used to examine specimens for specific microorganisms have been described. Two of the more widely used are the Gram stain and acid-fast stain. Because these stains are based on the chemical composition of cell walls, they are not useful in identifying bacteria without walls. Refer to standard references, such as the *Manual of Clinical Microbiology* published by the American Society for Microbiology, for details about other reagents and staining procedures.

Growth and Biochemical Characteristics

Typically microorganisms have been identified by their particular growth patterns and biochemical characteristics. These characteristics vary depending on whether the clinical microbiologist is dealing with viruses, rickettsias, chlamydiae, mycoplasmas, gram-positive or gram-negative bacteria, fungi (yeasts, molds), or parasites (protozoa, helminths).

Viruses

Viruses are identified by isolation in conventional cell (tissue) culture, by immunodiagnosis (fluorescent antibody, enzyme immunoassay,

radioimmunoassay, latex agglutination, and immunoperoxidase) tests, and by molecular detection methods such as nucleic acid probes and amplification assays. Several types of systems are available for virus cultivation: cell cultures, embryonated hen's eggs, and experimental animals. Immunological tests (section 33.3)

Cell cultures are divided into three general classes:

1. Primary cultures consist of cells derived directly from tissues such as monkey kidney and mink lung cells that have undergone one or two passages since harvesting.
2. Semicontinuous cell cultures or low-passage cell lines are obtained from subcultures of a primary culture and usually consist of diploid fibroblasts that undergo a finite number of divisions.
3. Continuous cell cultures, such as HEp-2 cells, are derived from transformed cells that are generally epithelial in origin. These cultures grow rapidly, are heteroploid (having a chromosome number that is not a simple multiple of the haploid number), and can be subcultured indefinitely.

Each type of cell culture favors the growth of a different array of viruses, just as bacterial culture media have differing selective and restrictive properties for growth of bacteria.

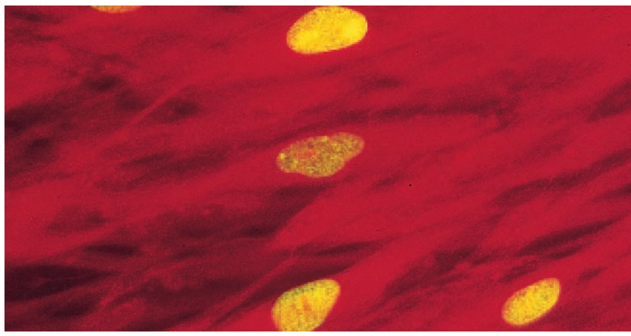
Viral replication in cell cultures is detected in two ways: (1) by observing the presence or absence of cytopathic effects (CPEs), and (2) by hemadsorption.

A **cytopathic effect** is an observable morphological change that occurs in cells because of viral replication (*see section 16.3*). Examples include ballooning, binding together, clustering, or even death of the culture cells (*see figure 16.3*). During the incubation period of a cell culture, red blood cells can be added. Several viruses alter the plasma membrane of infected culture cells so that red blood cells adhere firmly to them. This phenomenon is called **hemadsorption** (*see figure 33.10*).

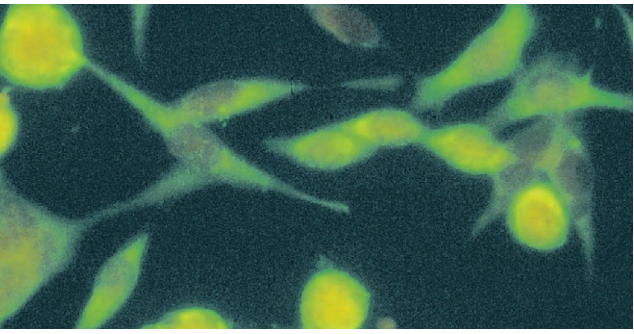
Embryonated hen's eggs can be used for virus isolation. There are three main routes of egg inoculation for virus isolation: (1) the allantoic cavity, (2) the amniotic cavity, and (3) the chorioallantoic membrane (*see figure 16.1*). Virus replication is recognized by the development of pocks on the chorioallantoic membrane, by the development of hemagglutinins (*see figure 33.10*) in the allantoic and amniotic fluid, and by death of the embryo.

Laboratory animals, especially suckling mice, are used for virus isolation. Inoculated animals are observed for specific signs of disease or death.

Several new serological tests for viral identification make use of monoclonal antibody-based immunofluorescence. These tests (**figure 36.4**) detect viruses such as the cytomegalovirus and herpes simplex virus in tissue-vial cultures.



(a)



(b)

Figure 36.4 Viral Identification Test Using Immunofluorescence in Tissue Culture. (**a**) Two infected nuclei in a cytomegalovirus (CMV) positive tissue culture. (**b**) Several infected cells in a herpes simplex virus positive tissue culture.

1. Name two specimens for which microscopy would be used in the initial diagnosis of an infectious disease.
2. Name three general classes of cell cultures.
3. Give two ways by which the presence of viral replication is detected in cell culture.
4. What are the three main routes of egg inoculation for virus isolation?

Fungi

Fungal infections (i.e., mold and yeast infections) often are diagnosed by direct microscopic (fluorescence) examination of specimens. For example, the identification of molds often can be made if a portion of the specimen is mixed with a drop of 10% Calcofluor White stain on a glass slide. Fungal cultures remain as the standard for the recovery of fungi from patient specimens; however, the time needed to culture fungi varies anywhere from a few days to several weeks depending on the organism. Fungal serology (e.g., complement fixation and immunodiffusion) is designed to detect serum antibody but is limited to a few fungi (*Blastomyces dermatitidis, Coccidioides immitis, Histoplasma capsulatum*). The cryptococcal latex antigen test is routinely used for the direct detection of *Cryptococcus neoformans* in serum and cerebrospinal fluid. In the clinical laboratory, nonautomated (conventional kits) and automated methods for rapid identification (4 to 24 hours) are used to detect most yeasts. Any biochemical methods used to detect fungi should always be accompanied by morphological studies examining for pseudohyphae, yeast cell structure, chlamydospores, and so on.

Table 36.1 Isolation of Pure Bacterial Cultures from Specimens

Selective Media

A selective medium is prepared by the addition of specific substances to a culture medium that will permit growth of one group of bacteria while inhibiting growth of some other groups. The following are examples:

Salmonella-Shigella agar (SS) is used to isolate *Salmonella* and *Shigella* species. Its bile salt mixture inhibits many groups of coliforms. Both *Salmonella* and *Shigella* species produce colorless colonies because they are unable to ferment lactose. Lactose-fermenting bacteria will produce pink colonies.

Mannitol salt agar (MS) is used for the isolation of staphylococci. The selectivity is obtained by the high (7.5%) salt concentration that inhibits growth of many groups of bacteria. The mannitol in this medium helps in differentiating the pathogenic from the nonpathogenic staphylococci, as the former ferment mannitol to form acid while the latter do not.

Bismuth sulfite agar (BS) is used for the isolation of *Salmonella typhi,* especially from stool and food specimens. *S. typhi* reduces the sulfite to sulfide, resulting in black colonies with a metallic sheen.

Differential Media

The incorporation of certain chemicals into a medium may result in diagnostically useful growth or visible change in the medium after incubation. The following are examples:

Eosin methylene blue agar (EMB) differentiates between lactose fermenters and nonlactose fermenters. EMB contains lactose, salts, and two dyes—eosin and methylene blue. *E. coli,* which is a lactose fermenter, will produce a dark colony or one that has a metallic sheen. *S. typhi,* a nonlactose fermenter, will appear colorless.

MacConkey agar is used for the selection and recovery of *Enterobacteriaceae* and related gram-negative rods. The bile salts and crystal violet in this medium inhibit the growth of gram-positive bacteria and some fastidious gram-negative bacteria. Because lactose is the sole carbohydrate, lactose-fermenting bacteria produce colonies that are various shades of red, whereas nonlactose fermenters produce colorless colonies.

Hektoen enteric agar is used to increase the yield of *Salmonella* and *Shigella* species relative to other microbiota. The high bile salt concentration inhibits the growth of gram-positive bacteria and retards the growth of many coliform strains.

Enrichment Media

The addition of blood, serum, or extracts to tryptic soy agar or broth will support the growth of many fastidious bacteria. These media are used primarily to isolate bacteria from cerebrospinal fluid, pleural fluid, sputum, and wound abscesses. The following are examples:

Blood agar (can also be a differential medium): addition of citrated blood to tryptic soy agar makes possible variable hemolysis, which permits differentiation of some species of bacteria. Three hemolytic patterns can be observed on blood agar.

1. α-hemolysis—greenish to brownish halo around the colony (e.g., *Streptococcus gordonii, Streptococcus pneumoniae*).
2. β-hemolysis—complete lysis of blood cells resulting in a clearing effect around growth of the colony (e.g., *Staphylococcus aureus* and *Streptococcus pyogenes*).
3. Nonhemolytic—no change in medium (e.g., *Staphylococcus epidermidis* and *Staphylococcus saprophyticus*).

Chocolate agar is made from heated blood, which provides necessary growth factors to support bacteria such as *Haemophilus influenzae* and *Neisseria gonorrhoeae.*

Characteristic Media

Characteristic media are used to test bacteria for particular metabolic activities, products, or requirements. The following are examples:

Urea broth is used to detect the enzyme urease. Some enteric bacteria are able to break down urea, using urease, into ammonia and CO_2.

Triple sugar iron (TSI) agar contains lactose, sucrose, and glucose plus ferrous ammonium sulfate and sodium thiosulfate. TSI is used for the identification of enteric organisms based on their ability to attack glucose, lactose, or sucrose and to liberate sulfides from ammonium sulfate or sodium thiosulfate.

Citrate agar contains sodium citrate, which serves as the sole source of carbon, and ammonium phosphate, the sole source of nitrogen. Citrate agar is used to differentiate enteric bacteria on the basis of citrate utilization.

Lysine iron agar (LIA) is used to differentiate bacteria that can either deaminate or decarboxylate the amino acid lysine. LIA contains lysine, which permits enzyme detection, and ferric ammonium citrate for the detection of H_2S production.

Sulfide, indole, motility (SIM) medium is used for three different tests. One can observe the production of sulfides, formation of indole (a metabolic product from tryptophan utilization), and motility. This medium is generally used for the differentiation of enteric organisms.

Parasites

Concentrated wet mounts of blood, stool, or urine specimens can be examined microscopically for the presence of eggs, cysts, larvae, or vegetative cells of parasites. Blood smears for sporozoan (malaria) and flagellate (trypanosome) parasites are stained with Giemsa. Some serological tests also are available.

Bacteria

Isolation and growth of bacteria are required before many diagnostic tests can be used to confirm the identification of the pathogen. The presence of bacterial growth usually can be recognized by the development of colonies on solid media or turbidity in liquid media. The time for visible growth to occur is an important variable in the clinical laboratory. For example, most pathogenic bacteria require only a few hours to produce visible growth, whereas it may take weeks for colonies of mycobacteria or mycoplasmas to become evident. The clinical microbiologist as well as the clinician should be aware of reasonable reporting times for various cultures.

The initial identity of a bacterial organism may be suggested by (1) the source of the culture specimen; (2) its microscopic appearance and Gram stain; (3) its pattern of growth on selective, differential, enrichment, or characteristic media (**table 36.1;** *see also figure 5.11*); and (4) its hemolytic, metabolic, and fermentative

Table 36.2 Some Biochemical Tests Used by Clinical Microbiologists in the Diagnosis of Bacteria from the Patient's Specimen

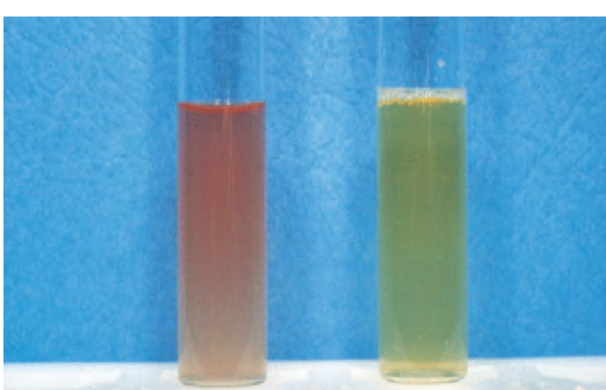
Biochemical Test	Description	Laboratory Application
Carbohydrate fermentation (figure 36.5*m*)	Acid and/or gas are produced during fermentative growth with sugars or sugar alcohols.	Fermentation of specific sugars used to differentiate enteric bacteria as well as other genera or species.
Casein hydrolysis	Detects the presence of caseinase, an enzyme able to hydrolyze milk protein casein. Bacteria that use casein appear as colonies surrounded by a clear zone.	Used to cultivate and differentiate aerobic actinomycetes based on casein utilization. For example, *Streptomyces* uses casein and *Nocardia* does not.
Catalase (figure 36.5*d,e*)	Detects the presence of catalase, which converts hydrogen peroxide to water and O_2.	Used to differentiate *Streptococcus* (−) from *Staphylococcus* (+) and *Bacillus* (+) from *Clostridium* (−).
Citrate utilization	When citrate is used as the sole carbon source, this results in alkalinization of the medium	Used in the classification of enteric bacteria. *Klebsiella* (+), *Enterobacter* (+), *Salmonella* (often +); *Escherichia* (−), *Edwardsiella* (−).
Coagulase	Detects the presence of coagulase. Coagulase causes plasma to clot.	This is an important test to differentiate *Staphylococcus aureus* (+) from *S. epidermidis* (−).
Decarboxylases (arginine, lysine, ornithine) (figure 36.5*g*)	The decarboxylation of amino acids releases CO_2 and amine.	Used in the classification of enteric bacteria.
Esculin hydrolysis	Tests for the cleavage of a glycoside.	Used in the differentiation of *Staphylococcus aureus, Streptococcus mitis,* and others (−) from *S. bovis, S. mutans,* and enterococci (+).
β-galactosidase (ONPG) test	Demonstrates the presence of an enzyme that cleaves lactose to glucose + galactose.	Used to separate enterics (*Citrobacter*+, *Salmonella*−) and to identify pseudomonads.
Gelatin liquefaction (figure 36.5*i*)	Detects whether or not a bacterium can produce proteases that hydrolyze gelatin and liquify solid gelatin medium.	Used in the identification of *Clostridium, Serratia, Pseudomonas,* and *Flavobacterium.*
Hydrogen sulfide (H_2S)	Detects the formation of hydrogen sulfide from the amino acid cysteine due to cysteine desulfurase.	Important in the identification of *Edwardsiella, Proteus,* and *Salmonella.*
IMViC (indole; methyl red; Voges-Proskauer; citrate) (figure 36.5*a,b,h*)	The indole test detects the production of indole from the amino acid tryptophan. Methyl red is a pH indicator to determine whether the bacterium has produced acid. VP (Voges-Proskauer) detects the production of acetoin. The citrate test determines whether or not the bacterium can use sodium citrate as a sole source of carbon.	Used to separate *Escherichia* (MR+, VP−, indole+) from *Enterobacter* (MR−, VP+, indole−) and *Klebsiella pneumoniae* (MR−, VP+, indole−); also used to characterize members of the genus *Bacillus.*
Lipid hydrolysis	Detects the presence of lipase, which breaks down lipids into simple fatty acids and glycerol.	Used in the separation of clostridia.
Nitrate reduction (figure 36.5*f*)	Detects whether a bacterium can use nitrate as an electron acceptor.	Used in the identification of enteric bacteria which are usually +.
Oxidase (figure 36.5*n,p*)	Detects the presence of cytochrome *c* oxidase that is able to reduce O_2 and artificial electron acceptors.	Important in distinguishing *Neisseria* and *Moraxella* spp. (+) from *Acinetobacter* (−), and enterics (all −) from pseudomonads (+).
Phenylalanine deaminase (figure 36.5*j*)	Deamination of phenylalanine produces phenylpyruvic acid, which can be detected colorimetrically.	Used in the characterization of the genera *Proteus* and *Providencia.*
Starch hydrolysis (figure 36.5*c*)	Detects the presence of the enzyme amylase, which hydrolyzes starch.	Used to identify typical starch hydrolyzers such as *Bacillus* spp.
Urease (figure 36.5*r*)	Detects the enzyme that splits urea to NH_3 and CO_2	Used to distinguish *Proteus, Providencia rettgeri,* and *Klebsiella pneumoniae* (+) from *Salmonella, Shigella* and *Escherichia* (−).

properties on the various media (table 36.1; *see also table 19.4*). After the microscopic and growth characteristics of a pure culture of bacteria are examined, specific biochemical tests can be performed. Some of the most common biochemical tests used to identify bacterial isolates are given in **table 36.2** and **figure 36.5.** Microbial nutrition and types of media (chapter 5)

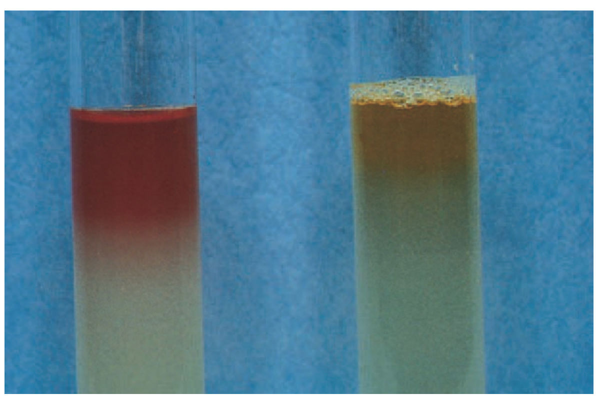
Classic dichotomous keys are coupled with the biochemical tests for the identification of bacteria from specimens. Generally, fewer than 20 tests are required to identify clinical bacterial isolates to the species level (**figure 36.6**).

Rickettsias

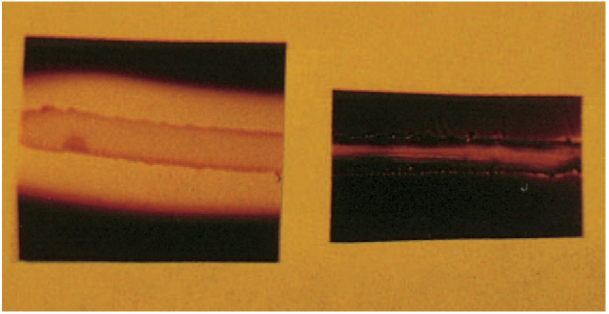
Although rickettsias, chlamydiae, and mycoplasmas are bacteria, they differ from other bacterial pathogens in a variety of ways. Therefore the identification of these three groups is discussed separately. Rickettsias can be diagnosed by immunoassays or by isolation of the microorganism. Because isolation is both hazardous to the clinical microbiologist and expensive, immunological methods are preferred. Isolation of rickettsias and diagnosis of rickettsial diseases is generally confined to reference and specialized research laboratories.



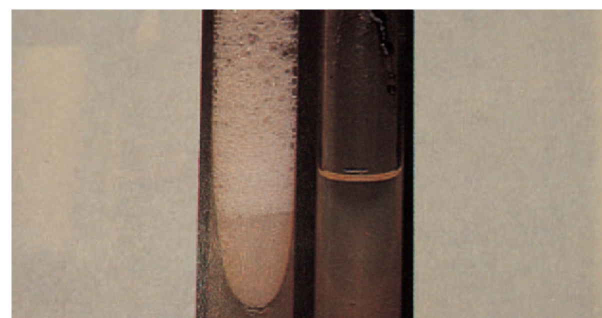
(**a**) **Methyl Red Test.** This is a qualitative test of the acidity produced by bacteria grown in MR-VP broth. After the addition of several drops of methyl red solution, a bright red color (left tube) is a positive test; a yellow or orange color (right tube) is a negative test. Used to separate enterics, for example *E. coli* is MR positive and *Enterobacter aerogenes* is MR negative.



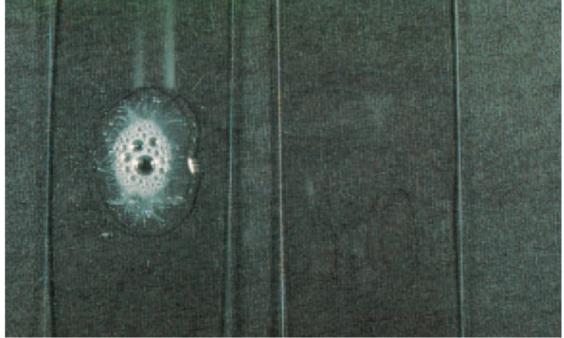
(**b**) **Voges-Proskauer Reaction.** VP-positive bacteria produce acetylmethylcarbinol or acetoin, which reacts with the reagents to produce a red color (left tube); a VP-negative tube is shown on the right. Used to differentiate *Bacillus* species and enterics. For example, *E. coli* is VP negative and *Enterobacter aerogenes* is VP positive.



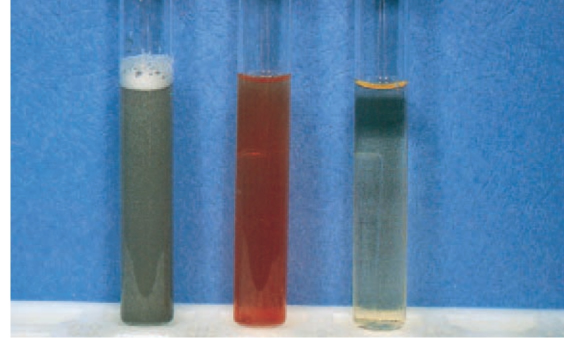
(**c**) **Starch Hydrolysis.** After incubation on starch agar, plates are flooded with iodine solution. A positive test is indicated by the colorless area around the growth (left); a negative test is shown on the right. Used to detect the production of α-amylase by certain bacteria.



(**d**) **Tube Catalase Test.** After incubation of slant cultures, 1 ml of 3% hydrogen peroxide is trickled down the slants. Catalase converts hydrogen peroxide to water and oxygen bubbles (left tube); a negative catalase test is shown in the right tube. Used to differentiate *Streptococcus* (catalase negative) from *Staphylococcus* (catalase positive).



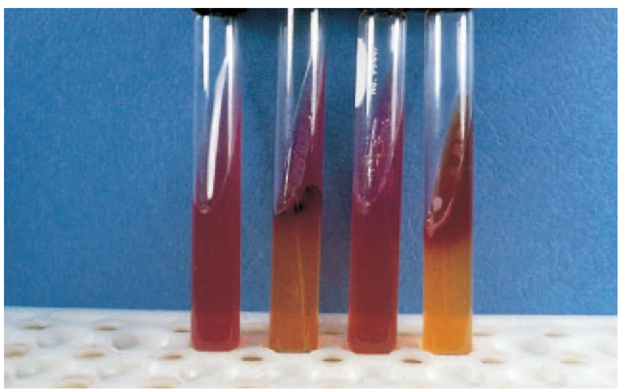
(**e**) **Slide Catalase Test.** A wooden applicator stick (or nichrome wire loop) is used to pick up a colony from a culture plate and place it in a drop of hydrogen peroxide on a glass slide. A positive catalase reaction (left slide) shows gas bubbles; a negative catalase reaction reveals an absence of gas bubbles (right slide). Used to differentiate *Streptococcus* (catalase negative) from *Staphylococcus* (catalase positive).



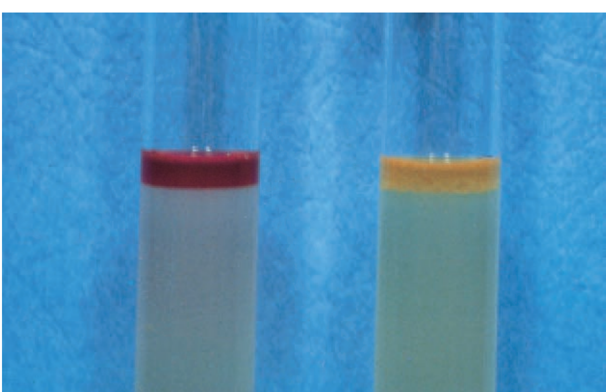
(**f**) **Nitrate Reduction.** After 24–48 hours of incubation, nitrate reagents are added to culture tubes. The tube on the left illustrates gas formation (a positive reaction for nitrate reduction); the tube in the middle is a positive reaction for nitrate reduction to nitrite as indicated by the red color; the tube on the right is a negative broth control. Used to test for miscellaneous gram-negative bacteria.

Figure 36.5 Some Common Diagnostic Tests Used in Microbiology.

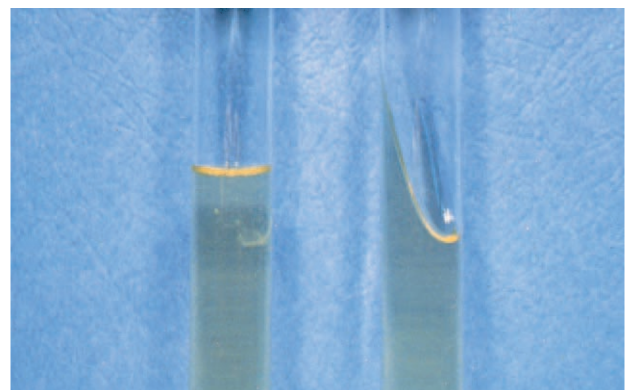
© The McGraw–Hill Companies, 2002



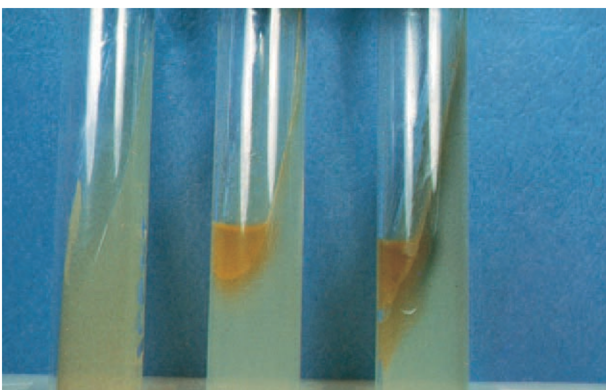
(**g**) **Test for Amino Acid Decarboxylase.** The tube on the left is an uninoculated control; the second tube from the left is lysine decarboxylase negative; the third tube is lysine decarboxylase positive; and the tube on the right is lysine deaminase positive. Used to classify enteric bacteria. Recommended for detection of arginine dihydrolase and lysine and ornithine decarboxylase activities.



(**h**) **Test for Indole.** Tryptophan can be broken down to indole by some bacteria. The presence of indole is detected by adding Kovacs' reagent. A red color on the surface is a positive test for indole (left tube) and an orange-yellow color is a negative test for indole (right tube). Used to separate enterics such as *E. coli* (indole positive) and *Enterobacter* (indole negative).

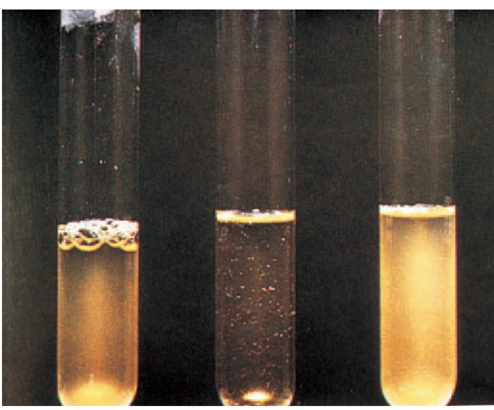


(**i**) **Gelatin Hydrolysis or Liquefaction.** If gelatin is hydrolyzed by the enzyme gelatinase, it does not gel when cooled but remains a liquid. Thus it flows when the culture is tilted backward (right tube). A negative control is on the left. Note that the solid gelatin does not flow when the tube is tilted. Used to differentiate a variety of heterotrophic bacteria, such as clostridia.

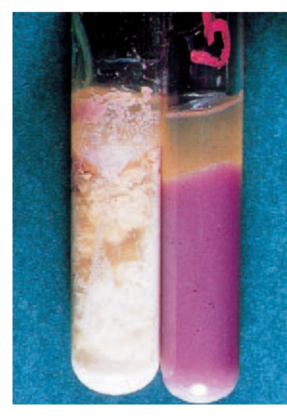


(**j**) **Phenylalanine Deamination Test.** When 10% ferric chloride is added to a phenylalanine deaminase agar slant culture, a dark green color (tube on the right) is a positive test for the enzyme. The tube on the left is an uninoculated control, and the tube in the middle is a negative test. Used to differentiate members of the *Proteus* group (*Proteus vulgaris,* positive, from *E. coli,* negative).

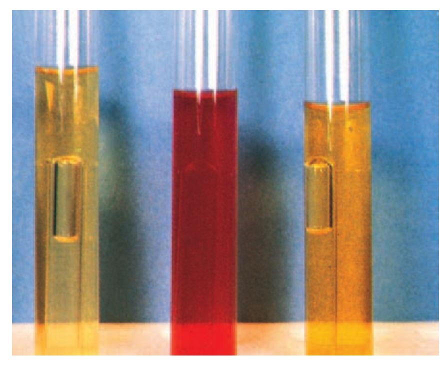
Figure 36.5 *continued*



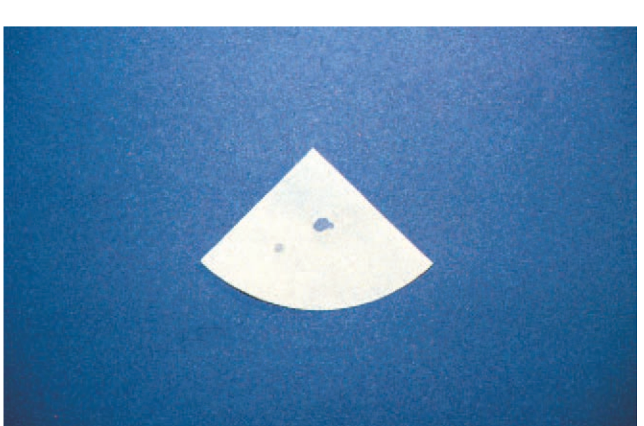
(**k**) **Bile Solubility for Pneumococcus.** The tube on the left and the one in the middle contain cultures of pneumococcus (*Streptococcus pneumoniae*). The tube on the right contains α-streptococcus. One-tenth ml of deoxycholate was added to the middle and right tubes, and 0.1 ml of distilled water was added to the left tube. The pneumococci in the center are bile soluble, as indicated by the clear suspension. The bacteria in the right tube are not bile soluble, as indicated by the turbidity.



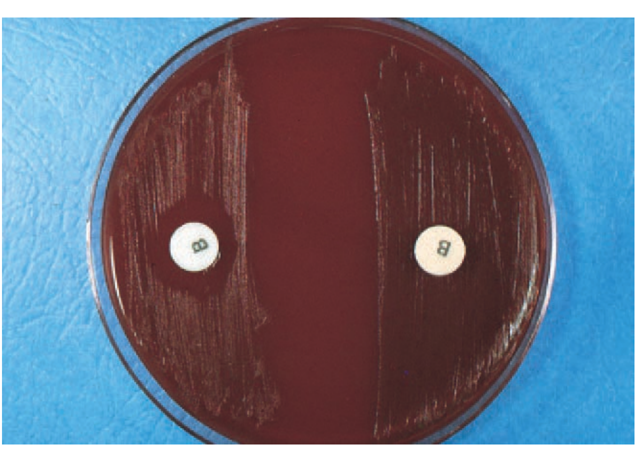
(**l**) **Stormy Fermentation of Litmus Milk.** The tube on the left shows fermentation; the tube on the right is negative for stormy fermentation. Used for the identification of *Clostridium* species.



(**m**) **Fermentation Reactions.** The tube on the left shows acid (yellow color) and gas in the Durham tube. The center tube shows no carbohydrate utilization to produce acid or gas. The tube on the right has less acid formation than that on the left. Used to separate enterics.



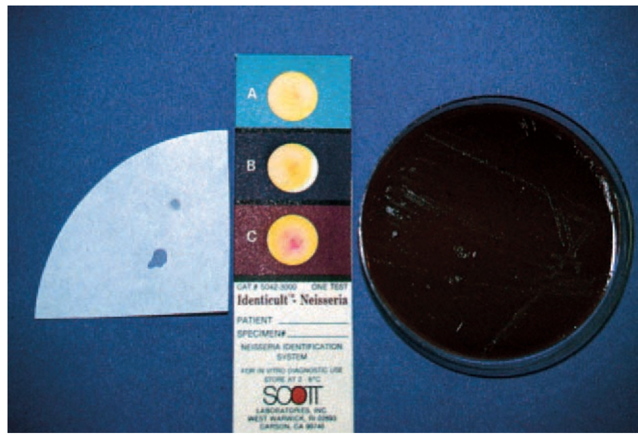
(**n**) **Oxidase Test.** Filter paper is moistened with a few drops of 1% tetramethyl-*p*-phenylenediamine dihydrochloride. With a wooden applicator, growth from an agar medium is smeared on the paper. A positive test is the development of a purple color within 10 seconds. Used to separate enterics from pseudomonads. For example, *Pseudomonas aeruginosa* is positive and *E. coli* is negative.



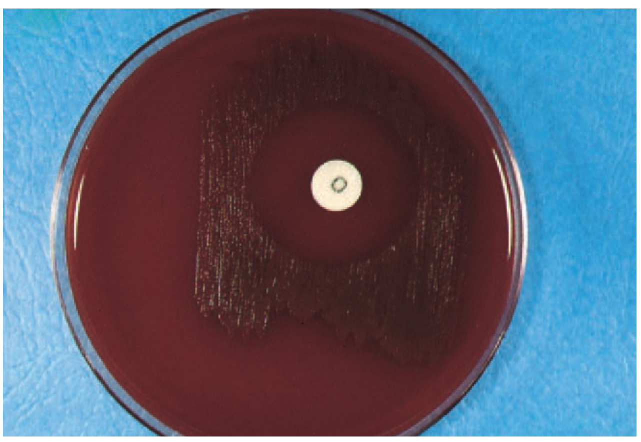
(**o**) **Bacitracin Sensitivity Test.** The bacteria on the left are presumptively identified as group A streptococci because of inhibition by the antibiotic bacitracin. The bacteria on the right (*Enterococcus faecalis*) are bacitracin resistant.

Figure 36.5 *continued*

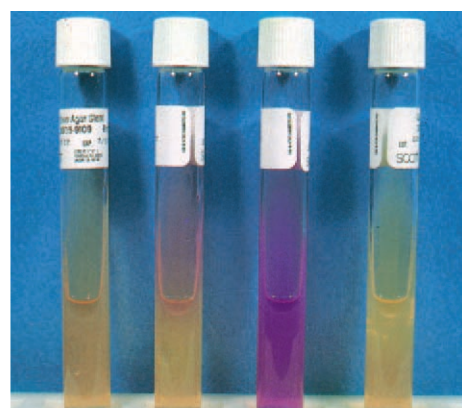
© The McGraw–Hill Companies, 2002



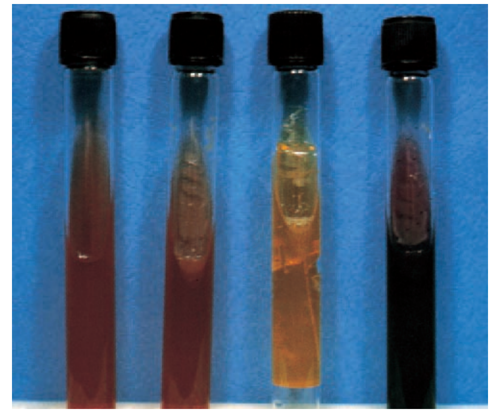
(**p**) **Identification of *Neisseria gonorrhoeae.*** Oxidase-positive test on filter paper is shown on the left. Identicult reaction for *N. gonorrhoeae* (center). The plate on the right shows characteristic growth on modified Thayer-Martin medium.



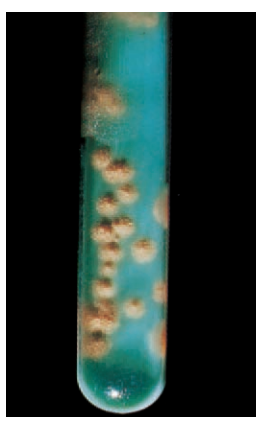
(**q**) **Optochin Sensitivity.** An optochin disk on blood agar specifically inhibits pneumococci. The optochin test for *Streptococcus pneumoniae* is based on the zone of inhibition.



(**r**) **Urease Production.** Christensen urea agar slants. Urease-positive bacteria hydrolyze urea to ammonia, which turns the phenol red indicator red-violet. From left to right: uninoculated control, delayed positive (>24 hrs), rapidly positive (<4 hrs), negative reaction. Used to separate enterics.



(**s**) **Triple Sugar Iron Agar Reactions.** Left to right: left tube is an uninoculated control, second tube is K/K (nonfermenter), third tube is A/A with gas indicating lactose or sucrose fermentation, and the right tube is K/A plus H_2S production. A stands for acid production, and K indicates that the medium becomes alkaline. Used for the differentiation of members of the *Enterobacteriaceae* based on the fermentation of lactose, sucrose, glucose, and the production of H_2S.



(**t**) **Lowenstein-Jensen Medium.** Growth of *Mycobacterium tuberculosis* showing nodular and nonpigmented growth.

Figure 36.5 *continued*

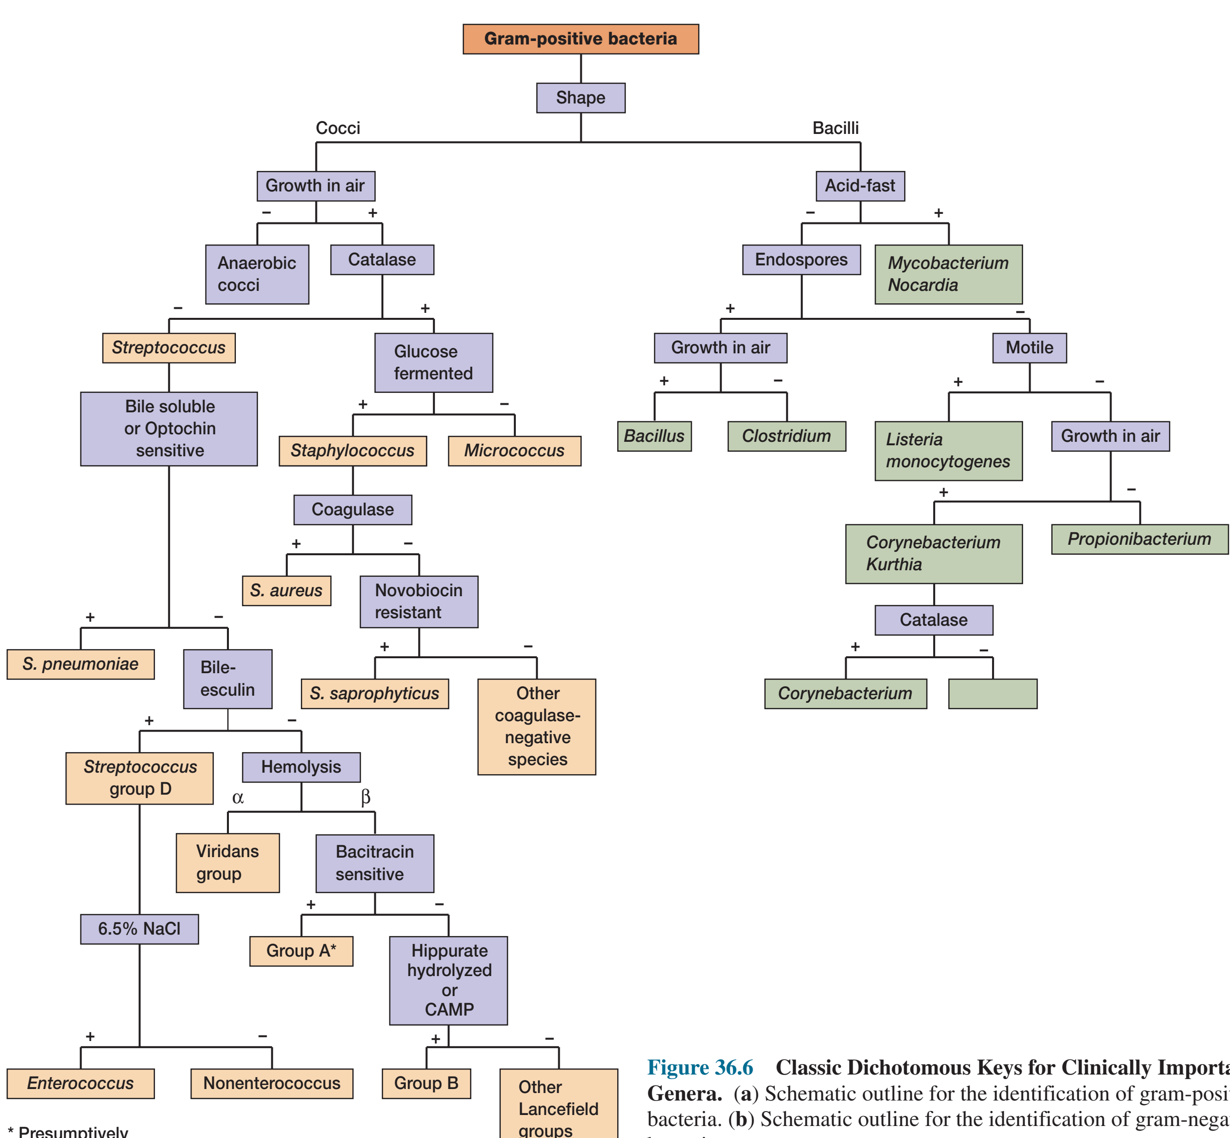


Figure 36.6 Classic Dichotomous Keys for Clinically Important Genera. (**a**) Schematic outline for the identification of gram-positive bacteria. (**b**) Schematic outline for the identification of gram-negative bacteria.

Chlamydiae

Chlamydiae can be demonstrated in tissues and cell scrapings with Giemsa staining, which detects the characteristic intracellular inclusion bodies (*see figure 21.13*). Immunofluorescent staining of tissues and cells with monoclonal antibody reagents is a more sensitive and specific means of diagnosis (**Box 36.2;** *see also figure 32.20*). The most sensitive methods for demonstrating chlamydiae in clinical specimens are DNA probes (*see p. 322*) and PCR methods (*see section 14.3*).

Mycoplasmas

The most routinely used techniques for identification of the mycoplasmas are immunological (hemagglutinin) or complement-fixing antigen-antibody reactions using the patient's sera. These microorganisms are slow growing; therefore positive results from isolation procedures are rarely available before 30 days—a long delay with an approach that offers little advantage over standard techniques. Recently DNA probes have been applied to the detection of *Mycoplasma pneumoniae* in clinical specimens.

1. How can fungi and parasites be detected in a clinical specimen? Rickettsias? Chlamydiae? Mycoplasmas?
2. Why must the clinical microbiologist know what are reasonable reporting times for various microbial specimens?
3. How can a clinical microbiologist determine the initial identity of a bacterium?
4. Describe a dichotomous key that could be used to identify a bacterium.

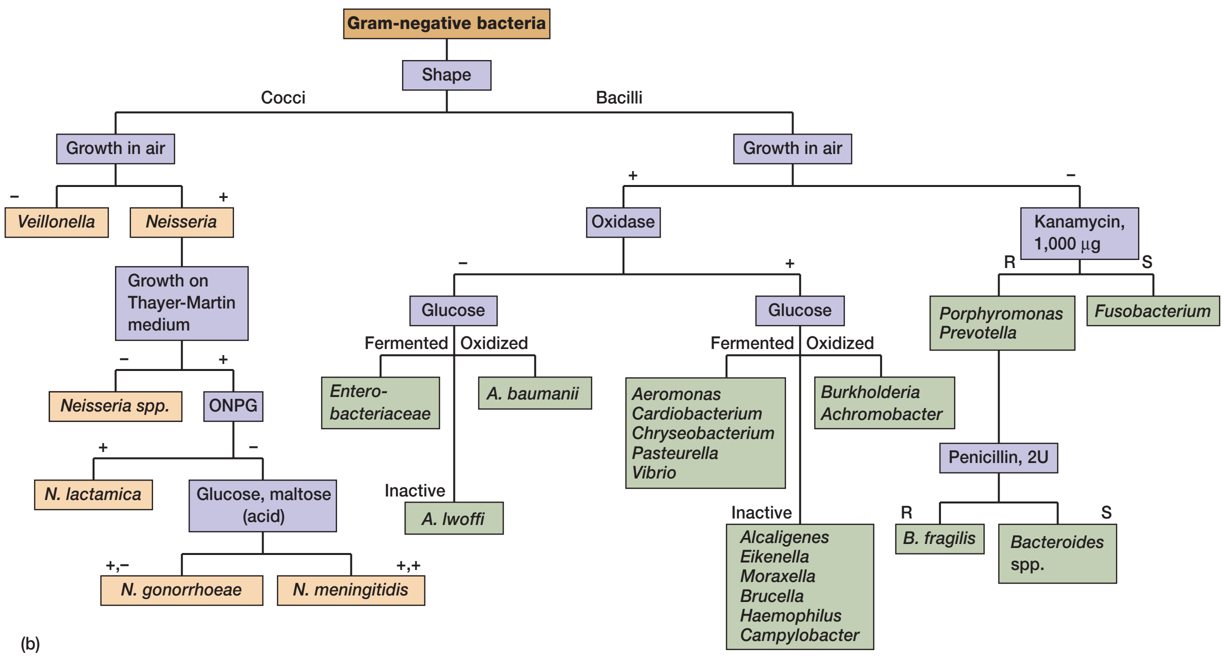

Figure 36.6 *continued*

Box 36.2

Monoclonal Antibodies in Clinical Microbiology

An important application of monoclonal antibody technology (*see hybridomas, section 32.3*) is the identification of microorganisms. Monoclonal antibodies have been prepared for a wide range of viruses, bacteria, fungi, and parasites; however, many remain as research tools and are not commercially available. If specific monoclonal antibodies are selected, immunologic assays can be created for different types of analyses. For example, monoclonal antibodies of cross-species or cross-genus reactivity have applications in the taxonomy of microorganisms. Those monoclonal antibodies that define species-specific antigens are extremely valuable in diagnostic reagents. Monoclonal antibodies that exhibit more restrictive specificity can be used to identify strains or biotypes within a species, to aid in studies of antigenic drift, and in epidemiological studies involving the matching of microbial strains. In addition, individual antigenic determinants on protein molecules can be mapped.

In the clinical microbiology laboratory, monoclonal antibodies to viral or bacterial antigens are replacing polyclonal antibodies for use in culture confirmation when accurate, rapid identification is required. With the use of sensitive techniques such as fluorescent antibody assays it is possible to perform culture identifications with improved accuracy, speed, and fewer microorganisms. The formulation of direct assays with monoclonal antibody reagents, which contain no contaminating antibodies and produce a minimum of artifacts, is now reality. The highly defined and reproducible properties of monoclonal antibodies invite their incorporation into immunoassays being developed for the next generation of instruments that will detect microbial antigens and serum antibodies for the clinical microbiologist.

Rapid Methods of Identification

Clinical microbiology has benefited greatly from technological advances in equipment, computer programs and data bases, molecular biology, and immunochemistry. With respect to the detection of microorganisms in specimens, there has been a shift from the multistep methods previously discussed to unitary procedures and systems that incorporate standardization, speed, reproducibility, miniaturization, mechanization, and automation. These rapid identification methods can be divided into three categories: (1) manual biochemical systems, (2) mechanized/automated systems, and (3) immunologic systems.

One example of a "kit approach" biochemical system for the identification of members of the family *Enterobacteriaceae* and other gram-negative bacteria is the API 20E system. It consists of a plastic strip (**figure 36.7**) with 20 microtubes containing dehydrated biochemical substrates that can detect certain biochemical characteristics. The biochemical substrates in the 20 microtubes are inoculated with a pure culture of bacteria evenly suspended in sterile physiological saline. After 5 hours or overnight incubation, the 20 test results are converted to a seven- or nine-digit profile (**figure 36.8**). This profile number can be

(a)

(b)

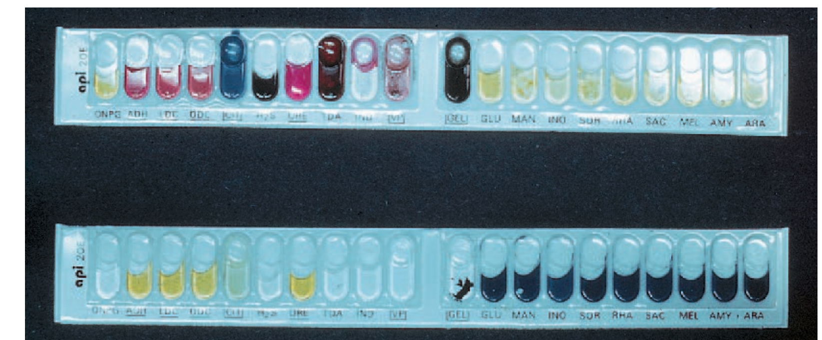

Figure 36.7 A "Kit Approach" to Bacterial Identification. The API 20E manual biochemical system for microbial identification. (**a**) Positive and (**b**) negative results.

(a) Normal 7-digit code 5 144 572 = *E. coli.*

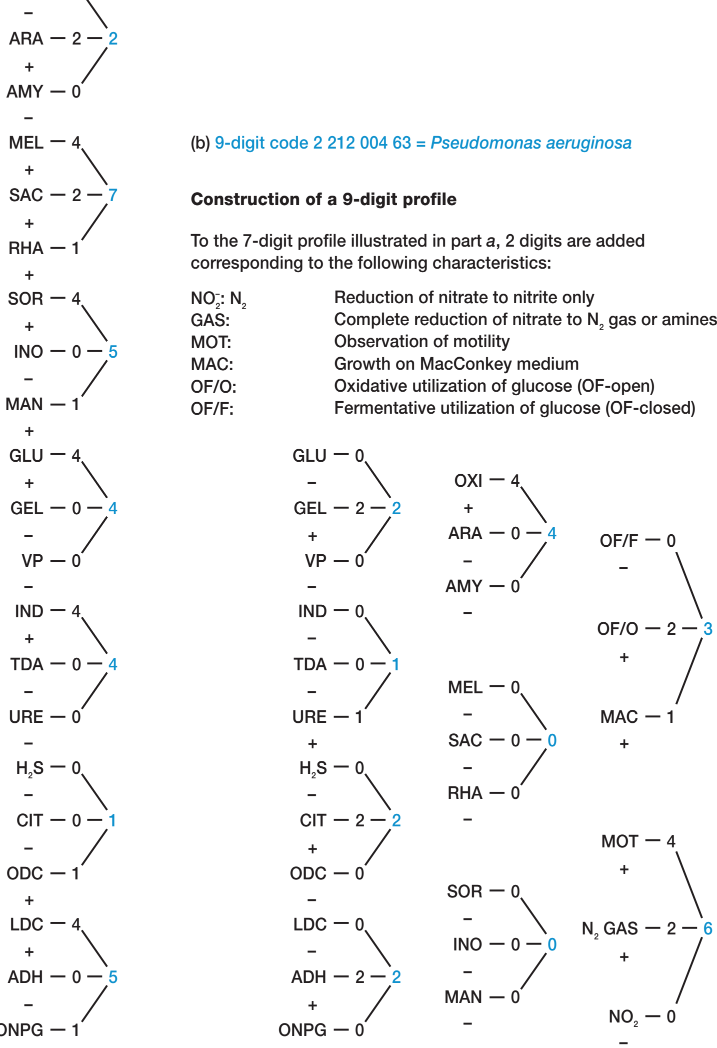

Figure 36.8 The API 20E Profile Number. The conversion of API 20E test results to the codes used in identification of unknown bacteria. The test results read top to bottom (and right to left in part *b*) correspond to the 7- and 9-digit codes when read in the right-to-left order. The tests required for obtaining a 7-digit code take an 18–24 hour incubation and will identify most members of the *Enterobacteriaceae.* The longer procedure that yields a 9-digit code is required to identify many gram-negative nonfermenting bacteria. The following tests are common to both procedures: ONPG (β-galactosidase); ADH (arginine dihydrolase); LDC (lysine decarboxylase); ODC (ornithine decarboxylase); CIT (citrate utilization); H_2S (hydrogen sulfide production); URE (urease); TDA (tryptophane deaminase); IND (indole production); VP (Voges-Proskauer test for acetoin); GEL (gelatin liquefaction); the fermentation of glucose (GLU), mannitol (MAN), inositol (INO), sorbitol (SOR), rhamnose (RHA), sucrose (SAC), melibiose (MEL), amygdalin (AMY), and arabinose (ARA); and OXI (oxidase test).

Table 36.3 Some Common Rapid Immunologic Test Kits for the Detection of Bacteria and Viruses in Clinical Specimens

Bactigen (Wampole Laboratories, Cranburg, N.J.)
The Bactigen kit is used for the detection of *Streptococcus pneumoniae, Haemophilus influenzae* type b, and *Neisseria meningitidis* groups A, B, C, and Y from cerebrospinal fluid, serum, and urine.
Culturette Group A Strep ID Kit (Marion Scientific, Kansas City, Mo.)
The Culturette kit is used for the detection of group A streptococci from throat swabs.
Directigen (Hynson, Wescott, and Dunning, Baltimore, Md.)
The Directigen Meningitis Test kit is used to detect *H. influenzae* type b, *S. pneumoniae,* and *N. meningitidis* groups A and C.
The Directigen Group A Strep Test kit is used for the direct detection of group A streptococci from throat swabs.
Gono Gen (Micro-Media Systems, San Jose, Calif.)
The Gono Gen kit detects *Neisseria gonorrhoeae.*
QuickVue *H. pylori* Test (Quidel, San Diego, Calif.)
A seven minute test for detection of IgG antibodies against *Helicobacter pylori* in human serum or plasma.
Staphaurex (Wellcome Diagnostics, Research Triangle Park, N.C.)
Staphaurex screens and confirms *Staphylococcus aureus* in 30 seconds.
Directigen RSV (Becton Dickinson Microbiology Systems, Cockeysville, Md.)
By using a nasopharyngeal swab, the respiratory syncytial virus can be detected in 15 minutes.
SureCell Herpes (HSV) Test (Kodak, Rochester, N.Y.)
Detects the herpes (HSV) 1 and 2 viruses in minutes.
SUDS HIV-1 Test (Murex Corporation, Norcross, Ga.)
Detects antibodies to HIV-1 antigens in about 10 minutes.

used with a computer or a book called the *API Profile Index* to find the name of the bacterium.

Immunologic Techniques

The culturing of certain viruses, bacteria, fungi, and parasites from clinical specimens may not be possible because the methodology remains undeveloped (*Treponema pallidum;* hepatitis A, B, C; and Epstein-Barr virus), is unsafe (rickettsias), or is impractical for all but a few clinical microbiology laboratories (mycobacteria). Cultures also may be negative because of prior antimicrobial therapy. Under these circumstances, detection of antibodies or antigens may be quite valuable diagnostically.

Immunologic systems for the detection and identification of pathogens from clinical specimens are easy to use, give relatively rapid reaction endpoints, and are sensitive and specific (they give a low percentage of false positives and negatives). Some of the more popular immunologic rapid test kits for viruses and bacteria are presented in **table 36.3**.

Each individual's immunologic response to a microorganism is quite variable. As a result the interpretation of immunologic tests is sometimes difficult. For example, a single elevated antibody IgM titer usually does not distinguish between active and past infections. Furthermore, the lack of a measurable antibody titer may reflect either a microorganism's lack of immunogenicity or an insufficient time for an antibody response to develop following the onset of the infectious disease. Some patients also are immunosuppressed due to other disease processes and/or treatment procedures (e.g., cancer and AIDS patients) and therefore do not respond. For these reasons, test selection and timing of specimen collection are essential to the proper interpretation of immunologic tests. Antibody titer (pp. 742, 776).

The most widely used immunologic techniques available to detect microorganisms in clinical specimens are covered in detail in section 33.3. No single technique is universally applicable for measuring an individual's immunologic response to all microorganisms. Techniques are therefore chosen based on their selectivity, specificity, ease, speed of performance, and cost-effectiveness.

1. Describe in general how biochemical tests are used in the API 20E system to identify bacteria.
2. Name the two basic immunologic procedures used in kits to identify microorganisms.
3. Why might cultures for some microorganisms be unavailable?
4. Why are test selection and timing of specimen collection essential to the proper interpretation of immunologic tests?

Bacteriophage Typing

Bacteriophages (phages) are viruses that attack members of a particular bacterial species, or strains within a species (*see chapter 17*). **Bacteriophage (phage) typing** is based on the specificity of phage surface receptors for cell surface receptors. Only those bacteriophages that can attach to these surface receptors can infect bacteria and cause lysis. On a petri dish culture, lytic bacteriophages cause plaques on lawns of sensitive bacteria. These plaques represent infection by the virus (*see figure 16.4*).

In bacteriophage typing the clinical microbiologist inoculates the bacterium to be tested onto a petri plate. The plate is heavily and uniformly inoculated with a cotton swab so that the bacteria will grow to form a solid sheet or lawn of cells. No uninoculated areas should be left. The plate is then marked off into squares (15 to 20 mm per side), and each square is inoculated with a drop of suspension from the different phages available for typing. After the plate is incubated for 24 hours, it is observed for plaques. The phage type is reported as a specific genus and species followed by the types that can infect the bacterium. For example, the series 10/16/24 indicates that this bacterium is sensitive to phages 10, 16, and 24, and belongs to a collection of strains, called a **phagovar,** that have this particular phage sensitivity. Bacteriophage typing remains a tool of the research and reference laboratory.

Molecular Methods and Analysis of Metabolic Products

With the application of new molecular technology, it is now possible to analyze the molecular characteristics of microorganisms in the clinical laboratory. Some of the most accurate approaches to microbial identification are through the analysis of proteins and nucleic acids. Examples previously discussed (*see chapter 19*) include comparison of proteins; physical, kinetic, and regulatory properties of microbial enzymes; nucleic acid–base composition (*see table 19.5*); nucleic acid hybridization; and nucleic acid sequencing.

Three other molecular methods being widely used are nucleic acid probes, gas-liquid chromatography, and plasmid fingerprinting.

Nucleic Acid–Based Detection Methods

A recent development in clinical microbiology is the use of nucleic acid–based diagnostic methods for the detection and identification of microorganisms. For example, DNA probe technology (*see section 14.4*) identifies a microorganism by probing its genetic composition. The use of cloned DNA as a probe is based upon the capacity of single-stranded DNA to bind (hybridize) with a complementary nucleic acid sequence present in test specimens to form a double-stranded DNA hybrid (**figure 36.9**). Thus a single-stranded sequence derived from one microorganism (the probe) is used to search for others containing the same sequence. This hybridization reaction may be applied to purified DNA preparations, to bacterial colonies, or to clinical specimens such as tissue, serum, sputum, and pus. Recently DNA probes have been developed that bind to complementary strands of ribosomal RNA. These DNA:rRNA hybrids are more sensitive than conventional DNA probes, give results in 2 hours or less, and require the presence of fewer microorganisms. DNA probe sensitivity can be increased by over one million-fold if the target DNA is first amplified using the polymerase chain reaction (*see section 14.3*). DNA:rRNA probes are available or are currently being developed for most clinically important microorganisms.

Ribosomal RNA from *E. coli* can be used to type bacterial strains by probing chromosomal DNA in Southern blots (*see figure 14.5*). This method of strain typing, called **ribotyping,** makes use of the fact that rRNA genes are scattered throughout the chromosome of most bacteria. When the chromosomes of several strains are cleaved using restriction endonucleases and the digests are analyzed with the Southern blotting procedure, rRNA probes will produce different patterns with different strains. Cloned rRNA genes also can be used as probes instead of *E. coli* rRNA, and similar banding patterns result.

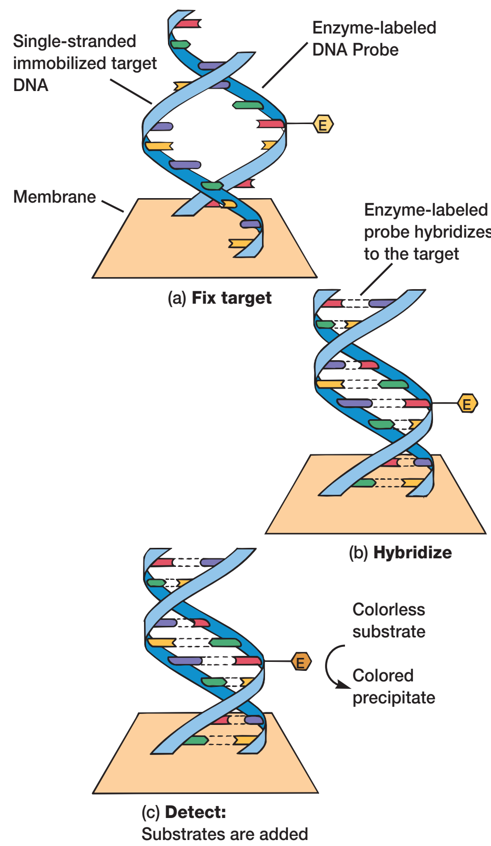

Figure 36.9 Basic Steps in A DNA Probe Hybridization Assay. (**a**) Single-stranded target nucleic acid is bound to a membrane. A DNA probe with attached enzyme (E) also is employed. (**b**) The probe is added to the membrane. If the probe hybridizes to the target DNA, a double-stranded DNA hybrid is formed. (**c**) A colorless substrate is added. The enzyme attached to the probe converts the substrate to a colored precipitate. This detection system is semiquantitative, in that color intensity is proportional to the quantity of hybridized target nucleic acid present.

Gas-Liquid Chromatography

During chromatography a chemical mixture carried by a liquid or gas is separated into its individual components because of processes such as adsorption, ion-exchange, and partitioning between different solvent phases. In gas-liquid chromatography (GLC), specific microbial metabolites, cellular fatty acids, and products from the pyrolysis (a chemical change caused by heat) of whole bacterial cells are analyzed and identified. These compounds are easily removed from growth media by extraction with an organic solvent such as ether. The ether extract is then injected into the GLC system. Both volatile and nonvolatile acids can be identified. Based on the pattern of fatty acid production, common bacteria isolated from clinical specimens can be identified.

The reliability, precision, and accuracy of GLC have been improved significantly with continued advances in instrumentation; the introduction of instruments for high-performance liquid chromatography; and the use of mass spectrometry, nuclear magnetic resonance spectroscopy, and associated analytical techniques for the identification of components separated by the chromatographic process. These combined techniques have recently been used to discover specific chemical markers of various infectious disease agents by direct analysis of body fluids.

Plasmid Fingerprinting

As presented in section 13.2, a plasmid is an autonomously replicating extrachromosomal molecule of DNA in bacteria. **Plasmid fingerprinting** identifies microbial isolates of the same or similar strains; related strains often contain the same number of plasmids with the same molecular weights and similar phenotypes. In contrast, microbial isolates that are phenotypically distinct have different plasmid fingerprints. Plasmid fingerprinting of many *E. coli, Salmonella, Campylobacter,* and *Pseudomonas* strains and species has demonstrated that this method often is more accurate

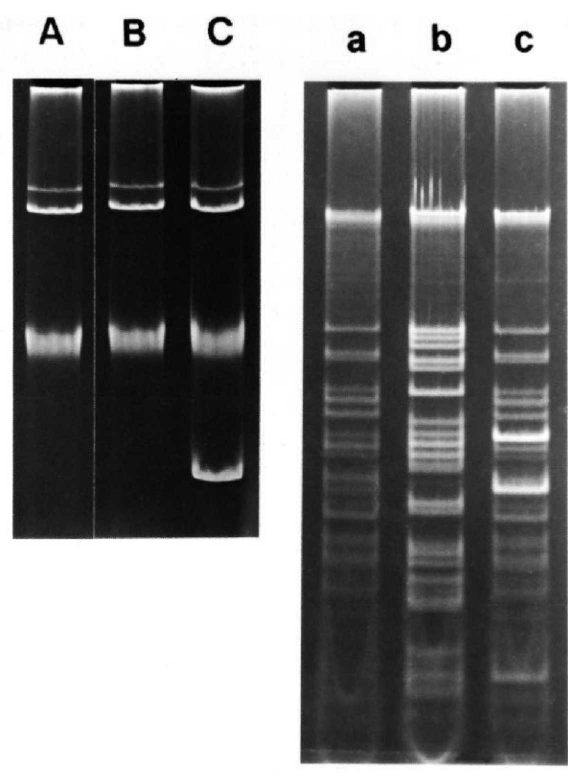

Figure 36.10 Plasmid Fingerprinting. Agarose gel electrophoresis of plasmid DNA.

than other phenotyping methods such as biotyping, antibiotic resistance patterns, phage typing, and serotyping.

The technique of plasmid fingerprinting involves five steps:

1. The bacterial strains are grown in broth or on agar plates.
2. The cells are harvested and lysed with a detergent.
3. The plasmid DNA is separated from the chromosomal DNA.
4. The plasmid DNA is applied to agarose gels and electrophoretically separated.
5. The gel is stained with ethidium bromide, which binds to DNA, causing it to fluoresce under UV light. The plasmid DNA bands are then located.

Because the migration rate of plasmid DNA in agarose is inversely proportional to the molecular weight, plasmids of a different size appear as distinct bands in the stained gel. The molecular weight of each plasmid species can then be determined from a plot of the distance that each species has migrated versus the log of the molecular weights of plasmid markers of known size that have been electrophoresed simultaneously in the same gel (**figure 36.10**).

36.3 Susceptibility Testing

Many clinical microbiologists believe that determining the susceptibility of a microorganism to specific antibiotics is one of the most important tests performed in the clinical microbiology laboratory. Results (figure 36.5*o*) can show the antibiotics to which a microorganism is most susceptible and the proper therapeutic dose needed to treat the infectious disease. (Dilution susceptibility tests, disk diffusion tests [Kirby-Bauer method], and drug concentration measurements in the blood are discussed in detail in section 35.3.)

1. What is the basis for bacteriophage typing?
2. How can nucleic acid–based detection methods be used by the clinical microbiologist? Gas-liquid chromatography?
3. How can a suspect bacterium be plasmid fingerprinted? Why is susceptibility testing so important in clinical microbiology?

36.4 Computers in Clinical Microbiology

Computer systems in the clinical microbiology laboratory are designed primarily to replace the handwritten mode of information acquisition and transmission. Computers improve the efficiency of the laboratory operation and increase the speed and clarity with which results can be reported to physicians. From a work-flow standpoint, the major functions involving the computer are test ordering, result entry, analysis of results, and report preparation (figure 36.1*h, i*).

Test orders may be entered into the computer from the hospital unit or laboratory. Standard order practices should include specific requests (e.g., rule out *Nocardia* and diphtheria), all pertinent patient data, and an accession number. Once the test order has been placed, the system should allow the usual work flow to proceed with the labeled clinical specimen, date, test order, and computer accession number.

After clinical results are obtained in the laboratory, they are entered into a written log and then into the computer. To meet the many needs of microbiological entry, the computer system must be rapid and flexible in its entry modes.

Printed reports of the patient's laboratory findings are the product of the computer system. Print programs also should permit flexible formatting of the reports so that additional data can be generated. For example, the computer system should be able to generate cumulative reports that summarize days to weeks of an inpatient stay.

Besides reporting laboratory tests, computers manage specimen logs, reports of overdue tests, quality control statistics, antimicrobial susceptibility probabilities, hospital epidemiological data, and many other items. The computer can be interfaced with various automated instruments for rapid and accurate calculation and transfer of clinical data.

1. What are some different ways in which computers can be used in the clinical microbiology laboratory?
2. From the standpoint of work flow, how can computers be specifically used in a clinical microbiology laboratory?

Summary

1. The major focus of the clinical microbiologist is to isolate and identify microorganisms from clinical specimens accurately and rapidly (**figure 36.1**). A clinical specimen represents a portion or quantity of biological material that is tested, examined, or studied to determine the presence or absence of specific microorganisms.
2. Specimens may be collected by various methods (**figure 36.2**) that include swabs, needle aspiration, intubation, catheters, and clean-catch techniques. Each method is designed to ensure that only the proper material will be sent to the clinical laboratory.
3. Immediately after collection the specimen must be properly handled and labeled. Speed in transporting the specimen to the clinical laboratory after it has been collected is of prime importance.
4. The clinical microbiology laboratory can provide preliminary or definitive identification of microorganisms based on (a) microscopic examination of specimens; (b) growth and biochemical characteristics of microorganisms isolated from cultures (**figure 36.5**); and (c) immunologic techniques that detect antibodies or microbial antigens.
5. Viruses are identified by isolation in living cells or immunologic tests. Several types of living cells are available: cell culture, embryonated hen's eggs, and experimental animals. Rickettsial disease can be diagnosed immunologically or by isolation of the organism. Chlamydiae can be demonstrated in tissue and cell scrapings with Giemsa stain, which detects the characteristic intracellular inclusion bodies. The most routinely used techniques for identification of the mycoplasmas are immunologic. Identification of fungi often can be made if a portion of the specimen is mixed with a drop of 10% Calcofluor White stain. Wet mounts of stool specimens or urine can be examined microscopically for the presence of parasites.
6. The initial identity of a bacterial organism may be suggested by (1) the source of the culture specimen; (2) its microscopic appearance; (3) its pattern of growth on selective, differential, enrichment, or characteristic media; and (4) its hemolytic, metabolic, and fermentative properties.
7. Rapid methods for microbial identification can be divided into three categories: (1) manual biochemical systems (**figure 36.7**), (2) mechanized/automated systems, and (3) immunologic systems.
8. Bacteriophage typing for bacterial identification is based on the fact that phage surface receptors bind to specific cell surface receptors. On a petri plate culture, bacteriophages cause plaques on lawns of bacteria with the proper receptors.
9. Various molecular methods and analyses of metabolic products also can be used to identify microorganisms. Examples include nucleic acid-based detection, gas-liquid chromatography, and plasmid fingerprinting.
10. After the microorganism has been isolated, cultured, and/or identified, samples are used in susceptibility tests to find which method of control will be most effective. The results are provided to the physician as quickly as possible.
11. Computer systems in clinical microbiology are designed to replace handwritten information exchange and to speed data evaluation and report preparation.

Questions for Thought and Review

1. How can clinical specimens be taken from a patient with various infectious diseases? Give specific examples of procedures used.
2. What precaution must be observed when a culture is obtained from the respiratory system?
3. Why is gas-liquid chromatography a useful approach to the identification of anaerobes?
4. How does a clinical microbiologist convert an API 20E test result to a numerical code for bacterial identification?
5. How is a dichotomous key used in bacterial identification?
6. What are some different ways in which biochemical reactions can be used to identify microorganisms?
7. What are some advantages of automation in the clinical microbiology laboratory?
8. When should laboratory animals be used in the identification of microorganisms?
9. Why is plasmid fingerprinting such an accurate method for the identification of microorganisms?

Critical Thinking Questions

1. As more new ways of identifying the characteristics of microorganisms emerge, the number of distinguishable microbial strains also seems to increase. Why do you think this occurs?
2. Why are miniaturized identification systems used in clinical microbiology? Describe one such system and its advantage over classic dichotomous keys.

CHAPTER 37

The Epidemiology of Infectious Disease

This is a photo of the Centers for Disease Control and Prevention (CDC). The CDC is located next to Emory University in Atlanta, Georgia. It is part of the United States Department of Health and Human Services, Public Health Service (USPHS). In these government facilities, thousands of microbiologists, physicians, statisticians, and social workers study all aspects of infectious human diseases.

Outline

- The Hospital Epidemiologist 866

Concepts

1. The science of epidemiology deals with the occurrence and distribution of disease within a given population. Infectious disease epidemiology is concerned with organisms or agents responsible for the spread of infectious diseases in human and other animal populations.
2. Because numbers and time are major epidemiological parameters, statistics is an important working tool in this discipline. Statistics are used to determine morbidity, frequency, and mortality rates.
3. To trace the origin and manner of spread of an infectious disease outbreak, it is necessary to learn what pathogen is responsible.
4. Epidemiologists investigate five links in the infectious disease cycle: (1) characteristics of the pathogen, (2) source and/or reservoir of the pathogen, (3) mode of transmission, (4) susceptibility of the host, and (5) exit mechanisms.
5. Emerging and reemerging diseases and pathogens are a major global concern, as is the potential threat of bioterrorism.
6. Global travel requires global health considerations.
7. The control of nosocomial (hospital acquired) infections has received increasing attention in recent years because of the number of individuals involved, increasing costs, and the length of hospital stays.

Epidemics of infectious disease are often compared with forest fires. Once fire has spread through an area, it does not return until new trees have grown up. Epidemics in humans develop when a large population of susceptible individuals is present. If most individuals are immune, then an epidemic will not occur.

—Andrew Cliff and Peter Haggett

This chapter describes the epidemiological parameters that are studied in the infectious disease cycle. The practical goal of epidemiology is to establish effective recognition, control, prevention, and eradication measures within a given population. Because emerging and reemerging diseases and pathogens as well as the potential threat of bioterrorism are worldwide concerns, these topics are covered here. Global travel requires global health considerations that are continually monitored by epidemiologists. Nosocomial (hospital) acquired infections have increased in recent years, and a brief synopsis of their epidemiology also is presented.

The science of epidemiology originated and evolved in response to the great epidemic diseases such as cholera, typhoid fever, smallpox, and yellow fever (**Box 37.1**). Today its scope encompasses all diseases: infectious diseases and those resulting from anatomical deformities, genetic abnormalities, metabolic dysfunction, malnutrition, neoplasms, psychiatric disorders, and aging. This chapter emphasizes only infectious disease epidemiology.

By definition, **epidemiology** [Greek *epi,* upon, and *demos,* people or population, and *logy,* study] is the science that evaluates the occurrence, determinants, distribution, and control of health and disease in a defined human population. **Health** is the condition in which the organism (and all of its parts) performs its vital functions normally or properly. It is a state of physical and mental well-being and not merely the absence of disease. A **disease** [French *des,* from, and *aise,* ease] is an impairment of the normal

Box 37.1

John Snow: The First Epidemiologist

Much of what we know today about the epidemiology of cholera is based on the classic studies conducted by the British physician John Snow between 1849 and 1854. During this period a series of cholera outbreaks occurred in London, England, and Snow set out to find the source of the disease. Some years earlier when he was still a medical apprentice, Snow had been sent to help during an outbreak of cholera among coal miners. His observations convinced him that the disease was usually spread by unwashed hands and shared food, not by “bad” air or casual direct contact.

Thus when the outbreak of 1849 occurred, Snow believed that cholera was spread among the poor in the same way as among the coal miners. He suspected that water, and not unwashed hands and shared food, was the source of the cholera infection among the wealthier residents. Snow examined official death records and discovered that most of the victims in the Broad Street area had lived close to the Broad Street pump or had been in the habit of drinking from it. He concluded that cholera was spread by drinking water from the Broad Street pump, which was contaminated with raw sewage containing the disease agent. When the pump handle was removed, the number of cholera cases dropped dramatically.

In 1854 another cholera outbreak struck London. Part of the city’s water supply came from two different suppliers: the Southwark and Vauxhall Company and the Lambeth Company. Snow interviewed cholera patients and found that most of them purchased their drinking water from the Southwark and Vauxhall Company. He also discovered that this company obtained its water from the Thames River below locations where Londoners had discharged their sewage. In contrast, the Lambeth Company took its water from the Thames before the river reached the city. The death rate from cholera was over eightfold lower in households supplied with Lambeth Company water. Water contaminated by sewage was transmitting the disease. Finally, Snow concluded that the cause of the disease must be able to multiply in water. Thus he nearly recognized that cholera was caused by a microorganism, though Robert Koch didn’t discover the causative bacterium (*Vibrio cholerae*) until 1883.

To commemorate these achievements, the John Snow Pub now stands at the site of the old Broad Street pump. Those who complete the Epidemiologic Intelligence Program at the Centers for Disease Control and Prevention receive an emblem bearing a replica of a barrel of Whatney’s Ale—the brew dispensed at the John Snow Pub.

state of an organism or any of its components that hinders the performance of vital functions. It is a response to environmental factors (e.g., malnutrition, industrial hazards, climate), specific infective agents (e.g., viruses, bacteria, fungi, protozoa, helminths), inherent defects of the body (e.g., various genetic or immunologic anomalies), or combinations of these.

Any individual who practices epidemiology is an **epidemiologist.** Epidemiologists are, in effect, disease detectives. Their major concerns are the discovery of the factors essential to disease occurrence and the development of methods for disease prevention.

37.1 Epidemiological Terminology

When a disease occurs occasionally, and at irregular intervals in a human population, it is a **sporadic disease** (e.g., typhoid fever). When it maintains a steady, low-level frequency at a moderately regular interval, it is an **endemic** [Greek *endemos,* dwelling in the same people] **disease** (e.g., the common cold). **Hyperendemic diseases** gradually increase in occurrence frequency beyond the endemic level but not to the epidemic level (e.g., the common cold during winter months). An **epidemic** [Greek *epidemios,* upon the people] is a sudden increase in the occurrence of a disease above the expected level (**figure 37.1**). Influenza is an example of a disease that often achieves epidemic status. The first case in an epidemic is called the **index case.** An **outbreak,** on the other hand, is the sudden, unexpected occurrence of a disease, usually focally or in a limited segment of a population (e.g., Legionnaires' disease). Although the epidemiology of an outbreak may be no different from that of an epidemic, the community regards the outbreak as less serious. A **pandemic** [Greek *pan,* all] is an increase in disease occurrence within a large population over a very wide region (usually the world). Usually, pandemic diseases spread among continents. The influenza outbreak of the 1960s and AIDS in the 1980s are good examples.

The discipline that deals with the factors that influence the frequency of a disease in an animal population is known as **epizootiology.** Moderate prevalence of a disease in animals is termed **enzootic,** a sudden outbreak is **epizootic,** and wide dissemination is **panzootic.** Animal diseases that can be transmitted to humans are termed **zoonoses** [Greek *zoon,* animal, and *nosos,* disease].

37.2 Measuring Frequency: The Epidemiologist's Tools

An important tool used in the study of modern epidemiology is statistics. **Statistics** is the branch of mathematics dealing with the collection, organization, and interpretation of numerical data. As a science particularly concerned with rates and the comparison of rates, epidemiology was the first medical field in which statistical methods were extensively used.

Measures of frequency usually are expressed as fractions. The numerator is the number of individuals experiencing the event—infection or other problem—and the denominator is the number of individuals in whom the event could have occurred, that is, the population at risk. The fraction is a proportion or ratio but is commonly called a rate because a time period is always specified. (A rate also can be expressed as a percentage.) In population statistics, rates usually are stated per 1,000 individuals, although other powers of 10 may be used for particular diseases (e.g., per 100 for very common diseases and per 10,000 or 100,000 for uncommon diseases).

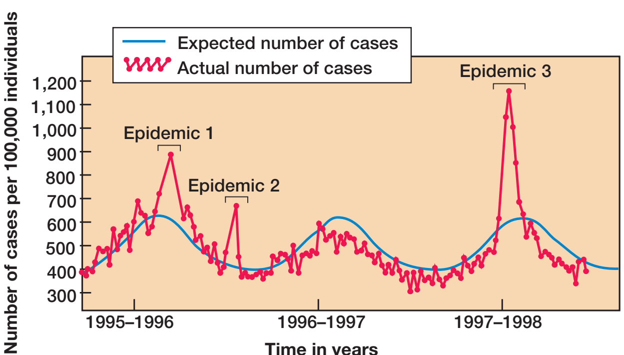

Figure 37.1 A Graph Illustrating Three Epidemics. The solid blue line indicates the expected number of endemic cases. The connected red dots indicate the actual number of cases. Epidemics (marked by brackets) are sharp increases in the number of cases of a disease above that which is normally expected (solid line).

A **morbidity rate** measures the number of individuals that become ill due to a specific disease within a susceptible population during a specific time interval. It is an incidence rate and reflects the number of new cases in a period. The rate is commonly determined when the number of new cases of illness in the general population is known from clinical reports. It is calculated as follows:

$$\text{Morbidity rate} = \frac{\text{number of new cases of a disease during a specific period}}{\text{number of individuals in the population}}$$

For example, if there were 700 new cases of influenza per 100,000 individuals, then the morbidity rate would be expressed as 700 per 100,000 or 0.7%.

The **prevalence rate** refers to the total number of individuals infected in a population at any one time no matter when the disease began. The prevalence rate depends on both the incidence rate and the duration of the illness.

The **mortality rate** is the relationship of the number of deaths from a given disease to the total number of cases of the disease. The mortality rate is a simple statement of the proportion of all deaths that are assigned to a single cause. It is calculated as follows:

$$\text{Mortality rate} = \frac{\text{number of deaths due to a given disease}}{\text{size of the total population with the same disease}}$$

For example, if there were 15,000 deaths due to AIDS in a year, and the total number of people infected was 30,000, the mortality rate would be 15,000 per 30,000 or 1 per 2 or 50%.

The determination of morbidity, prevalence, and mortality rates aids public health personnel in directing health-care efforts to control the spread of infectious diseases. For example, a sudden

© The McGraw−Hill Companies, 2002

increase in the morbidity rate of a particular disease may indicate a need for the implementation of preventive measures designed to reduce mortality.

1. What is epidemiology?
2. What terms are used to describe the occurrence of a disease in a human population? In an animal population?
3. Define morbidity rate, prevalence rate, and mortality rate.
4. How would you define a disease? Health?

37.3 Infectious Disease Epidemiology

An infectious disease is a disease resulting from an infection by microbial agents such as viruses, bacteria, fungi, protozoa, and helminths that can be transmitted from one host to another. The manifestations of an infectious disease can range from mild to severe to deadly depending on the agent and host. An epidemiologist studying an infectious disease is concerned with the causative agent, the source and/or reservoir of the disease agent (p. 854), how it was transmitted, what host and environmental factors could have aided development of the disease within a defined population, and how best to control or eliminate the disease. These factors describe the natural history or cycle of an infectious disease.

37.4 Recognition of an Infectious Disease in a Population

Epidemiologists can recognize an infectious disease in a population by using various surveillance methods. Surveillance is a dynamic activity that includes gathering information on the development and occurrence of a disease, collating and analyzing the data, summarizing the findings, and using the information to select control methods. Some combination of the following surveillance methods is used most often:

1. Generation of morbidity data from case reports
2. Collection of mortality data from death certificates
3. Investigation of actual cases
4. Collection of data from reported epidemics
5. Field investigation of epidemics
6. Review of laboratory results: surveys of a population for antibodies against the agent and specific microbial serotypes, skin tests, cultures, stool analyses, etc.
7. Population surveys using valid statistical sampling to determine who has the disease
8. Use of animal and vector disease data
9. Collection of information on the use of specific biologics—antibiotics, antitoxins, vaccines, and other prophylactic measures
10. Use of demographic data on population characteristics such as human movements during a specific time of the year
11. Use of remote sensing and geographic information systems

As noted, surveillance may not always require the direct examination of cases. However, to accurately interpret surveillance data and study the course of a disease in individuals, epidemiologists and other medical professionals must be aware of the pattern of infectious diseases. Often infectious diseases have characteristic signs and symptoms. **Signs** are objective changes in the body, such as a fever or rash, that can be directly observed. **Symptoms** are subjective changes, such as pain and loss of appetite, that are personally experienced by the patient. The term symptom is often used in a broader scope to include the clinical signs. A **disease syndrome** is a set of signs and symptoms that are characteristic of the disease. Frequently additional laboratory tests are required for an accurate diagnosis because symptoms and readily observable signs are not sufficient for diagnosis.

The course of an infectious disease usually has a characteristic pattern and can be divided into several phases. Knowledge of the pattern is essential in accurately diagnosing the disease.

1. The **incubation period** is the period between pathogen entry and the expression of signs and symptoms. The pathogen is spreading but has not reached a sufficient level to cause clinical manifestations. This period's length varies with disease.
2. The **prodromal stage** is the period in which there is an onset of signs and symptoms, but they are not yet specific enough to make a diagnosis. The patient often is contagious.
3. The illness period is the phase in which the disease is most severe and has characteristic signs and symptoms. The immune response has been triggered; B and T cells are becoming active.
4. In the period of decline, the signs and symptoms begin to disappear. The recovery stage often is referred to as convalescence.

Remote Sensing and Geographic Information Systems: Charting Infectious Diseases

Remote sensing and geographic information systems are map-based tools that can be used to study the distribution, dynamics, and environmental correlates of microbial diseases. **Remote sensing (RS)** is the gathering of digital images of the Earth's surface from satellites and transforming the data into maps. A **geographic information system (GIS)** is a data management system that organizes and displays digital map data from RS and facilitates the analysis of relationships between mapped features. Statistical relationships often exist between mapped features and diseases in natural host or human populations. Examples include the location of the habitats of the malaria parasite and mosquito vectors in Mexico and Asia, Rift Valley fever in Kenya, Lyme disease in the United States, and African trypanosomiasis and schistosomiasis in both humans and livestock in the southeastern United States. RS and GIS may also permit the assessment of human risk from pathogens such as Sin Nombre virus (the virus that causes hantavirus pulmonary syndrome in North America). RS and GIS are most useful if disease dynamics and distributions are clearly related to mapped environmental variables. For example, if a mi-

Box 37.2

"Typhoid Mary"

In the early 1900s there were thousands of typhoid fever cases, and many died of the disease. Most of these cases arose when people drank water contaminated with sewage or ate food handled by or prepared by individuals who were shedding the typhoid fever bacterium (*Salmonella typhi*). The most famous carrier of the typhoid bacterium was Mary Mallon.

Between 1896 and 1906 Mary Mallon worked as a cook in seven homes in New York City. Twenty-eight cases of typhoid fever occurred in these homes while she worked in them. As a result the New York City Health Department had Mary arrested and admitted to an isolation hospital on North Brother Island in New York's East River. Examination of Mary's stools showed that she was shedding large numbers of typhoid bacteria though she exhibited no external symptoms of the disease. An article published in 1908 in the *Journal of the American Medical Association* referred to her as "Typhoid Mary," an epithet by which she is still known today. After being released when she pledged not to cook for others or serve food to them, Mary changed her name and began to work as a cook again. For five years she managed to avoid capture while continuing to spread typhoid fever. Eventually the authorities tracked her down. She was held in custody for 23 years until she died in 1938. As a lifetime carrier, Mary Mallon was positively linked with 10 outbreaks of typhoid fever, 53 cases, and 3 deaths.

crobial disease is associated with certain vegetation types or physical characteristics (elevation, precipitation), RS and GIS can identify regions where risk is relatively high.

Correlation with a Single Causative Agent

After an infectious disease has been recognized in a population, epidemiologists correlate the disease outbreak with a specific organism—its exact cause must be discovered (**Box 37.2**). At this point the clinical or diagnostic microbiology laboratory enters the investigation. Its purpose is to isolate and identify the organism responsible for the disease.

37.5 Recognition of an Epidemic

As previously noted, an infectious disease epidemic is usually a short-term increase in the occurrence of the disease in a particular population (figure 37.1). Two major types of epidemic are recognized: common source and propagated.

A **common-source epidemic** is characterized as having reached a peak level within a short period of time (1 to 2 weeks) followed by a moderately rapid decline in the number of infected patients (**figure 37.2*a***). This type of epidemic usually results from a single common contaminated source such as food (food poisoning) or water (Legionnaires' disease).

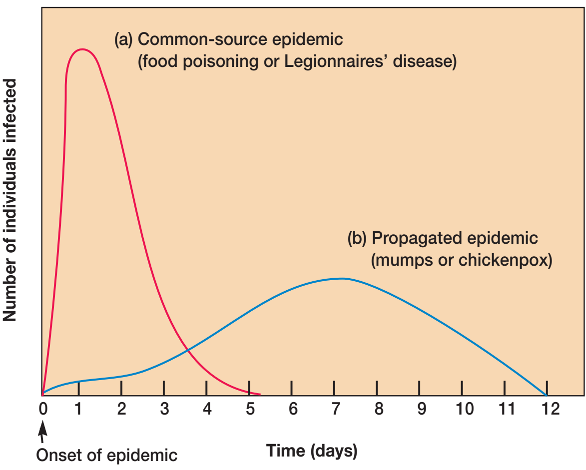

Figure 37.2 Epidemic Curves. (**a**) In a common-source epidemic, there is a rapid increase up to a peak in the number of individuals infected and then a rapid but more gradual decline. Cases usually are reported for a period that equals approximately one incubation period of the disease. (**b**) In a propagated epidemic the curve has a gradual rise and then a gradual decline. Cases usually are reported over a time interval equivalent to several incubation periods of the disease.

A **propagated epidemic** is characterized by a relatively slow and prolonged rise and then a gradual decline in the number of individuals infected (figure 37.2*b*). This type of epidemic usually results from the introduction of a single infected individual into a susceptible population. The initial infection is then propagated to others in a gradual fashion until many individuals within the population are infected. An example is the increase in mumps or chickenpox cases that coincides with new populations of sensitive children who arrive in classrooms each fall. Only one infected child is necessary to initiate the epidemic.

To understand how epidemics are propagated, consider **figure 37.3.** At time 0, all individuals in this population are susceptible to a hypothetical pathogen. The introduction of an infected individual initiates the epidemic outbreak (lower curve), which spreads and reaches a peak (day 15). As individuals recover from the disease, they become immune and no longer transmit the pathogen (upper curve). The number of susceptible individuals therefore decreases. The decline in the number of susceptibles to the threshold density (the minimum number of individuals necessary to continue propagating the disease) coincides with the peak of the epidemic wave, and the incidence of new cases declines because the pathogen cannot propagate itself.

Herd immunity is the resistance of a population to infection and pathogen spread because of the immunity of a large percentage

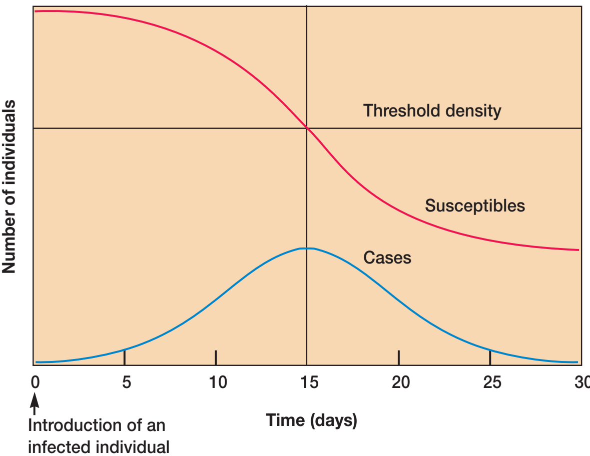

Figure 37.3 Diagrammatic Representation of the Spread of an Imaginary Propagated Epidemic. The lower curve represents the number of cases and the upper curve the number of susceptible individuals. Notice the coincidence of the peak of the epidemic wave with the threshold density of susceptibles.

of the population (**figure 37.4**). The larger the proportion of those immune, the smaller the probability of effective contact between infective and susceptible individuals—that is, many contacts will be with immunes, and thus the population will exhibit a group resistance. A susceptible member of such an immune population enjoys an immunity that is not of his or her own making (not selfmade) but instead arises because of membership in the group.

At times public health officials immunize large portions of the susceptible population in an attempt to maintain a high level of herd immunity. Any increase in the number of susceptibles may result in an endemic disease becoming epidemic. The proportion of immune to susceptible individuals must be constantly monitored because new susceptible individuals continually enter a population through migration and birth. In addition, pathogens can change so much through processes such as antigenic shift (see next paragraph) that immune individuals become susceptible again.

Many pathogens do not ordinarily change in nature. They cause endemic diseases because infected humans continually transfer them to others (e.g., sexually transmitted diseases) or because they continually reenter the human population from animal reservoirs (e.g., rabies). Other pathogens continue to evolve and may produce epidemics (e.g., AIDS, influenza virus [A strain], and *Legionella* bacteria). One way in which a pathogen changes is by **antigenic shift,** a major genetically determined change in the antigenic character of a pathogen. An antigenic shift can be so extensive that the pathogen is no longer recognized by the host's immune system. For example, influenza viruses frequently change by recombination from one antigenic type to another. Antigenic shift also occurs through the hybridization of different influenza virus serovars; two serovars of a virus intermingle to form a new antigenic type. Hybridization may occur between an animal strain and a human strain of the virus. Even though resistance in the human population becomes so high that the virus can no longer spread (herd immunity), it can be transmitted to animals, where the hybridization takes place. Smaller antigenic changes also can take place by a mutation in pathogen strains and help the pathogen avoid host immune responses. These smaller changes are called **antigenic drift.**

Whenever antigenic shift or drift occurs, the population of susceptibles increases because the immune system has not been exposed to the new mutant strain. If the percentage of susceptibles is above the threshold density (figure 37.3), the level of protection provided by herd immunity will decrease and the morbidity rate will increase. For example, the morbidity rates of diphtheria and measles among school children may reach epidemic levels if the number of susceptibles rises above 30% for the whole population. As a result the goal of public health agencies is to make sure that at least 70% of the population is immunized against these diseases to provide the herd immunity necessary for protection of those who are not immunized.

1. How can epidemiologists recognize an infectious disease in a population? Define sign, symptom, and disease syndrome. What are the four phases seen during the course of an infection?
2. How can remote sensing and geographic information systems chart infectious diseases?
3. Differentiate between common-source and propagated epidemics.
4. Explain herd immunity.
5. What is the significance of antigenic shift and drift in epidemiology?

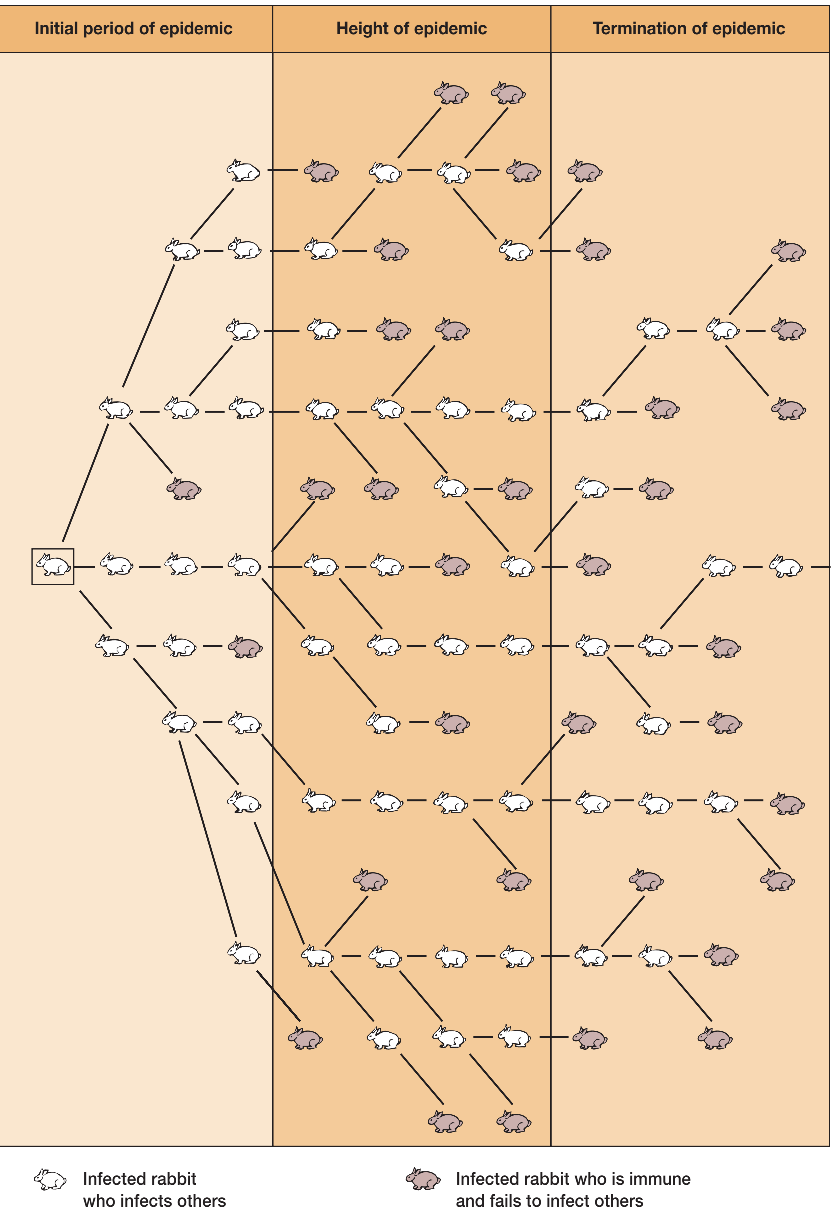
37.6 The Infectious Disease Cycle: Story of a Disease

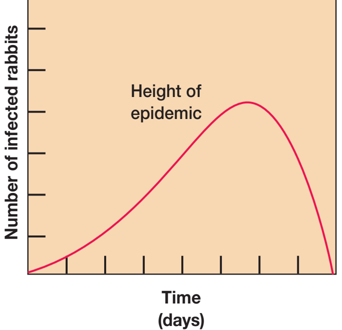
To continue to exist, a pathogen must reproduce and be disseminated among its hosts. Thus an important aspect of infectious disease epidemiology is a consideration of how reproduction and dissemination occur. The **infectious disease cycle** or **chain of infection** represents these events in the form of an intriguing epidemiological mystery story (**figure 37.5**).

What Pathogen Caused the Disease?

The first link in the infectious disease cycle is the pathogen. After an infectious disease has been recognized in a population, epidemiologists must correlate the disease outbreak with a specific pathogen. The disease's exact cause must be discovered. This is where Koch's postulates (*see section 1.3*), and modifications of them, are used to determine the etiology or cause of an infectious disease. At this point the clinical or diagnostic microbiology laboratory enters the investigation (*see section 36.1*). Its purpose is to isolate and identify the pathogen that caused the disease and to determine the pathogen's susceptibility to antimicrobial agents or methods that may assist in its eradication.

Many pathogens can cause infectious diseases in humans and will be discussed in detail in chapters 38 to 40. Often these pathogens are transmissible from one individual to another. A





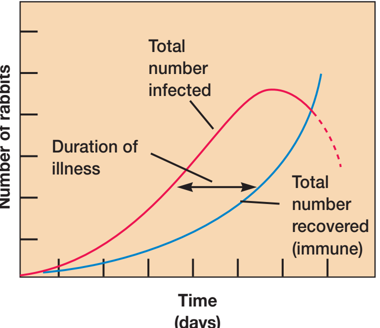


Figure 37.4 Herd Immunity. The kinetics of the spread of an infectious disease and the effect of increasing the number of immune individuals in the population in limiting the disease. On day 1, a single infected individual enters the population. The incubation period is 1 day, and recovery occurs in 2 days. The number of susceptibles is the total population on day 1. The number of infected and recovered are illustrated in the two graphs.

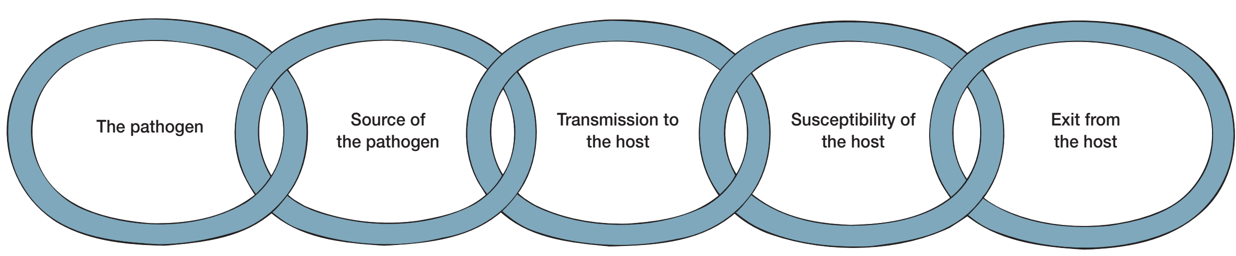

Figure 37.5 Infectious Disease Cycle or Chain of Infection. See text for further details.

Table 37.1 Infectious Organisms in Nonhuman Reservoirs That May Be Transmitted to Humans

Disease	Etiologic Agent	Usual or Suspected Nonhuman Host	Usual Method of Human Infection
Acquired human LCMV infection	Lymphocytic choriomeningitis virus	Viremic mice or hamsters	Contact with infected rodents
Anthrax	*Bacillus anthracis*	Cattle, horses, sheep, swine, goats, dogs, cats, wild animals, birds	Inhalation or ingestion of spores; direct contact
Babesiosis	*Babesia bovis, B. divergens, B. microti, B. equi*	*Ixodes* ticks of various species	Bite of infected tick
Brucellosis (undulant fever)	*Brucella melitensis, B. abortus, B. suis*	Cattle, goats, swine, sheep, horses, mules, dogs, cats, fowl, deer, rabbits	Milk; direct or indirect contact
Campylobacteriosis	*Campylobacter fetus, C. jejuni*	Cattle, sheep, poultry, swine, pets, other animals	Contaminated water and food
Cat-scratch disease	*Bartonella henselae*	Cats, dogs	Cat or dog scratch
Colorado tick fever	*Coltivirus*	Squirrels, chipmunks, mice, deer	Tick bite
Cowpox	Cowpox virus	Cattle, horses	Skin abrasions
Cryptosporidiosis	*Cryptosporidium* spp.	Calves	Contact with infected calves
Encephalitis (California)	Arbovirus	Rats, squirrels, horses, deer, hares, cows	Mosquito
Encephalitis (St. Louis)	Arbovirus	Birds	Mosquito
Encephalomyelitis (Eastern equine)	Arbovirus	Birds, ducks, fowl, horses	Mosquito
Encephalomyelitis (Venezuelan equine)	Arbovirus	Rodents, horses	Mosquito
Encephalomyelitis (Western equine)	Arbovirus	Birds, snakes, squirrels, horses	Mosquito
Giardiasis	*Giardia lamblia*	Rodents, deer, cattle, dogs, cats	Contaminated water
Glanders	*Pseudomonas mallei*	Horses	Skin contact; inhalation
Hantavirus pulmonary syndrome	Pulmonary syndrome hantavirus	Deer mice	Contact with the saliva, urine, or feces of deer mice; aerosolized viruses
Herpes B viral encephalitis	*Herpesvirus simiae*	Monkeys	Monkey bite; contact with material from monkeys
Leptospirosis	*Leptospira interrogans*	Dogs, rodents, wild animals	Direct contact with urine, infected tissue, and contaminated water
Listeriosis	*Listeria monocytogenes*	Sheep, cattle, goats, guinea pigs, chickens, horses, rodents, birds, crustaceans	Food-borne
Lyme disease	*Borrelia burgdorferi*	Ticks (*Ixodes scapularis*) or related ticks	Bite of infected tick
Lymphocytic choriomeningitis	Arbovirus	Mice, rats, dogs, monkeys, guinea pigs	Inhalation of contaminated dust; ingestion of contaminated food

communicable disease is an illness caused by a pathogen or its products that has been transmitted from an infected person or a reservoir, either directly or indirectly. Pathogens have the potential to produce disease (pathogenicity); this potential is a function of such factors as the number of pathogens, their virulence, and the nature and magnitude of host defenses.

What Was the Source and/or Reservoir of the Pathogen?

The source and/or reservoir of a pathogen is the second link in the infectious disease cycle. Identifying the source and/or reservoir is an important aspect of epidemiology. If the source or reservoir of the infection can be eliminated or controlled, the infectious disease cycle itself will be interrupted and transmission of the pathogen will be prevented (Boxes 37.1 and 37.2).

A **source** is the location from which the pathogen is immediately transmitted to the host, either directly through the environment or indirectly through an intermediate agent. The source can be either animate (e.g., humans or animals) or inanimate (e.g., water, soil, or food). The **period of infectivity** is the time during which the source is infectious or is disseminating the pathogen.

The **reservoir** is the site or natural environmental location in which the pathogen is normally found living and from which infection of the host can occur. Thus a reservoir sometimes functions as a source. Reservoirs also can be animate or inanimate.

Much of the time, human hosts are the most important animate sources of the pathogen and are called carriers. A **carrier** is an infected individual who is a potential source of infection for

Table 37.1 Continued

Disease	Etiologic Agent	Usual or Suspected Nonhuman Host	Usual Method of Human Infection
Mediterranean fever (boutonneuse fever, African tick typhus)	*Rickettsia conorii*	Dogs	Tick bite
Melioidosis	*Pseudomonas pseudomallei*	Rats, mice, rabbits, dogs, cats	Arthropod vectors, water, food
Orf (contagious ecthyma)	Virus	Sheep, goats	Through skin abrasions
Pasteurellosis	*Pasteurella multocida*	Fowl, cattle, sheep, swine, goats, mice, rats, rabbits	Animal bite
Plague (bubonic)	*Yersinia pestis*	Domestic rats, many wild rodents	Flea bite
Psittacosis	*Chlamydia psittaci*	Birds	Direct contact, respiratory aerosols
Q fever	*Coxiella burnetii*	Cattle, sheep, goats	Inhalation of infected soil and dust
Rabies	Rabies virus (Rhabdovirus group)	Dogs, bats, opposums, skunks, foxes, cats, cattle	Bite of rabid animal
Rat bite fever	*Spirillum minus*	Rats, mice, cats	Rat bite
	Streptobacillus moniliformis	Rats, mice, squirrels, weasels, turkeys, contaminated food	Rat bite
Relapsing fever (borreliosis)	*Borrelia* spp.	Rodents, porcupines, opposums, armadillos, ticks, lice	Tick or louse bite
Rickettsialpox	*Rickettsia akari*	Mice	Mite bite
Rocky Mountain spotted fever	*Rickettsia rickettsii*	Rabbits, squirrels, rats, mice, groundhogs	Tick bite
Salmonellosis	*Salmonella* spp. (except *S. typhosa*)	Fowl, swine, sheep, cattle, horses, dogs, cats, rodents, reptiles, birds, turtles	Direct contact; food
Scrub typhus	*Rickettsia tsutsugamushi*	Wild rodents, rats	Mite bite
Tuberculosis	*Mycobacterium bovis*	Cattle, horses, cats, dogs	Milk; direct contact
Tularemia	*Francisella tularensis*	Wild rabbits, most other wild and and domestic animals	Direct contact with infected carcass, usually rabbit; tick bite, biting flies
Typhus fever (endemic)	*Rickettsia mooseri*	Rats	Flea bite
Vesicular stomatitis	Virus (Rhabdovirus group)	Cattle, swine, horses	Direct contact
Weil's disease (leptospirosis)	*Leptospira interrogans*	Rats, mice, skunks, opposums, wildcats, foxes, raccoons, shrews, bandicoots, dogs, cattle, swine	Through skin, drinking water, eating food
Yellow fever (jungle)	Yellow fever virus	Monkeys, marmosets, lemurs, mosquitoes	Mosquito

others. Carriers play an important role in the epidemiology of disease. Four types of carriers are recognized:

1. An **active carrier** is an individual who has an overt clinical case of the disease.
2. A **convalescent carrier** is an individual who has recovered from the infectious disease but continues to harbor large numbers of the pathogen.
3. A **healthy carrier** is an individual who harbors the pathogen but is not ill.
4. An **incubatory carrier** is an individual who is incubating the pathogen in large numbers but is not yet ill.

Convalescent, healthy, and incubatory carriers may harbor the pathogen for only a brief period (hours, days, or weeks) and then are called **casual, acute,** or **transient carriers.** If they harbor the pathogen for long periods (months, years, or life), they are called **chronic carriers.**

As noted earlier, infectious diseases called zoonoses occur in animals and are occasionally transmitted to humans; thus these animals also can serve as reservoirs. Humans contract the pathogen by several mechanisms: coming into direct contact with diseased animal flesh (tularemia); drinking contaminated cow's milk (tuberculosis and brucellosis); inhaling dust particles contaminated by animal excreta or products (Q fever, anthrax); or eating insufficiently cooked infected flesh (anthrax, trichinosis). In addition, being bitten by arthropod **vectors** (organisms that spread disease from one host to another) such as mosquitoes, ticks, fleas, mites, or biting flies (equine encephalomyelitis and malaria, Lyme disease, Rocky Mountain spotted fever, plague, scrub typhus, and tularemia); or being bitten by a diseased animal (rabies) can lead to infection.

Table 37.1 lists some more common zoonoses found in the Western Hemisphere. This table is noninclusive in scope; it merely abbreviates the enormous spectrum of zoonotic diseases that are relevant to human epidemiology. Domestic animals are

Figure 37.6 A Sneeze. High-speed photograph of an aerosol generated by an unstifled sneeze. The particles seen are comprised of saliva and mucus laden with microorganisms. These airborne particles may be infectious when inhaled by a susceptible host. Even a surgical mask will not prevent the spread of all particles.

the most common source of zoonoses because they live in greater proximity to humans than do wild animals. Diseases of wild animals that are transmitted to humans tend to occur sporadically because close contact is infrequent. Other major reservoirs of pathogens are water, soil, and food. These reservoirs are discussed in detail in chapters 29, 30, and 41.

How Was the Pathogen Transmitted?

To maintain an active infectious disease in a human population, the pathogen must be transmitted from one host or source to another. Transmission is the third link in the infectious disease cycle and occurs by four main routes: airborne, contact, vehicle, and vector-borne.

Airborne Transmission

Because air is not a suitable medium for the growth of a pathogen, any pathogen that is airborne must have originated from a source such as humans, other animals, plants, soil, food, or water. In **airborne transmission** the pathogen is truly suspended in the air and travels over a meter or more from the source to the host. The pathogen can be contained within droplet nuclei or dust. **Droplet nuclei** are small particles, 1 to 4 μm in diameter, that result from the evaporation of larger particles (10 μm or more in diameter) called droplets. Droplet nuclei can remain airborne for hours or days and travel long distances.

When animals or humans are the source of the airborne pathogen, it usually is propelled from the respiratory tract into the air by an individual's coughing, sneezing, or vocalization. For example, enormous numbers of moisture droplets are aerosoled during a typical sneeze (**figure 37.6**). Each droplet is about 10 μm in diameter and initially moves about 100 m/second or more than 200 mi/hour!

Dust also is an important route of airborne transmission. At times a pathogen adheres to dust particles and contributes to the number of airborne pathogens when the dust is resuspended by some disturbance. A pathogen that can survive for relatively long periods in or on dust creates an epidemiological problem, particularly in hospitals, where dust can be the source of hospital-acquired infections. **Table 37.2** summarizes some human airborne pathogens and the diseases they cause.

Contact Transmission

Contact transmission implies the coming together or touching of the source or reservoir of the pathogen and the host (**Box 37.3**). Contact can be direct, indirect, or by droplet spread. Direct contact implies an actual physical interaction with the infectious source. This route is frequently called person-to-person contact. Person-to-person transmission occurs primarily by touching, kissing, or sexual contact (sexually transmitted diseases); by contact with oral secretions or body lesions (herpes and boils); by nursing mothers (staphylococcal infections); and through the placenta (AIDS, syphilis). Some infectious pathogens also can be transmitted by direct contact with animals or animal products (*Salmonella* and *Campylobacter*).

Indirect contact refers to the transmission of the pathogen from the source to the host through an intermediary—most often an inanimate object. The intermediary is usually contaminated by an animate source. Common examples of intermediary inanimate objects include thermometers, eating utensils, drinking cups, and

Table 37.2 Some Airborne Pathogens and the Diseases They Cause in Humans

Microorganism	Disease	Microorganism	Disease
Viruses		**Bacteria**	
Varicella	Chickenpox	*Actinomyces* spp.	Lung infections
Influenza	Flu	*Bordetella pertussis*	Whooping cough
Rubeola	Measles	*Chlamydia psittaci*	Psittacosis
Rubella	German measles	*Corynebacterium diphtheriae*	Diphtheria
Mumps	Mumps	*Mycoplasma pneumoniae*	Pneumonia
Poliomyelitis	Polio	*Mycobacterium tuberculosis*	Tuberculosis
Acute respiratory viruses	Viral pneumonia	*Neisseria meningitidis*	Meningitis
Pulmonary syndrome hantavirus	Hantavirus pulmonary syndrome	*Streptococcus* spp.	Pneumonia, sore throat
		Fungi	
		Blastomyces spp.	Lung infections
		Coccidioides spp.	Coccidioidomycosis
		Histoplasma capsulatum	Histoplasmosis

Box 37.3

The First Indications of Person-to-Person Spread of an Infectious Disease

In 1773 Charles White, an English surgeon and obstetrician, published his "Treatise on the Management of Pregnant and Lying-In Women." In it, he appealed for surgical cleanliness to combat childbed or puerperal fever. (**Puerperal fever** is an acute febrile condition that can follow childbirth and is caused by streptococcal infection of the uterus and/or adjacent regions.) In 1795 Alexander Gordon, a Scottish obstetrician, published his "Treatise on the Epidemic Puerperal Fever of Aberdeen," which demonstrated for the first time the contagiousness of the disease. In 1843 Oliver Wendell Holmes, a noted physician and anatomist in the United States, published a paper entitled "On the Contagiousness of Puerperal Fever" and also appealed for surgical cleanliness to combat this disease.

However, the first person to realize that a pathogen could be transmitted from one person to another was the Hungarian physician Ignaz Phillip Semmelweis. Between 1847 and 1849 Semmelweis observed that women who had their babies at the hospital with the help of medical students and physicians were four times as likely to contract puerperal fever as those who gave birth with the help of midwives. He concluded that the physicians and students were infecting women with material remaining on their hands after autopsies and other activities. Semmelweis thus began washing his hands with a calcium chloride solution before examining patients or delivering babies. This simple procedure led to a dramatic decrease in the number of cases of puerperal fever and saved the lives of many women. As a result Semmelweis is credited with being the pioneer of antisepsis in obstetrics. Unfortunately, in his own time, most of the medical establishment refused to acknowledge his contribution and adopt his procedures. After years of rejection Semmelweis had a nervous breakdown in 1865. He died a short time later of a wound infection. It is very probable that it was a streptococcal infection, arising from the same pathogen he had struggled against his whole professional life.

bedding. *Pseudomonas* bacteria are easily transmitted by this route. This mode of transmission is often also considered a form of vehicle transmission (see next section).

In droplet spread the pathogen is carried on particles larger than 5 μm. The route is through the air but only for a very short distance—usually less than a meter. Because these particles are large, they quickly settle out of the air. As a result droplet transmission of a pathogen depends on the proximity of the source and the host. Measles is an example of a droplet-spread disease.

Vehicle Transmission

Inanimate materials or objects involved in pathogen transmission are called **vehicles.** In **common vehicle transmission** a single inanimate vehicle or source serves to spread the pathogen to multiple hosts but does not support its reproduction. Examples include surgical instruments, bedding, and eating utensils. In epidemiology these common vehicles are called **fomites** [s., fomes or fomite]. A single source containing pathogens (blood, drugs, IV fluids) can contaminate a common vehicle that causes multiple infections. Food and water are important common vehicles for many human diseases (*see tables 39.5 and 41.6*).

Vector-Borne Transmission

As noted earlier, living transmitters of a pathogen are called vectors. Most vectors are arthropods (insects, ticks, mites, fleas) or vertebrates (dogs, cats, skunks, bats). **Vector-borne transmission** can be either external or internal. In external (mechanical)

transmission the pathogen is carried on the body surface of a vector. Carriage is passive, with no growth of the pathogen during transmission. An example would be flies carrying *Shigella* organisms on their feet from a fecal source to a plate of food that a person is eating.

In internal transmission the pathogen is carried within the vector. Here it can go into either a harborage or biologic transmission phase. In **harborage transmission** the pathogen does not undergo morphological or physiological changes within the vector. An example would be the transmission of *Yersinia pestis* (the etiologic agent of plague) by the rat flea from rat to human. **Biologic transmission** implies that the pathogen does go through a morphological or physiological change within the vector. An example would be the developmental sequence of the malarial parasite inside its mosquito vector. Malaria (pp. 954–55)

Why Was the Host Susceptible to the Pathogen?

The fourth link in the infectious disease cycle is the host. The susceptibility of the host to a pathogen depends on both the pathogenicity of the organism and the nonspecific and specific defense mechanisms of the host. These susceptibility factors are the basis for chapters 31 and 32 and are outside the realm of epidemiology.

How Did the Pathogen Leave the Host?

The fifth and last link in the infectious disease cycle is release or exit of the pathogen from the host. It is equally important that the pathogen escapes from its host as it is that the pathogen originally contacts and enters the host. Unless a successful escape occurs, the disease cycle will be interrupted and the pathogenic species will not be perpetuated. Escape can be active or passive, although often a combination of the two occurs. Active escape takes place when a pathogen actively moves to a portal of exit and leaves the host. Examples include the many parasitic helminths that migrate through the body of their host, eventually reaching the surface and exiting. Passive escape occurs when a pathogen or its progeny leaves the host in feces, urine, droplets, saliva, or desquamated cells. Microorganisms usually employ passive escape mechanisms.

1. What are some epidemiologically important characteristics of a pathogen? What is a communicable disease?
2. Define source, reservoir, period of infectivity, and carrier.
3. What types of infectious disease carriers does epidemiology recognize?
4. Describe the four main types of infectious disease transmission and give examples of each.
5. Define the terms droplet nuclei, vehicle, fomite, and vector.

37.7 Virulence and the Mode of Transmission

There is evidence that a pathogen's virulence may be strongly influenced by its mode of transmission and ability to live outside its host. When the pathogen uses a mode of transmission such as direct contact, it cannot afford to make the host so ill that it will not be transmitted effectively. This is the case with the common cold, which is caused by rhinoviruses and several other respiratory viruses. If the virus reproduced too rapidly and damaged its host extensively, the person would be bedridden and not contact others. The efficiency of transmission would drop because rhinoviruses shed from the cold sufferer could not contact new hosts and would be inactivated by exposure. Cold sufferers must be able to move about and directly contact others. Thus virulence is low and people are not incapacitated by the common cold.

On the other hand, if a pathogen uses a mode of transmission not dependent on host health and mobility, then the person's health will not be a critical matter. The pathogen might be quite successful—that is, transmitted to many new hosts even though it kills its host relatively quickly. Host death will mean the end of any resident pathogens, but the species as a whole can spread and flourish as long as the increased transmission rate outbalances the loss due to host death. This situation may arise in several ways.

When a pathogen is transmitted by a vector, it will be benefitted by extensive reproduction and spread within the host. If pathogen levels are very high in the host, a vector such as a biting insect has a better chance of picking up the pathogen and transferring it to a new host. Indeed, pathogens transmitted by biting arthropods such as mosquitoes often are very virulent (e.g., malaria, typhus, sleeping sickness). It is important that such pathogens take good care of their vectors, and the vector generally remains healthy, at least long enough for pathogen transmission.

Virulence also is often directly correlated with a pathogen's ability to survive in the external environment. If a pathogen cannot survive well outside its host and does not use a vector, it depends on host survival and will tend to be less virulent. When a pathogen can survive for long periods outside its host, it can afford to leave the host and simply wait for a new one to come along. This seems to promote increased virulence. Host health is not critical, but extensive multiplication within the host will increase the efficiency of transmission. Good examples are tuberculosis and diphtheria. *Mycobacterium* and *Corynebacterium* survive for a long time, at least weeks to months, outside human hosts.

Human cultural patterns and behavior almost certainly also affect pathogen virulence. Waterborne pathogens such as *Vibrio cholerae* (which causes diarrhea) are transmitted through drinking water systems. They can be virulent because immobile hosts still shed pathogens, which frequently reach the water. By this argument, establishment of uncontaminated drinking water supplies should reduce cholera virulence, and this seems to be the case. The same appears to be true of *Shigella* and bacillary dysentery. Often one of the best ways to reduce virulence may be to reduce the frequency of transmission.

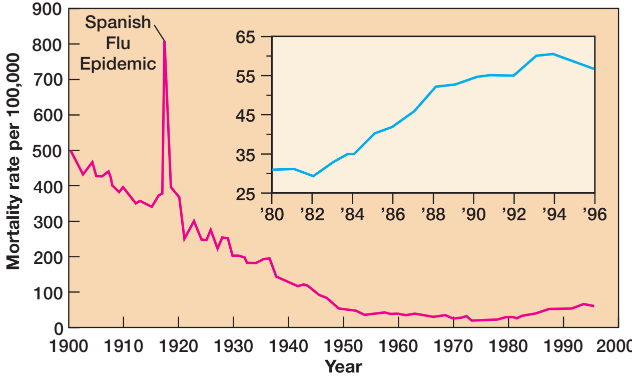

Figure 37.7 Infectious Disease Mortality in the United States Decreased Greatly during Most of the Twentieth Century. The insert is an enlargement of the right-hand portion of the graph and shows that the death rate from infectious diseases increased between 1980 and 1994.

37.8 Emerging and Reemerging Infectious Diseases and Pathogens

Only a few decades ago, a grateful public trusted that science had triumphed over infectious diseases by building a fortress of health protection. Antibiotics, vaccines, and aggressive public health campaigns had yielded a string of victories over old enemies like whooping cough, pneumonia, polio, and smallpox. In developed countries, people were lulled into believing that microbial threats were a thing of the past. Trends in the number of deaths caused by infectious diseases in the United States from 1900 through 1982 supported this conclusion (**figure 37.7**). However, this downward trend ended in 1982 and the death rate has risen in the past 20 years. In these 20 years, the world has seen the global spread of AIDS, the resurgence of tuberculosis, and the appearance of new enemies like hantavirus pulmonary syndrome, hepatitis C and E, Ebola virus, Lyme disease, cryptosporidiosis, and the deadly *E. coli* O157:H7. In addition, during this same time period:

- A "bird flu" virus that had never before attacked humans began to kill people in Hong Kong.
- A new variant of a fatal brain disease, Creutzfeldt-Jakob disease (*see section 38.5 and table 38.6*), was identified in the United Kingdom, apparently transmitted by beef from animals with "mad cow disease."
- *Staphylococcus* bacteria with increased resistance to vancomycin, long the antibiotic of first choice, were seen for the first time.
- The United States was hit with several major multistate foodborne outbreaks, including those caused by parasites on raspberries, viruses on strawberries, and bacteria in produce, ground beef, cold cuts, and breakfast cereal.
- A new strain of tuberculosis that is resistant to many drugs, and occurs most often in people infected with HIV, arose in the city of New York and other large cities.

By the 1990s, the idea that infectious diseases no longer posed a serious threat to human health was obsolete. It is now clear that globally, humans will continually be faced with both new infectious diseases and the reemergence of older diseases once thought to be conquered (e.g., tuberculosis, dengue hemorrhagic fever, yellow fever). William H. McNeill in *Plagues and Peoples* (1976) addresses this problem as follows: "Ingenuity, knowledge, and organization alter but cannot cancel humanity's vulnerability to invasion by parasitic forms of life. Infectious disease which antedated the emergence of humankind will last as long as humanity itself, and will surely remain, as it has been hitherto, one of the fundamental parameters and determinants of human history."

The Centers for Disease Control and Prevention (CDC) has defined these diseases as "new, reemerging, or drug-resistant infections whose incidence in humans has increased within the past two decades or whose incidence threatens to increase in the near future." Some of the most recent examples of these diseases are shown in **figure 37.8.** The increased importance of emerging and reemerging infectious diseases has stimulated the establishment of a field called **systematic epidemiology,** which focuses on the ecological and social factors that influence the development of these diseases.

After a century marked by dramatic advances in medical research and drug discovery, technology development, and sanitation, why are viruses, bacteria, fungi, and parasites posing such a problem and challenge? Many factors characteristic of the modern world undoubtedly favor the development and spread of these microorganisms and their diseases. Examples include:

1. Unprecedented worldwide population growth, population shifts (demographics), and urbanization
2. Increased international travel
3. Increased worldwide transport (commerce), migration, and relocation of animals and food products
4. Changes in food processing, handling, and agricultural practices
5. Changes in human behavior, technology, and industry
6. Human encroachment on wilderness habitats that are reservoirs for insects and animals that harbor infectious agents
7. Microbial evolution (e.g., selection pressure) and the development of resistance to antibiotics and other antimicrobial drugs (e.g., penicillin-resistant *Streptococcus pneumoniae,* methicillin-resistant *Staphylococcus aureus,* and vancomycin-resistant enterococci)
8. Changes in ecology and climate
9. Modern medicine (e.g., immunosuppression)

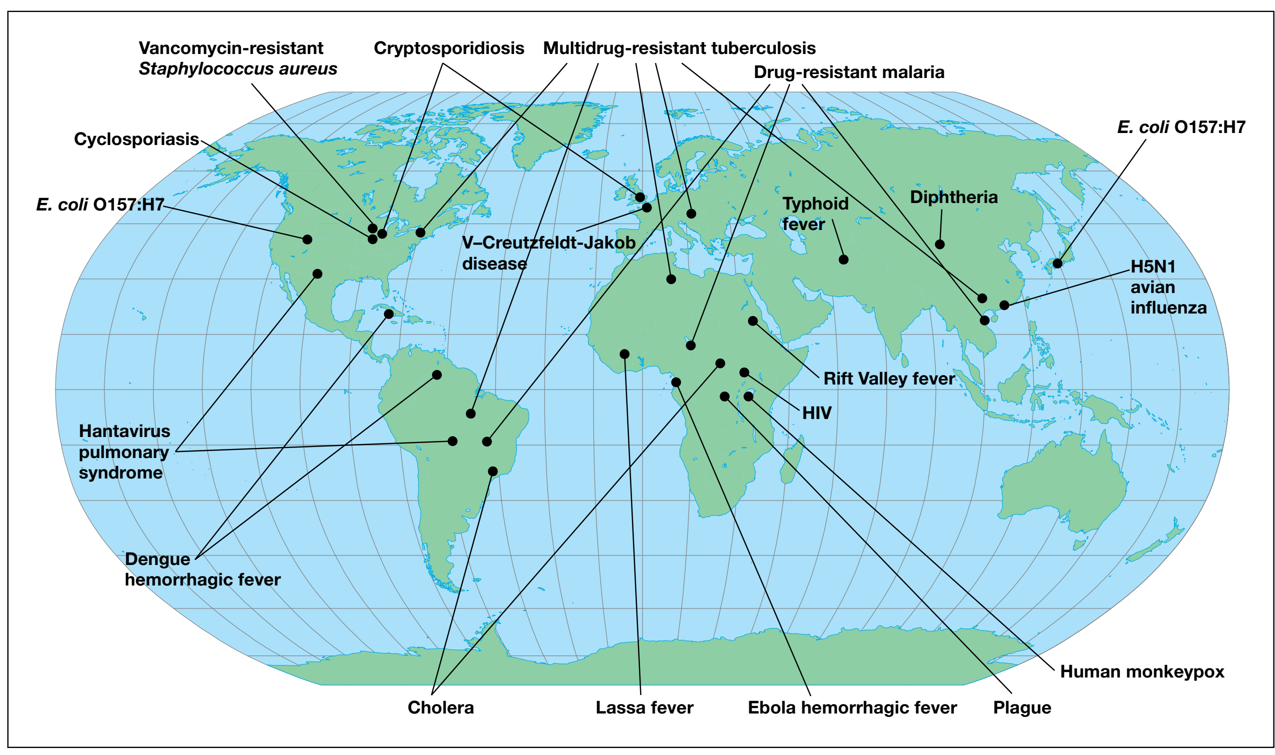

Figure 37.8 Some Examples of Emerging and Reemerging Infectious Diseases. Although diseases such as HIV are indicated in only one or two significant locations, they are very widespread and a threat in many regions. See text for further details.

10. Inadequacy of public infrastructure and vaccination programs
11. Social unrest and civil wars
12. The possibility of bioterrorism (section 37.10)
13. Virulence-enhancing mechanisms of pathogens (e.g., the mobile genetic elements—bacteriophages, plasmids, transposons)

A more detailed discussion of some of these examples now follows.

Reasons for Increases in Emerging and Reemerging Infectious Diseases

As just noted, many factors contribute to increases in infectious disease. Economic or military forces that cause population shifts create fertile ground for diseases to emerge and spread. Changes in human behavior, whether in sexual practices, the use of IV drugs, or food preferences, affect microbial spread.

Food practices that include handling, cutting, refrigeration, and other treatments to maintain quality also disseminate pathogenic microorganisms and select for those that grow under these conditions. The globalization of food processing and supply centers has created the potential for widespread outbreaks of food-borne microbial diseases originating from a single batch of tainted processed foods or contaminated raw foods, mishandling of food shipments, or distribution of microbe-laden fresh produce. The CDC estimates that food-borne diseases cause approximately 76 million illnesses, 350,000 hospitalizations, and 5,000 deaths each year in the United States alone. Known pathogens are responsible for only 18% of these illnesses, and *Listeria, Salmonella,* and *Toxoplasma* are responsible for 75% of food-related deaths globally. Among the incidences in recent years are the following: (1) the 1994 outbreak of salmonellosis due to contaminated ice cream; (2) the 1996 and 1997 outbreaks of *Cyclospora* infections linked to Guatemalan raspberries; and (3) the periodic outbreaks in recent years of *E. coli* O157:H7 related to consumption of raw or undercooked beef and unpasteurized apple juice (it should be noted that this pathogen causes hemolytic uremic syndrome in children; *see section 39.4*).

As population density increases in cities, the dynamics of microbial exposure and evolution increase in humans themselves. Urbanization often crowds humans and increases exposure to microorganisms. Crowding leads to unsanitary conditions and hinders the effective implementation of adequate medical care, enabling more widespread transmission and propagation of pathogens. In modern societies, crowded workplaces, community-living settings, day-care centers, large hospitals, and public transportation all facilitate microbial transmission. Furthermore,

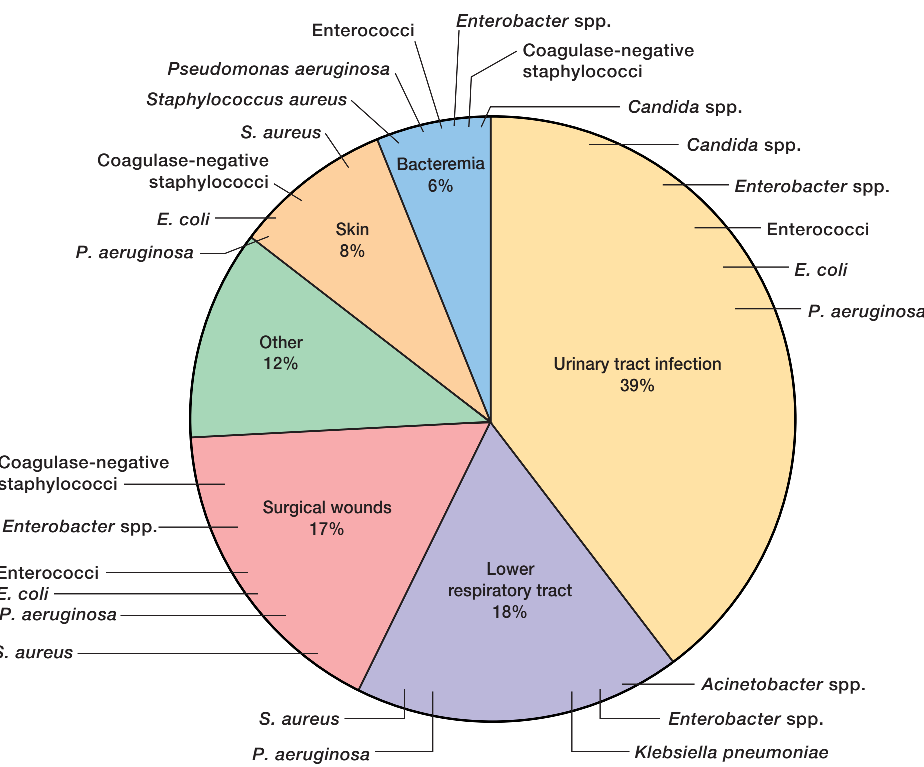

Figure 37.9 Nosocomial Infections. Relative frequency by body site. These data are from the National Nosocomial Infections Surveillance, which is conducted by the Centers for Disease Control and Prevention (CDC).

land development and the exploration and destruction of natural habitats have increased the likelihood of human exposure to new pathogens and may put selective pressures on pathogens to adapt to new hosts and changing environments. The introduction of pathogens to a new environment or host can alter transmission and exposure patterns, leading to sudden proliferation of disease. For example, the spread of Lyme disease in New England probably was due partly to ecological disruption that eliminated predators of deer. An increase in deer and the deer tick populations provided a favorable situation for pathogen spread to humans. Whenever there is alteration of the environment and new environments are created, this may not only confer a survival advantage, but may also increase a pathogen's virulence and alter its drug susceptibility profile. When there are changes in climate or ecology, it should not be surprising to find changes in both beneficial and detrimental microorganisms. Global warming also affects microorganism selection and survival. Finally, mass migrations of refugees, workers, and displaced persons have led to a steady growth of urban centers at the expense of rural areas.

Microbiologists are all too familiar with the development of resistance to antibiotics used in human medicine. The distribution of nosocomial pathogens (**figure 37.9**) has changed throughout the antibiotic era. Hospital acquired infections were dominated early on by staphylococci, which initially responded to penicillin. During subsequent years, the emergence of methicillin-resistant *Staphylococcus aureus* (MRSA) increased from 2% in 1975, to 14% in 1987, and to over 40% in 1999; similar patterns are emerging for penicillin-resistant *Streptococcus pneumoniae. S. aureus* with intermediate resistance to vancomycin began to appear in 1997 and the CDC believes that glycopeptide-resistant *S. aureus* infections are inevitable. Glycopeptide-resistant *Enterococcus faecium* was first reported in the late 1980s; in 1993 nearly 14% of enterococci-associated nosocomial infections were caused by vancomycin-resistant enterococci and that number rose to 25% in 1998. In recent years, gram-positive cocci have reemerged as significant nosocomial pathogens. Newly recognized nosocomial, gram-positive species include *Corynebacterium jeikeium* and *Rhodococcus equi.* The incidences of infections by the gram-negative pathogens *P. aeruginosa* and *Acinetobacter* have increased. With respect to the extended-spectrum β-lactamase-resistant gram-negative bacilli, bacteria such as *Klebsiella pneumoniae, Escherichia coli,* other *Klebsiella* spp., *Proteus* spp., *Morganella* spp., *Citrobacter* spp., *Salmonella* spp., and *Serratia marcescens* are resistant to penicillins; first-generation cephalosporins; and some third-generation cephalosporins such as cefotaxime (Claforan), ceftriaxone (Rocephin), ceftazidime, and aztreonam (Azactam). Newly renamed gram-negative bacterial pathogens include *Burkholderia cepacia* and *Stenotrophomonas maltophilia.*

Without a doubt, the key factors responsible for the rise in drug-resistant pathogens have been the excessive or inappropriate use of antimicrobial therapy and the sometimes indiscriminant

use of broad-spectrum antibiotics. Although the CDC acknowledges that it is too late to solve the resistance problem simply by using antimicrobial agents more prudently, it is no less true that the problem of drug resistance will continue to worsen if this does not occur. Also needed (especially in underdeveloped countries) is a renewed emphasis on alternate prevention and control strategies that prevailed in the years before antimicrobial chemotherapy. These include improved sanitation and hygiene, isolation of infected persons, antisepsis, and vaccination. Drug resistance (pp. 818–20).

One of the paradoxes of modern medicine is that while we are managing and even eradicating some infectious diseases, others are emerging. Immunosuppression, either by another disease agent such as the AIDS virus or by drugs taken upon organ transplantation, increases the number of individuals susceptible to new pathogens. Immunocompromised patients represent an expanding intermediate habitat, providing the opportunity (not available in immunocompetent patients) for a pathogen to adapt to the human host and acquire the capability to circumvent the immune system of a healthy person. These immunocompromised populations can then serve as a reservoir for emerging and reemerging infections, which may eventually spread beyond the confines of institutional settings to the community at large.

In this new millennium, the speed and volume of international travel are major factors contributing to the global emergence of infectious diseases. The spread of a new disease often used to be limited by the travel time needed to reach a new host population. If the travel time was sufficiently long, as when a ship crossed the ocean, the infected travelers would either recover or die before reaching a new population. Because travel by air has obliterated time between exposure and disease outbreak, a traveler can spread virtually any human disease in a matter of hours. Vehicles of human transport, such as aircraft and ships, also transport the infectious agents and their vectors.

It is probably best to view emerging and reemerging pathogens and their diseases as the outcome of many different factors. Because the world is now so interrelated, we cannot isolate ourselves from other countries and continents. Changes in the disease status of one part of the world may well affect the health of the remainder. As Nobel laureate Joshua Lederberg has so eloquently stated, "The microbe that felled one child in a distant continent yesterday can reach your child today and seed a global pandemic tomorrow."

1. Describe how virulence and the mode of transmission may be related. What might cause the development of new human diseases?
2. How would you define emerging or reemerging infectious diseases?
3. What are some of the factors responsible for the emergence or reemergence of pathogens?
4. What are some key factors responsible for the rise in drug-resistant bacteria?

37.9 Control of Epidemics

The development of an infectious disease is a complex process involving many factors, as is the design of specific epidemiological control measures. Epidemiologists must consider available resources and time constraints, adverse effects of potential control measures, and human activities that might influence the spread of the infection. Many times control activities reflect compromises among alternatives. To proceed intelligently, one must identify components of the infectious disease cycle that are primarily responsible for a particular epidemic. Control measures should be directed toward that part of the cycle that is most susceptible to control—the weakest link in the chain.

There are three types of control measures. The first type is directed toward reducing or eliminating the source or reservoir of infection:

1. Quarantine and isolation of cases and/or carriers
2. Destruction of an animal reservoir of infection
3. Treatment of sewage to reduce water contamination
4. Therapy that reduces or eliminates infectivity of the individual

The second type of control measure is designed to break the connection between the source of the infection and susceptible individuals. Examples include general sanitation measures:

1. Chlorination of water supplies
2. Pasteurization of milk
3. Supervision and inspection of food and food handlers
4. Destruction of vectors by spraying with insecticides

The third type of control measure reduces the number of susceptible individuals and raises the general level of herd immunity by immunization. Examples include the following:

1. Passive immunization to give a temporary immunity following exposure to a pathogen or when a disease threatens to take an epidemic form
2. Active immunization to protect the individual from the pathogen and the host population from the epidemic

The Role of the Public Health System: Epidemiological Guardian

The control of an infectious disease relies heavily on a well-defined network of clinical microbiologists, nurses, physicians, epidemiologists, and infection control personnel who supply epidemiological information to a network of local, state, national, and international organizations. These individuals and organizations comprise the public health system. For example, each state has a public health laboratory that is involved in infection surveillance and control. The communicable disease section of a state laboratory includes specialized laboratory services for the examination of specimens or cultures submitted by physicians, the local health department, hospital laboratories, sanitarians, epidemiologists, and others. These groups share their findings with other health agencies in the state, the Centers for Disease Control and Prevention, and the World Health Organization (WHO).

37.10 The Emerging Threat of Bioterrorism

Today, **bioterrorism** (Greek *bios,* life, and terrorism, the systematic use of terror to demoralize, intimidate, and subjugate) is a reality. The Centers for Disease Control and Prevention recently defined bioterrorism as "the intentional or threatened use of viruses, bacteria, fungi, or toxins from living organisms to produce death or disease in humans, animals, and plants." At the end of this past century, Iraq used chemical weapons on Iran and on its own citizens, and concealed a biological weapons program. During this same time period, the hitherto-unknown Japanese cult Aum Shinrikyo used sarin nerve gas in a Tokyo subway. Currently terrorist incidents and hoaxes involving toxic or infectious agents have been on the rise. Somewhere, sometime in the future, terrorists may well threaten to use, or attempt to use, a biological weapon against the United States or another country. Although the arsenal of the terrorist is potentially large, this discussion of bioterrorism focuses only on the biological threats.

Among weapons of mass destruction, biological weapons are more destructive than chemical weapons, including nerve gas. In certain circumstances, biological weapons can be as devastating as a nuclear explosion—a few kilograms of anthrax can kill as many people as a Hiroshima-size nuclear bomb. In 1998, the U.S. government launched the first national effort to create a biological weapons defense. The initiatives include (1) the first-ever procurement of specialized vaccines and medicines for a national civilian protection stockpile; (2) invigoration of research and development in the science of biodefense; (3) investment of more time and money in genome sequencing, new vaccine research, and new therapeutic research; (4) development of improved detection and diagnostic systems; and (5) preparation of clinical microbiologists and the clinical microbiology laboratory as members of the "first responder" team, which is to respond in a timely manner to acts of bioterrorism.

The list of biological agents that could pose the greatest public health risk in the event of a bioterrorist attack is short and includes viruses, bacteria, parasites, and toxins (**table 37.3**). Although short, the list includes agents that, if acquired and properly disseminated, could become a difficult public health challenge in terms of limiting the numbers of casualties and controlling damage.

As noted in section 33.1, vaccination has been the single most cost-effective public health intervention that has shielded populations from a dozen serious and sometimes fatal naturally transmitted illnesses. In evaluating the role of vaccines for protecting civilian populations from bioterrorism, new problems arise. Despite the protective efficacy of vaccines against individual microorganisms, the very high costs and the great difficulties involved in vaccinating large populations, along with the broad spectrum of potential agents, make it impossible to use vaccines to protect a population against bioterrorism.

In the United States, the U.S. Food and Drug Administration has been charged to foster the development of vaccines, drugs and diagnostic products, food supply safeguards, and other measures needed to respond to bioterrorist threats (**table 37.4**). The expected outcomes of these activities include safe and effective products to treat or prevent toxicity of biological and chemical agents; methods to rapidly detect, identify, and decontaminate hazardous microorganisms; a greater ability to ensure the safety of the food supply; and greater capacity to provide appropriate medical care and a public health response.

Table 37.3 Biological Agents Associated with Bioterrorism or Biocrimes

	Traditional Biological Warfare Agents	Agents of Biocrimes and Bioterrorism
Pathogens	Smallpox virus	*Ascaris suum*
	Viral encephalitides	*Bacillus anthracis*
	Viral hemorrhagic fevers	*Coxiella burnetii*
	Bacillus anthracis	*Giardia lamblia*
	Brucella suis	HIV
	Coxiella burnetii	*Rickettsia prowazekii* (typhus)
	Francisella tularensis	*Salmonella typhi*
	Yersinia pestis	*Schistosoma* spp.
		Vibrio cholerae
		Viral hemorrhagic fevers (Ebola)
		Yellow fever virus
		Yersinia enterocolitica
		Yersinia pestis (plague)
Toxins	Botulinum	Botulinum
	Ricin	Cholera endotoxin
	Staphylococcal enterotoxin B	Diphtheria toxin
		Nicotine
		Ricin
		Snake toxin
		Tetrodotoxin
Anticrop agents	Rice blast	
	Rice stem rust	
	Wheat stem rust	

Source: Adapted from the 2000 *NATO Handbook on the Medical Aspects of NBC Defensive Operations.*

1. In what three general ways can epidemics be controlled? Give one or two specific examples of each type of control measure.
2. Name some of the microorganisms that can be used to commit biocrimes. From this list, which two pose the greatest risk for causing large numbers of casualties?
3. Why are biological weapons more destructive than chemical weapons?
4. What kinds of things can be done to defend a population against bioterrorism?

37.11 Global Travel and Health Considerations

From a global health perspective, developed countries such as Australia, the European countries, Israel, New Zealand, and the United States have highly effective public health systems. Approximately 25% of the nearly 6 billion people on our planet

© The McGraw–Hill Companies, 2002

Table 37.4 Activities of the U.S. Food and Drug Administration to Counter Bioterrorism

1. Enhancing the expeditious development and licensure of new vaccines and biological therapeutics through research and review activities—anthrax vaccine and antisera to botulinum toxin, for example
2. Enhancing the timeliness of application reviews of new drugs and biological products and new and existing products
3. Participation in the planning and coordination of public health and medical responses to a terrorist attack involving biological or chemical agent(s)
4. Participation in the development of rapid detection and decontamination for agents of bioterrorism such as *Clostridium botulinum* toxins, *Yersinia pestis,* and *Bacillus anthracis*
5. Ensuring the safety of regulated foods, drugs, medical devices, and biological products; arranging for seizure and disposal of affected products
6. Developing techniques for detection of genetic modifications of microorganisms to make them more toxic or more antibiotic- or vaccine-resistant
7. Rapidly determining a microorganism's sensitivity to drug therapies
8. Determining the mechanism of replication and pathogenicity or virulence of identified microorganisms, including elements that can be transferred to other organisms to circumvent detection, prevention, or treatment
9. Enhancing bioterrorism agent reporting and surveillance capabilities

Earth live in these countries. As a result, of the approximately 12 million deaths in these countries per year, only about 500,000 are due to infectious diseases. Underdeveloped areas such as Africa, Central and South America, India, the New Independent States of the former Soviet Union, and Asia do not have highly developed public health systems and represent the other 75% of the human population. It is in these regions that infectious diseases are the major cause of death; for example, of approximately 38.5 million deaths per year, about 18 million are attributed to infectious microbial diseases.

The high incidence of infectious microbial diseases in underdeveloped countries must be of great concern for people traveling to these destinations. Each year 1 billion passengers travel by air, and over 50 million people from developed countries visit underdeveloped countries. Furthermore, the time required to circumnavigate the globe has decreased from 365 days to fewer than 3 days.

Several kinds of precautions can be taken by individuals to prevent travel-related infectious diseases. Examples include:

1. If one is traveling to an area where malaria is endemic, weekly prophylaxis before entering the area and after leaving the area is recommended.
2. When traveling, individuals often have a sense of anonymity; they may feel less inhibited sexually and place themselves at greater risk of acquiring sexually transmitted diseases. Travelers should recall the benefits of abstinence or protective sexual practices, especially the use of condoms. Hepatitis B vaccine should be administered if it is indicated.
3. Travelers should avoid uncooked food, nonbottled water and beverages, and unpasteurized dairy products. Use bottled water for drinking, making ice cubes, and brushing teeth.
4. Wash hands with soap and water frequently, especially before each meal.
5. To prevent respiratory infections, avoid excessive outdoor activities in areas of heavy air pollution during hot or humid parts of the day. Consider tuberculin skin testing before and after travel.
6. Minimize skin exposure and use repellents to prevent arthropod-borne illnesses (e.g., malaria, dengue, yellow fever, Japanese encephalitis).
7. Avoid skin-perforating procedures (e.g., acupuncture, body piercing, tattooing, venipuncture, sharing of razors).
8. Do not pet or feed animals, especially dogs and monkeys.
9. Avoid swimming or wading in nonchlorinated freshwater.

Vaccinations are one of the most important strategies of prophylaxis in travel medicine. A medical consultation before travel is an excellent opportunity to update routine immunizations. Selection of immunizations should be based on requirements and risk of infection at the travel destination. According to International Health Regulations, many countries require proof of yellow fever vaccination on the International Certificate of Vaccination. Additionally, a few countries still require proof of vaccination against cholera, diphtheria, and meningococcal disease. The basic CDC immunization recommendations for those traveling abroad are presented in **table 37.5.** In the not-too-distant future, travelers will be offered a variety of oral vaccines against the microorganisms causing dengue fever and travelers' diarrhea (e.g., enterotoxigenic *Escherichia coli, Campylobacter, Shigella*); vaccines against malaria and AIDS, the infections causing most deaths in travelers, are much farther in the future.

In addition, a traveler should:

1. Read carefully CDC information about the destination and follow recommendations
2. Begin the vaccination process early
3. Find a travel clinic for information and specialized immunizations
4. Plan ahead when traveling with children or if there are special needs
5. Learn about safe food and water (contaminated food and water are the major sources of stomach or intestinal illness while traveling), protection against insects, and other precautions
6. Prepare for medical emergencies and for nonmedical emergencies such as crime and natural disasters

Table 37.5 Vaccine Recommendations for Travelers Aged 2 Years or Older

For Travelers Aged 2 Years or Older, the Following Immunizations Normally Given During Childhood (*see figure 33.1*) *Should Be Up-to-Date:*

1. Measles, mumps, and rubella (MMR) vaccine—at least 1 dose given on or after 12 months of age
2. Diphtheria, tetanus, and acellular pertussis (DtaP)—4 or 5 doses until age 7; after age 7, 1 dose of adult tetanus and diphtheria (Td) vaccine every 10 years
3. Polio vaccine—at least 3 doses
4. *Haemophilus influenzae* type b (Hib) vaccine—not recommended after 5 years of age
5. Hepatitis B vaccine—3 doses
6. Varicella vaccine (for persons who have never had chickenpox)

In Addition, Depending on the Country, Travelers Should Consider:

1. Influenza (flu) vaccine—recommended for adults 65 years or older and for other high-risk individuals
2. Pneumococcal vaccine—recommended for adults 65 years or older and for other high-risk individuals

Booster or Additional Doses:

1. A booster dose of adult tetanus-diphtheria (Td) recommended every 10 years
2. For persons who have received a complete series of polio vaccine, an additional single dose of inactivated polio vaccine should be given to persons over 18 traveling to the following areas: Africa, Asia, the Middle East, India, and the New Independent States of the former Soviet Union
3. Persons born after 1957 should have a second dose of measles vaccine before traveling abroad

The Following Immunizations Are Recommended Based on Destination:

Immunization	*Destination*
Yellow fever	Africa and South America
Hepatitis A or immune globulin (IG)	To all areas except Japan, Australia, New Zealand, northern and western Europe, and North America (excluding Mexico)
Hepatitis B (if staying 6 or more months)	Southeast Asia, Africa, the Middle East, the islands of South and Western Pacific, and the Amazon region of South America
Typhoid	In all developing countries and for those travelers spending time in areas where food and water precautions are recommended
Meningococcus	Sub-Saharan Africa
Japanese encephalitis or tick-borne encephalitis	Areas of risk
Cholera	The risk of cholera to U.S. travelers is so low that it is questionable whether cholera vaccine is of benefit

Spacing of Immunobiologics

All vaccines (except cholera and yellow fever) may be safely administered simultaneously without any decrease in effectiveness. Immune globulin (IG) may be simultaneously administered at different body locations with an inactivated vaccine such as DtaP, IPV, Hib, and hepatitis A and B vaccines. However, IG diminishes the effectiveness of live virus MMR and varicella vaccines if IG is given simultaneously. IG does not interfere with either oral polio vaccine (OPV) or yellow fever vaccine when given simultaneously.

Women who are pregnant or who are likely to become pregnant within 3 months should not receive MMR or varicella vaccines. Yellow fever vaccine or OPV should be given to pregnant women only if there is a substantial risk of exposure.

Source: *National Center for Infectious Diseases, Travelers' Health,* CDC Vaccine Recommendations (Year 2000).

Space Travel

Space travel entails unique circumstances that influence the health of astronauts, most notably the limitations imposed by zero-gravity environments. The impact of weightlessness on human physiology is substantial and affects various body systems: neurologic, psychologic, vestibular, cardiovascular, musculoskeletal, endocrine, hematologic, and immunologic. For example, recent studies on the immune system have documented a decrease in cell-mediated immunity. The space environment also challenges the growth of microorganisms. Increased antimicrobial resistance has been noted among *E. coli* and *Staphylococcus aureus* bacteria in space, and fungal overgrowths can be a problem because of changes in humidity and pockets of increased condensation aboard spacecraft and space stations.

The primary strategies used by NASA to prevent health-related mishaps associated with space travel include selecting exceptionally fit, healthy crew members and imposing preflight protective quarantines. Access to astronauts is restricted to family members beginning 10 days before departure and a strict 7-day pre-launch quarantine is imposed.

1. Give some examples where population movements affect microbial disease transmission.
2. In addition to vaccinations, what are some additional precautions global travelers should take?
3. What are some of the health problems associated with space travel?

37.12 Nosocomial Infections

Nosocomial infections [Greek *nosos,* disease, and *komeion,* to take care of] result from pathogens that develop within a hospital or other type of clinical care facility and are acquired by patients while they are in the facility. Besides harming patients, nosocomial infections can affect nurses, physicians, aides, visitors, salespeople, delivery personnel, custodians, and anyone who has contact with the hospital. Most nosocomial infections become clinically apparent while patients are still hospitalized; however, disease onset can occur after patients have been discharged. Infections that are incubating when patients are admitted to a hospital are not nosocomial; they are community acquired. However, because such infections can serve as a ready source or reservoir of pathogens for other patients or personnel, they are also considered in the total epidemiology of nosocomial infections.

The Centers for Disease Control and Prevention estimate that 5 to 10% of all hospital patients acquire some type of nosocomial infection. Because approximately 40 million people are admitted to hospitals annually, about 2 to 4 million people may develop an infection they did not have upon entering the hospital. Thus nosocomial infections represent a significant proportion of all infectious diseases acquired by humans.

Nosocomial diseases are usually caused by bacteria, most of which are noninvasive and part of the normal microbiota; viruses, protozoa, and fungi are rarely involved. Figure 37.9 summarizes the most common types of nosocomial infections and the most common nosocomial pathogens.

Source

The nosocomial pathogens that cause diseases come from either endogenous or exogenous sources. Endogenous sources are the patient's own microbiota; exogenous sources are microbiota other than the patient's. Endogenous pathogens are either brought into the hospital by the patient or are acquired when the patient becomes colonized after admission. In either case the pathogen colonizing the patient may subsequently cause a nosocomial disease (e.g., when the pathogen is transported to another part of the body or when the host's resistance drops). If it cannot be determined that the specific pathogen responsible for a nosocomial disease is exogenous or endogenous, then the term autogenous is used. An **autogenous infection** is one that is caused by an agent derived from the microbiota of the patient, despite whether it became part of the patient's microbiota following his or her admission to the hospital.

There are many potential exogenous sources in a hospital. Animate sources are the hospital staff, other patients, and visitors. Some examples of inanimate exogenous sources are food, urinary catheters, intravenous and respiratory therapy equipment, and water systems (softeners, dialysis units, and hydrotherapy equipment).

Control, Prevention, and Surveillance

In the United States nosocomial infections prolong hospital stays by 4 to 13 days, result in over 4.5 billion dollars a year in direct hospital charges, and lead to over 20,000 direct and 60,000 indirect deaths annually. The enormity of this problem has led most hospitals to allocate substantial resources to the development of methods and programs for the surveillance, prevention, and control of nosocomial infections.

All personnel involved in the care of patients should be familiar with basic infection control measures such as isolation policies of the hospital; aseptic techniques; proper handling of equipment, supplies, food, and excreta; and surgical wound care and dressings. To adequately protect their patients, hospital personnel must practice proper aseptic technique and hand-washing procedures, and must wear gloves when contacting mucous membranes, secretions, and "moist body substances." Patients should be monitored with respect to the frequency, distribution, symptomatology, and other characteristics common to nosocomial infections. A dynamic control and surveillance program can be invaluable in preventing many nosocomial infections, patient discomfort, extended stays, and further expense.

The Hospital Epidemiologist

Because of nosocomial infections, all hospitals desiring accreditation by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) must have a designated individual directly responsible for developing and implementing policies governing control of infections and communicable diseases. This individual may be a registered nurse and is known as a hospital epidemiologist, nurse epidemiologist, infection control nurse, infection control practitioner, or a clinical microbiologist/technologist. In larger hospitals, a physician is the hospital epidemiologist and should be trained in infectious diseases. He or she oversees a staff that includes nurse epidemiologists, quality assurance specialists, fellows in infectious disease/hospital epidemiology, and epidemiology technicians. The hospital epidemiologist must meet with an infection control committee composed of various professionals who have expertise in the different aspects of infection control and hospital operation. The infection control committee periodically evaluates laboratory reports, patients' charts, and surveys done by the hospital epidemiologist to determine whether there has been any increase in the frequency of particular infectious diseases or potential pathogens.

Overall, the services provided by the hospital epidemiologist should include at least the following:

1. Research in infection control
2. Evaluation of disinfectants, rapid test systems, and other products
3. Efforts to encourage appropriate legislation related to infection control, particularly at the state level

4. Efforts to contain hospital operating costs, especially those related to fixed expenses such as the DRGs (diagnosis-related groups)
5. Surveillance and comparison of endemic and epidemic infection frequencies
6. Direct participation in a variety of hospital activities relating to infection control and maintenance of employee health
7. Education of hospital personnel in communicable disease control and disinfection and sterilization procedures
8. Establishment and maintenance of a system for identifying, reporting, investigating, and controlling infections and communicable diseases of patients and hospital personnel
9. Maintenance of a log of incidents related to infections and communicable diseases
10. Monitoring trends in the antimicrobial drug resistance of infectious agents

Recently computer software packages have been developed to aid the infection control practitioner. Such packages generate standard reports, cause-and-effect tabulations, and graphics for the daily epidemiological monitoring that must be done.

1. Describe a nosocomial infection.
2. What two general sources are responsible for nosocomial infections? Give some specific examples of each general source.
3. Why are nosocomial infections important?
4. What does a hospital epidemiologist do to control nosocomial infections?

Summary

1. Epidemiology is the science that evaluates the determinants, occurrence, distribution, and control of health and disease in a defined population.
2. Specific epidemiological terminology is used to communicate disease incidence in a given population. Frequently used terms include sporadic disease, endemic disease, hyperendemic disease, epidemic, index case, outbreak, and pandemic.
3. An important tool used in the study of modern epidemiology is statistics.
4. Epidemiological data can be obtained from such factors as morbidity, prevalence, and mortality rates.
5. An infectious disease is caused by microbial agents such as viruses, bacteria, fungi, protozoa, and helminths that can be transmitted from one host to another.
6. The manifestations of an infectious disease can range from mild to severe to deadly, depending on the agent and host.
7. Surveillance is necessary for recognizing a specific infectious disease within a given population. This consists of gathering data on the occurrence of the disease, collating and analyzing the data, summarizing the findings, and applying the information to control measures.
8. Remote sensing and geographic information systems can be used to gather epidemiological data on the environment.
9. A common-source epidemic is characterized by a sharp rise to a peak and then a rapid, but not as pronounced, decline in the number of individuals infected (**figure 37.2**). A propagated epidemic is characterized by a relatively slow and prolonged rise and then a gradual decline in the number of individuals infected.
10. Herd immunity is the resistance of a population to infection and pathogen spread because of the immunity of a large percentage of the individuals within the population (**figure 37.4**).
11. The infectious disease cycle or chain involves the characteristics of the pathogen, the source and/or reservoir of the pathogen, the transmission of the pathogen, the susceptibility of the host, the exit mechanism of the pathogen from the body of the host, and its spread to a new reservoir or host (**figure 37.5**).
12. There are four major modes of transmission: airborne, contact, vehicle, and vector-borne.
13. The degree of virulence may be influenced by the pathogen's preferred mode of transmission. New human diseases may arise and spread because of ecosystem disruption, rapid transportation, human behavior, and other factors.
14. It is now clear that globally, humans will continually be faced with both new infectious diseases and the reemergence of older diseases once thought to be conquered.
15. CDC has defined these diseases as "new, reemerging, or drug-resistant infections whose incidence in humans has increased within the past two decades or whose incidence threatens to increase in the near future" (**figure 37.8**).
16. Many factors characteristic of the modern world undoubtedly favor the development and spread of these microorganisms and their diseases.
17. The public health system consists of individuals and organizations that function in the control of infectious diseases and epidemics.
18. Epidemiological control measures can be directed toward reducing or eliminating infection sources, breaking the connection between sources and susceptible individuals, or isolating the susceptible individuals and raising the general level of herd immunity by immunization.
19. Today bioterrorism is a reality. Terrorist incidents and hoaxes involving toxic or infectious agents have been on the rise.
20. Among weapons of mass destruction, biological weapons are more destructive than chemical weapons. The list of biological agents that could pose the greatest public health risk in the event of a bioterrorist attack is short and includes viruses, bacteria, parasites, and toxins (**table 37.3**).
21. Certain precautions and health considerations should be taken into consideration when traveling globally.
22. Vaccinations are one of the most important strategies of prophylaxis in travel medicine (**table 37.5**).
23. Space travel entails unique considerations that influence the health of astronauts, most notably limitations imposed by zero-gravity environments. The space environment also challenges the growth of microorganisms.
24. Nosocomial infections are infections acquired during hospitalization and are produced by a pathogen acquired during a patient's stay. These infections come from either endogenous or exogenous sources (**figure 37.9**).
25. Hospitals must designate an individual to be responsible for identifying and controlling nosocomial infections. This person is known as a hospital epidemiologist, nurse epidemiologist, infection control nurse, or infection control practitioner.

Key Terms

active carrier *854*
acute carrier *854*
airborne transmission *854*
antigenic drift *852*

Questions for Thought and Review

1. Why is international cooperation a necessity in the field of epidemiology?
2. Are any risks involved in attempting to eliminate a pathogen from the world?
3. Why is a knowledge of statistics important to an epidemiologist?
4. What is the role of the Centers for Disease Control and Prevention in epidemiology?
5. What common sources of infectious disease are found in your community? How can the etiologic agents of such infectious diseases spread from their source or reservoir to members of your community?
6. How could you experimentally prove the cause of an infectious disease?
7. How do epidemiologists recognize an infectious disease within a given population?
8. How could you prove that an epidemic of a given infectious disease was occurring?
9. Why is the infectious disease cycle also referred to as a chain?
10. How can epidemics be controlled?
11. Why are nosocomial infections so important to humans?
12. Why do some epidemiologists believe it is impossible to prevent all nosocomial infections?
13. What is the difference between a fomite and a vector? A reservoir and a source?
14. How can changes in herd immunity contribute to an outbreak of a disease on an island?
15. What is an index case?
16. Where in the world would you expect new human diseases to arise? Why?
17. Contrast mortality due to infectious diseases in developing and developed countries.
18. What are some of the factors that are important in the reemergence of a potential pathogen?
19. Why should we be worried about bioterrorism?
20. What precautions should you take when traveling abroad?

Critical Thinking Questions

1. College dormitories are notorious for outbreaks of flu and other infectious diseases. This is particularly prevalent during final exam weeks. Using your knowledge of the immune response and epidemiology, suggest practices that could be adopted to minimize the risks at such a critical time of the term.
2. Space exploration presents an area of concern. What sort of precautions should have been taken to prevent contamination of the Martian terrain with Earth microorganisms when the Mars Lander touched down on the planet?

CHAPTER 38

Human Diseases Caused by Viruses

These mechanical respirators, also called iron lungs, were used to keep patients alive during the polio epidemics of the 1940s through the mid 1950s. In 1955 Jonas Salk, an American microbiologist, developed the inactivated poliovirus vaccine (IPV) and in 1961, Albert Sabin, an American virologist, developed the oral poliovirus vaccine (OPV). As a result, polio has been eradicated in the United States and iron lungs are part of our history.

Outline

38.1 Airborne Diseases 871
- Chickenpox (Varicella) and Shingles (Zoster) 871
- Influenza (Flu) 872
- Measles (Rubeola) 873
- Mumps 875
- Respiratory Syndromes and Viral Pneumonia 875
- Rubella (German Measles) 875
- Smallpox (Variola) 876

38.2 Arthropod-Borne Diseases 877
- Colorado Tick Fever 878
- Yellow Fever 878

38.3 Direct Contact Diseases 878
- Acquired Immune-Deficiency Syndrome (AIDS) 878
- Cold Sores 884
- Common Cold 884
- Cytomegalovirus Inclusion Disease 885
- Genital Herpes 885
- Human Herpesvirus 6 Infections 887
- Human Parvovirus B19 Infections 887
- Leukemia 887
- Mononucleosis (Infectious) 888
- Rabies 888
- Viral Hepatitides 889

38.4 Food-Borne and Waterborne Diseases 891
- Gastroenteritis (Viral) 891
- Hepatitis A 892
- Hepatitis E 892
- Poliomyelitis 892

38.5 Slow Virus and Prion Diseases 893

38.6 Other Diseases 894
- Warts 894

Concepts

1. Some viruses can be transmitted through the air and directly or indirectly involve the respiratory system. Most of these viruses are highly communicable and cause diseases such as chickenpox, influenza, measles, mumps, respiratory syndromes and viral pneumonia, rubella, and hantavirus pulmonary syndrome.
2. The arthropod-borne diseases are transmitted by arthropod vectors from human to human or animal to human. Examples include the various encephalitides, Colorado tick fever, West Nile encephalitis, and historically important yellow fever.
3. Some viruses are so sensitive to environmental influences that they are unable to survive for significant periods of time outside their hosts. These viruses are transmitted from host to host by direct contact and cause diseases such as AIDS, cold sores, the common cold, cytomegalovirus inclusion disease, genital herpes, human herpesvirus 6 infections, human parvovirus B19 infections, certain leukemias, infectious mononucleosis, human papillomavirus, rabies, and viral hepatitides.
4. Viruses that can be transmitted by food and water and usually either grow in or pass through the intestinal system leave the body in the feces and are acquired through the oral route. Examples of such diseases include viral gastroenteritis, hepatitis A and E, and poliomyelitis.
5. The slow virus diseases represent progressive pathological processes caused by viruses or prions that remain clinically silent during a prolonged period of months or years, after which progressive clinical disease becomes apparent, usually ending months later in profound disability or death. Examples include new variant Creutzfeldt-Jakob disease, kuru, progressive multifocal leukoencephalopathy, Gerstmann-Sträussler-Scheinker syndrome, and subacute sclerosing panencephalitis.
6. One other disease associated with viruses but that does not fit into any of the foregoing categories is warts.

Only once in human history have we witnessed the total eradication of a dreaded disease, and that was smallpox more than two decades ago. Now humanity stands on the brink of a second: the global eradication of polio.

—From UNICEF's Polio Website

Chapters 16, 17, and 18 provide a review of the general biology of viruses and an introduction to basic virology. Chapter 38 continues this coverage by discussing viruses that are pathogenic to humans. Viruses are grouped according to their mode of acquisition and transmission, and viral diseases that occur in the United States are emphasized.

More than 400 different viruses can infect humans. Human diseases caused by viruses are unusually interesting, considering the small amount of genetic information introduced into a host cell. This apparent simplicity belies the severe pathological features, clinical consequences, and death that result from many viral diseases. With few exceptions, only prophylactic or supportive treatment is available. Collectively these diseases are some of the most common and yet most puzzling of all infectious diseases. The resulting frustration is compounded when year after year familiar diseases of unknown etiology or new diseases become linked to virus infections (**table 38.1**).

Table 38.1 Some Examples of Human Viral Diseases Recognized Since 1967

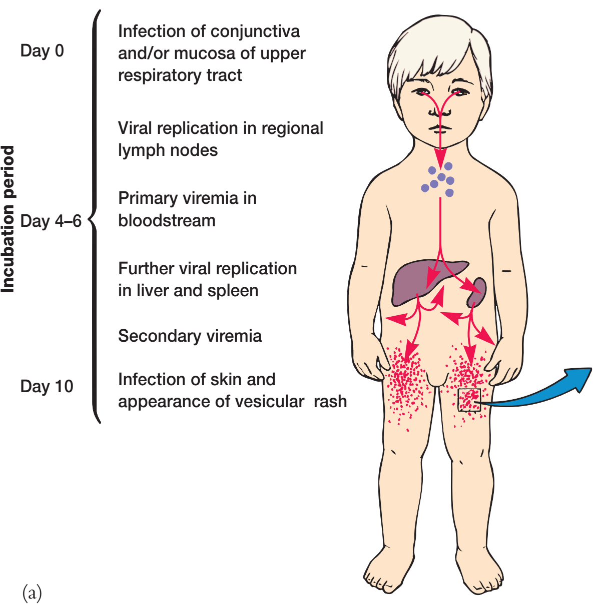
Year	Virus	Disease
1967	Marburg virus	Hemorrhagic fever
1973	Rotavirus	Major cause of infantile diarrhea worldwide
1975	Parvovirus	Aplastic crisis in chronic hemolytic anemia
1977	Ebola virus	Ebola hemorrhagic fever
1977	Hanta virus	Hemorrhagic fever with renal syndrome
1980	Human T-cell lymphotrophic virus 1 (HTLV-1)	Adult T-cell leukemia
1982	Human T-cell lymphotrophic virus 2 (HTLV-2)	Hairy-cell leukemia
1983	Human immunodeficiency virus (HIV)	Acquired immunodeficiency syndrome (AIDS)
1988	Human herpesvirus 6 (HHV-6)	Sixth disease (roseola subitum); may be associated with multiple sclerosis
1988	Hepatitis E	Enterically transmitted non-A, non-B hepatitis
1989	Hepatitis C	Parenterally transmitted non-A, non-B liver infection
1991	Guanarito virus	Venezuelan hemorrhagic fever
1992	Lymphocytic choriomeningitis virus	Central nervous system infection often leading to meningitis, encephalomyelitis, or other diseases
1993	Sin Nombre virus	Adult respiratory distress syndrome
1994	Sabia virus	Brazilian hemorrhagic fever
1994	Ross River virus	Ross River viral disease (Australia)
1995	Human herpesvirus 8 (HHV-8)	Associated with Kaposi's sarcoma in AIDS patients
1996	O'nyoung-nyong virus	Epidemic O'nyong fever
1997	Deer tick virus	Enzootic tick-borne encephalitis
1997	West Nile virus	West Nile fever
1997	Chicken flu (H5N1) virus	Influenzalike illness
1997	Transfusion-transmitted virus (TTV)	Hepatitis
1999	Australian bat lyssavirus (ABL)	ABL infection

38.1 Airborne Diseases

Because air does not support virus growth, any virus that is airborne must have originated from a source such as another human. When humans are the source of the airborne virus, it usually is propelled from the respiratory tract by an individual's coughing, sneezing, or vocalizing.

Chickenpox (Varicella) and Shingles (Zoster)

Chickenpox (varicella) is a highly contagious skin disease primarily of children 2 to 7 years of age. It is estimated that about 4 million cases occur annually in the United States. The causative agent is the varicella-zoster virus, a member of the family *Herpesviridae,* which is acquired by droplet inhalation into the respiratory system. The virus produces at least six glycoproteins that play a role in viral



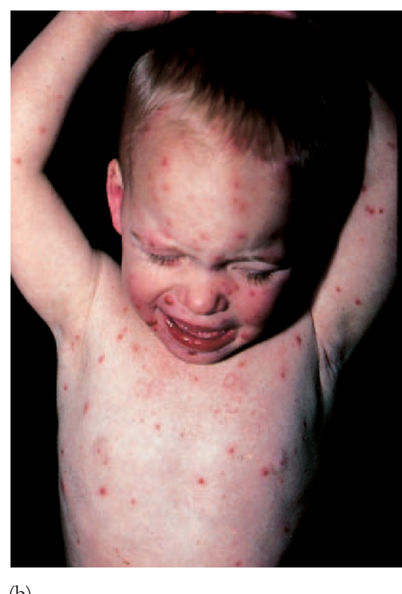


Figure 38.1 Chickenpox (Varicella). (**a**) Pathogenesis. (**b**) Typical vesicular skin rash. This rash occurs all over the body, but is heaviest on the trunk and diminishes in intensity toward the periphery.

attachment to specific receptors on respiratory epithelial cells, and their recognition by the human immune system results in humoral and cellular immunity. Following an incubation period of from 10 to 23 days, small vesicles erupt on the face or upper trunk, fill with pus, rupture, and become covered by scabs (**figure 38.1**). Healing of the vesicles occurs in about 10 days. During this time intense itching often occurs. Chickenpox can be prevented or the infection shortened with an attenuated varicella vaccine (Varivax; *see table 33.1*) or the drug acyclovir (Zovirax or Valtrex).

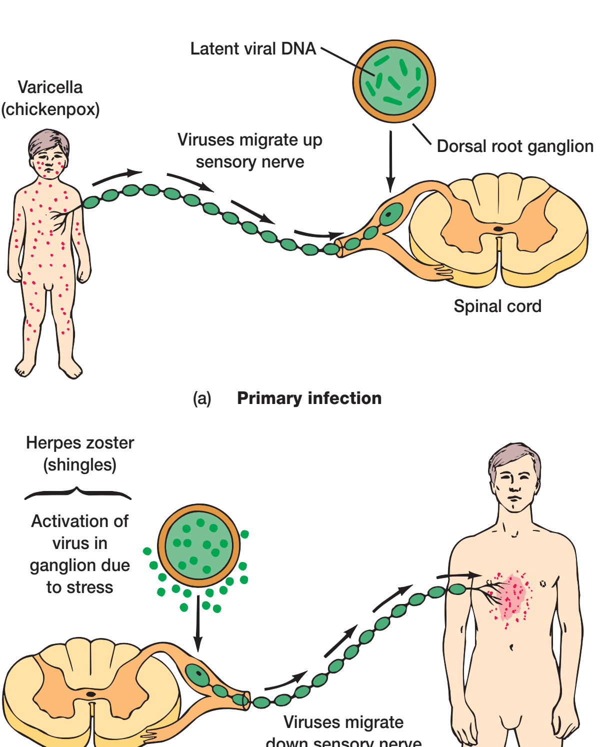
Individuals who recover from chickenpox are subsequently immune to this disease; however, they are not free of the virus, as viral DNA resides in a dormant (latent) state within the nuclei of cranial nerves and sensory neurons in the dorsal root ganglia. This viral DNA is maintained in infected cells but virions cannot be detected (**figure 38.2*a***). When the infected person becomes immunocompromised by such factors as age, AIDS, or psychological or physiological stress, the viruses may become activated (figure 38.2*b*). They migrate down sensory nerves, initiate viral replication, and produce painful vesicles (figure 38.2*c*) because of sensory nerve damage. This syndrome is called **postherpetic neuralgia.** This reactivated form of chickenpox is termed **shingles (zoster).** Most cases occur in people over 50 years of age. Shingles does not require specific therapy; however, in immunocompromised individuals, acyclovir (Zovirax or Valtrex; *see figure 35.14*), vidarabine (Vira-A), or famciclovir (Famvir) are recommended. More than 300,000 cases of zoster occur annually in the United States.

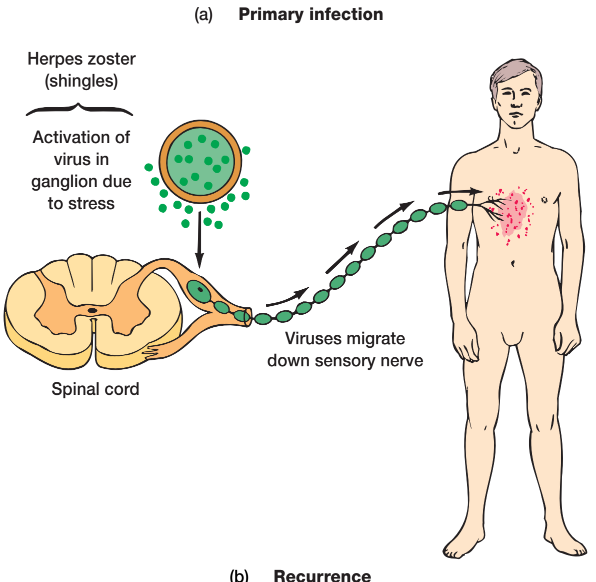
Influenza (Flu)

Influenza [Italian, to be influenced by the stars—*un influenza di freddo*], or the **flu,** is a respiratory system disease caused by orthomyxoviruses. Influenza viruses (*see figures 16.10*i, *16.17*a, b) are classified into A, B, and C groups based on the antigens (H and N) of their protein coats. One unique feature of the influenza viruses is the frequency with which changes in antigenicity occur. These changes are called antigenic variation. If the variation is small, it is called antigenic drift; if it is large, it is called antigenic shift. Antigenic variation occurs almost yearly with the influenza A virus, less frequently with the B virus, and has not been demonstrated with the C virus.

Animal reservoirs are critical to the epidemiology of human influenza. For example, rural China is one region of the world where chickens, pigs, and humans live in close, crowded conditions. Influenza is widespread in chickens; although chickens can't transmit the virus to humans, they can transfer it to pigs. Pigs can transfer it to humans and humans, back to pigs. Recombination between human and avian strains thus occurs in pigs, leading to major antigenic shifts. This explains why influenza continues to be a major epidemic disease and frequently produces worldwide pandemics. The worst pandemic on record occurred in 1918 and killed more than 20 million people. This disaster, traced to the Spanish influenza virus (*see figure 37.7*), was followed by pandemics of Asian flu (1957), Hong Kong flu (1968), and Russian flu (1977). (The names reflect popular impressions of where the episodes began, although all are now thought to have originated in China.)

The virus (*see figures 16.17*a, *18.7, 18.9*) is acquired by inhalation or ingestion of virus-contaminated respiratory secretions. During an incubation period of 1 to 2 days, the virus adheres to the epithelium of the respiratory system (the neuraminidase present in envelope spikes may hydrolyze the mucus that covers the epithelium). The virus attaches to the epithelial cell by its hemagglutinin spike protein, causing part of the cell's plasma membrane to bulge inward, seal off, and form a vesicle (receptor-mediated endocytosis). This encloses the virus in an endosome. The hemagglutinin molecule in the virus envelope undergoes a dramatic conformational change when the endosomal pH decreases.The hydrophobic ends of the





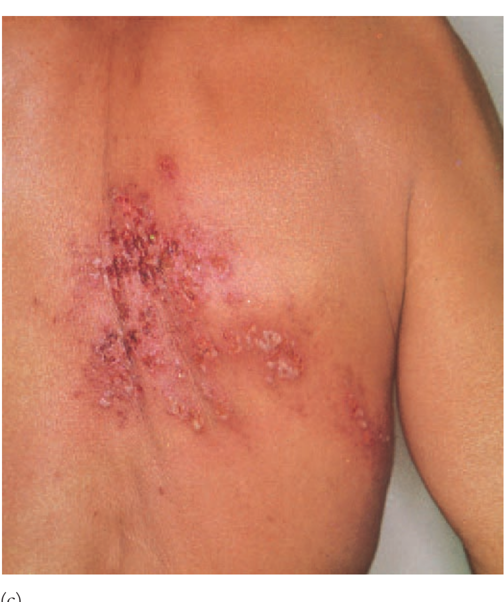


Figure 38.2 Pathogenesis of the Varicella-Zoster Virus. (**a**) After an initial infection with varicella (chickenpox), the viruses migrate up sensory peripheral nerves to their ganglia, producing a latent infection. (**b**) When a person becomes immunocompromised or is under psychological or physiological stress, the viruses may be activated. (**c**) They migrate down sensory nerve axons, initiate viral replication, and produce painful vesicles. Since these vesicles usually appear around the trunk of the body, the name *zooster* (Greek for girdle) was originally used.

hemagglutinin spring outward and extend toward the endosomal membrane. After they contact the membrane, fusion occurs and the RNA nucleocapsid is released into the cytoplasmic matrix.

Influenza is characterized by chills, fever, headache, malaise, and general muscular aches and pains. These symptoms arise from the death of respiratory epithelial cells, probably due to attacks by activated T cells. Recovery usually occurs in 3 to 7 days, during which coldlike symptoms appear as the fever subsides. Influenza alone usually is not fatal. However, death may result from pneumonia caused by secondary bacterial invaders such as *Staphylococcus aureus, Streptococcus pneumoniae,* and *Haemophilus influenzae.* A commercially available identification technique is Directigen FLU-A (an enzyme immunoassay [EIA] rapid test). This test can detect influenza A virus in clinical specimens in less than 15 minutes.

As with many other viral diseases, only the symptoms of influenza usually are treated. However, the antiviral drugs amantadine (Symmetrel) (*see figure 35.14*), rimantadine (Flumadine), zanamivir (Relenza), and oseltamivir (Tamiflu) have been shown to reduce the duration and symptoms of type A influenza if administered during the first two days of illness. All four of these drugs attack the virus directly by plugging the catalytic site of the enzyme neuramidase. With the enzyme inactivated, viral particles can't travel from cell to cell. Aspirin (salicylic acid) should be avoided in children younger than 14 years to reduce the risk of Reye's syndrome (**Box 38.1**). The mainstay for prevention of influenza since the late 1940s has been inactivated virus vaccines, (*see table 33.1*), especially for the chronically ill, individuals over age 65, residents of nursing homes, and health-care workers in close contact with people at risk. Antiviral drugs (pp. 821–22).

Currently three influenza A virus subtypes are epidemic in humans: those with H1N1, H2N1, and H3N2 hemagglutinin and neuraminidase surface glycoproteins. Influenza A infections usually peak in the winter and involve 10% or more of the population, with rates of 50 to 75% in school-age children. Influenza B usually accounts for only 3% of all flu cases in the United States.

Measles (Rubeola)

Measles [**rubeola:** Latin *rubeus,* red] is a highly contagious skin disease that is endemic throughout the world. The measles virus, a member of the genus *Morbillivirus* and the family *Paramyxoviridae.* The measles virus is monotypic, but small variations at the epitope level have been described. The variations are based on genetic variability in the virus genes. Such variations, however, have no effect on protective function since a measles infection still provides a lifelong immunity against reinfection. The virus

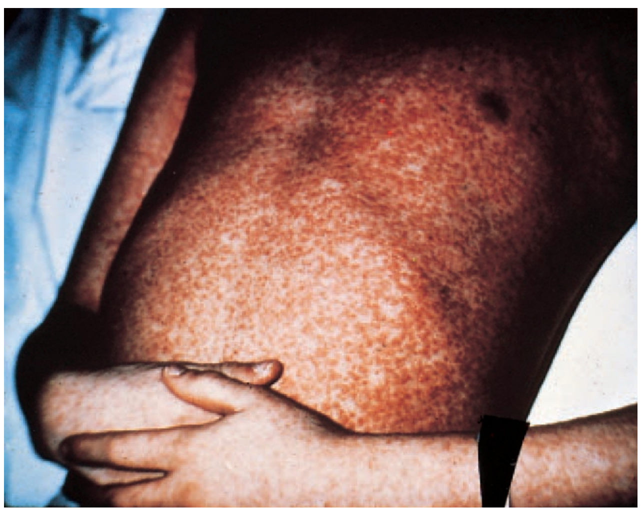
Box 38.1

Reye's and Guillain-Barré Syndromes

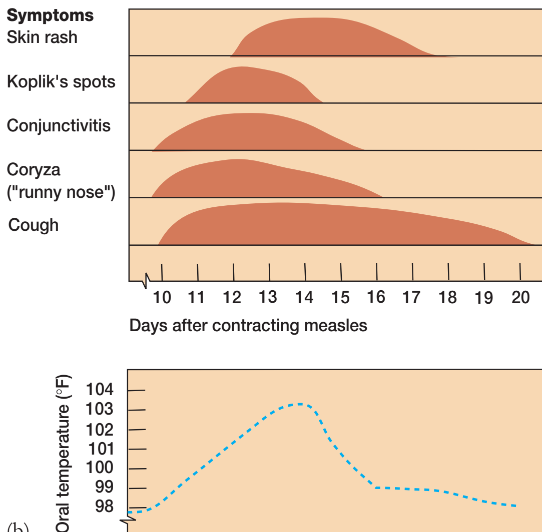
An occasional complication of influenza, chickenpox, and a few other viral diseases in children under 14 years of age is **Reye's syndrome.** After the initial infection has disappeared, the child suddenly begins to vomit persistently and experiences convulsions followed by delirium and a coma. Pathologically, the brain swells with injury to the neuronal mitochondria, fatty infiltration into the liver occurs, blood ammonia is elevated, and both serum glutamic oxaloacetic transaminase (SGOT) and serum glutamic pyruvic transaminase (SGPT) are elevated in the blood. Diagnosis is made by the measurement of the levels of these enzymes and ammonia.

The relationship between the initial viral infection and the brain and liver damage is unknown. Treatment is nonspecific and directed toward reducing intracranial pressure and correcting metabolic and electrolyte abnormalities. Some children who recover have residual neurological deficits—impaired mental capacity, seizures, and hemiplegia (paralysis on one side of the body). Mortality ranges from 10 to 40%. It is suspected that the use of aspirin or salicylate-containing products to lower the initial viral fever increases one's chances of acquiring Reye's syndrome.

Another condition that involves the central nervous system and is associated with influenza infections is **Guillain-Barré syndrome** (sometimes called **French polio**). In this disorder the individual suffers a delayed reaction (usually within 8 weeks) either to the actual virus infection or to vaccines against influenza. The virus or viral antigen in the vaccine damages the Schwann cells that myelinate the peripheral nerves and thus causes demyelination. As a result a prominent feature of this syndrome is a symmetric weakness of the extremities and sensory loss. Fortunately recovery usually is complete because the remaining undamaged Schwann cells eventually proliferate and wrap around the demyelinated nerves.



(a)



(b)

Figure 38.3 Measles (Rubeola). (**a**) The rash of small, raised spots is typical of measles. The rash usually begins on the face and moves downward to the trunk. (**b**) Signs and symptoms of a measles infection.

enters the body through the respiratory tract or the conjunctiva of the eyes. The receptor for the measles virus has recently been shown to be the complement regulator CD46, also known as membrane cofactor protein.

The incubation period is usually 10 to 21 days, and the first symptoms begin about the tenth day with a nasal discharge, cough, fever, headache, and conjunctivitis. Within 3 to 5 days skin eruptions occur as faintly pink maculopapular lesions that are at first discrete, but gradually become confluent (**figure 38.3**). The rash normally lasts about 5 to 10 days. Lesions of the oral cavity include the diagnostically useful bright-red **Koplik's spots** with a bluish-white speck in the center of each. Koplik's spots represent a viral exanthem (a skin eruption) occurring in the form of macules or papules as a result of the viral infection. Very infrequently there occurs a progressive degeneration of the central nervous system called **subacute sclerosing panencephalitis** (table 38.6). No specific treatment is available for measles. The use of attenuated measles vaccine (Attenuvax) or in combination (MMR vaccine; **m**easles, **m**umps, **r**ubella) is recommended for all children (*see table 33.1*). Since public health immunization programs began in 1963, there has been over a 99% decrease in measles cases. Currently there are about 2,000 to 3,000 cases a year in the United States, and 90% of these

Figure 38.4 Mumps. Child with diffuse swelling of the salivary (parotid) glands due to the mumps virus.

are among unvaccinated individuals. In less well-developed countries, however, the morbidity and mortality in young children from measles infection remain high. It has been estimated that measles infects 50 million people and kills about 4 million a year worldwide. Serious outbreaks of measles are still reported in North America and Europe, especially among college students.

Mumps

Mumps is an acute generalized disease that occurs primarily in school-age children. The mumps virus is a member of the genus *Rubulavirus* in the family *Paramyxoviridae.* This virus (*see figure 16.10*b) is a pleomorphic, enveloped virus that contains a helical nucleocapsid composed of negative-sense, single-stranded RNA and three nucleocapsid-associated proteins (L, NP, and P). The virus is transmitted in saliva and respiratory droplets to nonimmune contacts. The portal of entry is the respiratory tract. The most prominent manifestations of mumps are swelling and tenderness of the salivary (parotid) glands 16 to 18 days after infection of the host by the virus (**figure 38.4**). The swelling usually lasts for 1 to 2 weeks and is accompanied by a low grade fever. Meningitis and inflammation of the epididymis and testes (**orchitis**) can be important complications associated with this disease—especially in the postpubescent male. Therapy of mumps is limited to symptomatic and supportive measures. A live, attenuated mumps virus vaccine is available. It usually is given as part of the triple MMR vaccine (*see table 33.1*). There are currently about 3,000 cases of mumps in the United States each year. Recently a few outbreaks have occurred among unvaccinated children in states without a comprehensive school immunization law. Prevention and control involves keeping children with mumps from school or other associated activities for about 2 weeks.

Respiratory Syndromes and Viral Pneumonia

Acute viral infections of the respiratory system are among the most common causes of human disease. The infectious agents are called the acute respiratory viruses and collectively produce a variety of clinical manifestations, including rhinitis (inflammation of the mucous membrane of the nose), tonsillitis, laryngitis, and bronchitis. The adenoviruses, coxsackievirus A, coxsackievirus B, echovirus, influenza viruses, parainfluenza viruses, poliovirus, respiratory syncytial virus, and reovirus are thought to be responsible. It should be emphasized that for most of these viruses there is a lack of specific correlation between the agent and the clinical manifestation—hence the term syndrome. Immunity is not complete, and reinfection is common. The best treatment is rest. Disease syndromes, signs, and symptoms (p. 850); Classification of animal viruses (pp. 399–402; appendix V).

In those cases of pneumonia for which no cause can be identified, viral pneumonia may be assumed if mycoplasmal pneumonia has been ruled out. The clinical picture is nonspecific. Symptoms may be mild, or there may be severe illness and death.

Respiratory syncytial virus (RSV) often is described as the most dangerous cause of lower respiratory infections in young children. In the United States over 90,000 infants are hospitalized each year and over 4,000 die. The RSV is a member of the RNA virus family, *Paramyxoviridae.* It is a negative single-stranded RNA virus that is enveloped with two virally specific glycoproteins as part of the structure. One of them, the large glycoprotein or G, is responsible for the binding of the virus to the host cell; the other, the fusion protein or F, permits fusion of the viral envelope with the host cell plasma membrane, leading to entry of the virus. The F protein also induces the fusion of the plasma membranes of infected cells. RSV thus gets its name from the resulting formation of a syncytium or multinucleated mass of fused cells. The multinucleated syncytia are responsible for inflammation, alveolar thickening, and the filling of alveolar spaces with fluid. The source of the RSV is hand contact and respiratory secretions of humans. Clinical manifestations consist of an acute onset of fever, cough, rhinitis, and nasal congestion. In infants and young children, this often progresses to severe bronchitis and viral pneumonia. Diagnosis is by either Directigen RSV or Test-Pack RSV rapid test kits. The virus is found worldwide and causes seasonal (November to May) outbreaks lasting several months. Treatment is with inhaled ribavirin (Virazole). A recently developed series of antibody (RSV-immune globulin) injections has been shown to reduce the severity of this disease in infants by 75%. Prevention and control consists of isolation for RSV-infected individuals, use of gowns when contact with secretions is likely, and strict attention to good handwashing practices.

Rubella (German Measles)

Rubella [Latin *rubellus,* reddish] was first described in Germany in the 1800s and was subsequently called **German measles.** It is a moderately contagious disease that occurs primarily in children 5 to 9 years of age. It is caused by the rubella virus, a single-stranded RNA virus that is a member of the family *Togaviridae.* Rubella is worldwide in distribution and occurs more frequently during the winter and spring months. This virus is spread in droplets that are

© The McGraw−Hill Companies, 2002

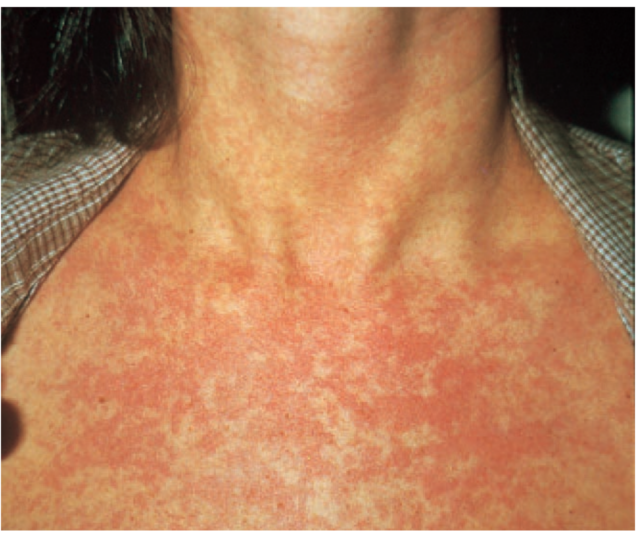


Figure 38.5 German Measles (Rubella). This disease is characterized by a rash of red spots. Notice that the spots are not raised above the surrounding skin as in measles (rubeola; see figure 38.3).

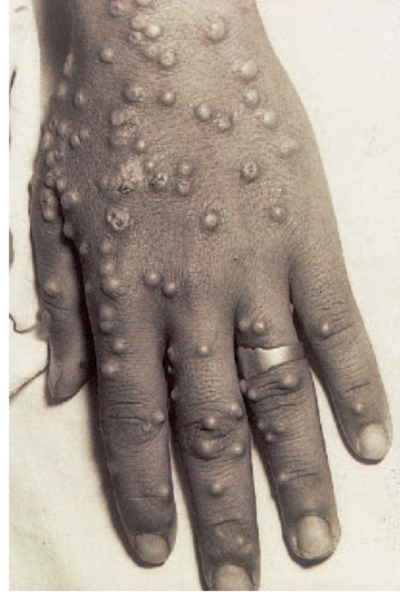

Figure 38.6 Smallpox. Back of hand showing single crop of smallpox vesicles.

shed from the respiratory secretions of infected individuals. Once the virus is inside the body, the incubation period ranges from 12 to 23 days. A rash of small red spots (**figure 38.5**), usually lasting no more than 3 days, and a light fever are the normal symptoms. (This is why rubella is sometimes referred to as the "three-day measles.") The rash appears as immunity develops and the virus disappears from the blood, suggesting that the rash is immunologically mediated and not caused by the virus infecting skin cells.

Rubella can be a disastrous disease (**congenital rubella syndrome**) in the first trimester of pregnancy and can lead to fetal death, premature delivery, or a wide array of congenital defects that affect the heart, eyes, and ears.

Because rubella is usually such a mild infection, no treatment is indicated. All children and women of childbearing age who have not been previously exposed to rubella should be vaccinated. The live attenuated rubella vaccine (part of MMR, *see table 33.1*) is recommended. Because routine vaccination began in the United States in 1969, fewer than 1,000 cases of rubella and 10 cases of congenital rubella occur annually.

Smallpox (Variola)

Smallpox (variola) was once one of the most prevalent of all diseases. The variola virus belongs to the family *Poxviridae.* The virion is large, brick-shaped, and contains a dumbell-shaped core. It is of interest to note that the size of the smallpox virus is slightly larger than the size of the smallest bacteria—for example, *Chlamydia.* The genome inside the core consists of a single linear molecule of double-stranded DNA (*see figure 16.18*).

Variola was transmitted between humans by aerosol or contact. The virus produced a severe fever, prostration, and rash. Toxemia and septic shock led to case fatality rates of up to 30%. The infection progressed from a skin rash that developed through stages of macule, papule, vesicle, and pustule (**figure 38.6**).

Since the advent of immunization with the vaccinia virus, and because of concerted efforts by the World Health Organization, the disease smallpox has been eradicated throughout the world. (The last case from a natural infection occurred in Somalia in 1977.) This was possible because a disease such as smallpox has obvious clinical features, virtually no asymptomatic carriers, only a human reservoir, and a short period of infectivity (3 to 4 weeks). Because humans are the only hosts, the spread of smallpox virus was prevented until no new cases developed, effectively eradicating the disease. The virus, however, is still kept in two locations: the CDC in Atlanta, Georgia, and the Russian State Center for Research on Virology and Biotechnology, Koltsovo, Novosibirsk region, Russia.
Disease (smallpox) and the early colonization of America (p. 363)

1. Why are chickenpox and shingles discussed together? What is their relationship?
2. Briefly describe the course of an influenza infection and how the virus causes the symptoms associated with the flu. Why has it been difficult to develop a single flu vaccine?
3. What are some common symptoms of measles?
4. What are Koplik's spots?
5. What is one side effect that mumps can cause in a young postpubescent male?
6. Describe some clinical manifestations caused by the acute respiratory viruses.
7. Is viral pneumonia a specific disease? Explain.
8. When is a German measles infection most dangerous and why?

Box 38.2

Viral Hemorrhagic Fevers: A Microbial History Lesson

Scientists know of several viruses lurking in the tropics that—with a little help from nature—could wreak far more loss of life than will likely result from the AIDS pandemic. Collectively these viruses produce what is known as the **hemorrhagic fevers.** The viruses are passed among wild vertebrates, which serve as reservoir hosts. Arthropods transmit the viruses among vertebrates, and humans are infected when they invade the environment of the natural host. These diseases, distributed throughout the world, are known by over 70 names, usually denoting the geographic area where they were first described.

Viral hemorrhagic fevers can be fatal. Patients suffer headache, muscle pain, flushing of the skin, massive hemorrhaging either locally or throughout the body, circulatory shock, and death.

Despite the lack of public awareness, recent outbreaks may foreshadow much broader outbreaks in the future. For example, in the late 1960s dozens of scientists in West Germany fell seriously ill, and several died, from a mysterious new disease. Victims suffered from a breakdown of liver function and a bizarre combination of bleeding and blood clots. The World Health Organization traced the outbreak to a batch of fresh monkey cells the scientists had used to grow polioviruses. The cells from the imported Ugandan monkeys were infected with the lethal tropical Marburg virus and the scientists suffered from **Marburg viral hemorrhagic fever.**

In 1977 the *Plebovirus* causing Rift Valley Fever in sheep and cattle moved from these animals into the South African population. The virus, which causes severe weakness, incapacitating headaches, damage to the retina, and hemorrhaging, then made its way to Egypt, where millions of humans became infected and thousands died.

Among the most frightening hemorrhagic outbreak was that of the **Ebola virus hemorrhagic fever** in Zaire and Sudan in 1976. This disease infected more than 1,000 people and left over 500 dead. It became concentrated in hospitals, where it killed many of the Belgian physicians and nurses treating infected patients. A similar outbreak occurred in this same area in 1995 but was quickly contained.

In the United States in 1989, epidemiologists provided new evidence that rats infected with a potentially deadly hemorrhagic virus are prevalent in Baltimore slums. The virus appears to be taking a previously unrecognized toll on the urban poor by causing **Korean hemorrhagic fever.**

In the summer of 1993, reports appeared in the news media about a mysterious illness that had caused over 30 deaths among the Navajo nation in the four-corners area of the southwestern United States. The CDC finally determined the causative agent to be a hantavirus, a negative single-stranded RNA virus that is a member of the family *Bunyaviridae.* Hantaviruses are endemic in rodents, such as deer mice, in many areas of the world. Deer mice shed the virus in their saliva, feces, and urine. Humans contract the disease when they inhale aerosolized particles containing the excreted virus. Throughout Asia and central Europe, hantaviruses cause hemorrhagic fever with renal syndrome in humans. But the type of virus found in the Southwest had not been previously recognized, and no hantavirus anywhere in the world has been associated with the clinical syndrome initially seen among the Navajo; namely, the **hantavirus pulmonary syndrome** in which the virus destroys the lungs. In 1993 the CDC named this virus **pulmonary syndrome hantavirus** (sometimes called the Sin Nombre or no-name virus) and to date, isolated cases have been reported from almost every state. Prevention involves wearing gloves when handling mice and spraying the feces and urine of all mice with a disinfectant.

Although to date, these epidemics have not become global, they do provide a humbling vision of humankind's viral vulnerability. History shows that the life-threatening viral hemorrhagic outbreaks often have arisen when humans moved into unexplored terrain or when living conditions deteriorated in ways that generated new viral hosts. In each case medical and scientific resources have been reactive, not proactive.

Table 38.2 Summary of the Seven Major Human Arbovirus Diseases That Occur in the United States

Disease	Distribution	Vectors	Mortality Rate
California encephalitis (La Crosse)	North Central, Atlantic, South	Mosquitoes (*Aedes* spp.)	Fatalities rare
Colorado tick fever	Pacific Coast (mountains)	Ticks (*Dermacentor andersoni*)	Fatalities rare
Eastern equine encephalitis (EEE)	Atlantic, Southern Coast	Mosquitoes (*Aedes* spp.)	50–70%
St. Louis encephalitis (SLE)	Widespread	Mosquitoes (*Culex* spp.)	10–30%
Venezuelan equine encephalitis (VEE)	Southern United States	Mosquitoes (*Aedes* spp. and *Culex* spp.)	20–30% (children) <10% (adults)
Western equine encephalitis (WEE)	Mountains of the West	Mosquitoes (*Culex* spp.)	3–7%
West Nile encephalitis	Most of Atlantic Coast	Mosquitoes (various spp.)	?

38.2 Arthropod-Borne Diseases

The arthropod-borne viruses (arboviruses) are transmitted by bloodsucking arthropods from one vertebrate host to another. They multiply in the tissues of the arthropod without producing disease, and the vector acquires a lifelong infection. Approximately 150 of the recognized arboviruses cause illness in humans. Diseases produced by the arboviruses can be divided into three clinical syndromes: (1) fevers of an undifferentiated type with or without a rash; (2) encephalitis (inflammation of the brain), often with a high fatality rate; and (3) hemorrhagic fevers, also frequently severe and fatal (**Box 38.2**). **Table 38.2** summarizes the seven major human arbovirus diseases that occur in the United States. For all these diseases, immunity is believed to be

permanent after a single infection. No vaccines are available for the human arthropod-borne diseases listed in table 38.2, although supportive treatment is beneficial.

Colorado Tick Fever

Colorado tick fever is caused by an RNA virus of the genus *Coltivirus.* The tick, *Dermacentor andersoni,* is the main vector that transmits the disease to humans. Ground squirrels, rabbits, and deer are the principal reservoirs. The disease occurs in mountainous regions in western states. Approximately 300 cases are reported annually in the United States, but the actual incidence is probably much higher. After a 3 to 6 day incubation period, there is an abrupt onset of fever, chills, severe headache, photophobia, rash, and muscle pain. These symptoms persist for 5 to 8 days and then disappear; complications are rare. Serology is used to confirm the diagnosis. No specific treatments exist for Colorado tick fever; therapy is limited to supportive care. Prevention involves common tick precautions (*see pp. 910–11*).

Yellow Fever

Yellow fever is not now endemic to the United States, but because of its historical importance, it is briefly discussed here. Yellow fever was the first human disease found to be caused by a virus. (Walter Reed discovered this in 1901.) It also provided the first confirmation (by Carlos Juan Finley) that an insect could transmit a virus. Yellow fever is caused by a flavivirus that is endemic in many tropical areas, such as Mexico, South America, and Africa.

The disease received its first name, yellow jack, because jaundice is a prominent sign in severe cases. The jaundice is due to the deposition of bile pigments in the skin and mucous membranes because of damage to the liver. The disease is spread through a population in two epidemiological patterns. In the urban cycle human-to-human transmission is by *Aedes aegypti* mosquitoes. In the sylvatic cycle the mosquitoes transmit the virus between monkeys and from monkeys to humans (sylvatic means in the woods or affecting wild animals).

Once inside a person the virus spreads to local lymph nodes and multiplies; from this site it moves to the liver, spleen, kidneys, and heart, where it can persist for days. In the early stages of the disease, the infected person experiences fever, chills, headache, and backache, followed by nausea and vomiting. In severe cases the virus produces lesions in the infected organs and hemorrhaging occurs.

There is no specific treatment for yellow fever. Diagnosis is by serology. An active immunity to yellow fever results from an initial infection or from vaccines containing the attenuated yellow fever 17D strain or the Dakar strain virus. Prevention and control of this disease involves vaccination (*see table 33.1*) and control of the insect vector.

38.3 Direct Contact Diseases

Acquired Immune Deficiency Syndrome (AIDS)

It is now recognized that **AIDS (acquired immune deficiency syndrome)** is the first great pandemic of the second half of the twentieth century. First described in 1981 AIDS is the result of an

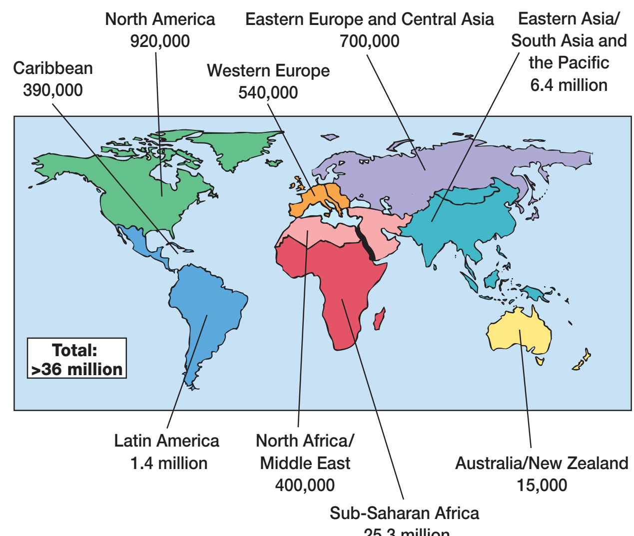

Figure 38.7 Distribution of HIV/AIDS in Adults by Continent or Region. The figure shows data from a 2000 United Nations report. According to recent estimates by the UN, the number of HIV/AIDS cases may be over 36 million. *Source of data: UNAIDS.*

infection by the **human immunodeficiency virus (HIV),** a lentivirus within the family *Retroviridae.* The disease appears to have begun in central Africa as early as the 1950s; HIV may have developed in the human population in the 1930s, or even earlier. Simian immunodeficiency viruses (SIVs) related to HIV-1 and HIV-2, the strains primarily responsible for AIDS, have been isolated from African primates. The SIV from chimpanzees seems to have infected humans and developed into HIV-1; HIV-2 may have arisen from the SIV that infects sooty mangabeys. Once established, HIV-1 spread to the Caribbean and then to the United States and Europe.

Epidemiologically AIDS occurs worldwide (**figure 38.7**). The groups most at risk in acquiring AIDS are (in descending order of risk) homosexual/bisexual men; intravenous (IV) drug users; heterosexuals who have intercourse with drug users, prostitutes (sex trade workers), and bisexuals; transfusion patients or hemophiliacs who must receive clotting factor preparations made from donated blood; and children born of infected mothers. The mortality rate from AIDS is extremely high.

In the United States, AIDS is caused primarily by the HIV-1 virus (some cases result from an HIV-2 infection). This virus is a retrovirus and closely related to HTLV-1, the cause of adult T-cell leukemia, and HTLV-2, which has been isolated from individuals with hairy-cell leukemia (see leukemia, pp. 887–88). HIV-1 is an enveloped lentivirus and a member of the family *Retroviridae* (*see section 18.1*) with a cylindrical core inside its capsid (**figure 38.8**). The core contains two copies of its plus single-stranded RNA genome and several enzymes. Thus far 10 virus-specific proteins have been discovered. One of them, the gp120 envelope protein, participates in HIV-1 attachment to $CD4^+$ cells (T-helper cells; see figure 38.9).

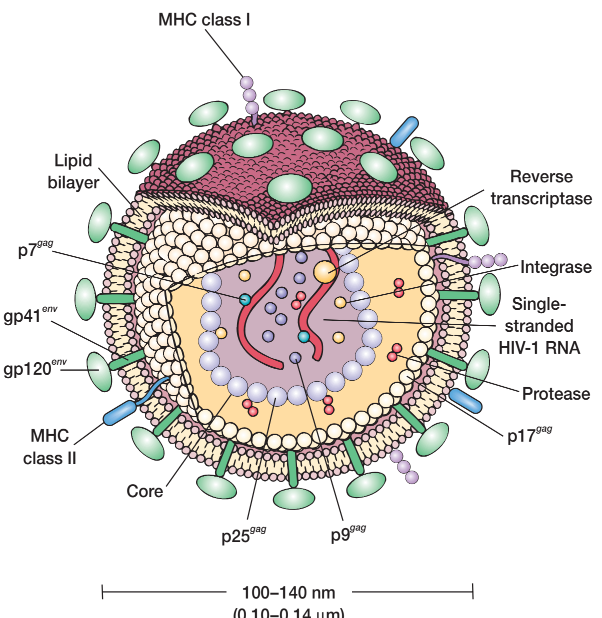

Figure 38.8 Schematic Diagram of the HIV-1 Virion. The HIV-1 virion is an enveloped structure containing 72 external spikes. These spikes are formed by the two major viral-envelope proteins, gp120 and gp41. (Gp stands for glycoprotein—the proteins are linked to sugars—and the number refers to the mass of the protein, in thousands of daltons.) The HIV-1 lipid bilayer is also studded with various host proteins, including class I and class II major histocompatibility complex molecules, acquired during virion budding. The cone-shaped core of HIV-1 contains four nucleocapsid proteins (p25, p17, p9, p7) each of which is proteolytically cleaved from a 53 kDa *gag* precursor by the HIV-1 protease. The phosphorylated p25 polypeptide forms the chief component of the inner shelf of the nucleocapsid, whereas the p17 protein is associated with the inner surface of the lipid bilayer and stabilizes the exterior and interior components of the virion. The p7 protein binds directly to the genomic RNA through a zinc-finger structural motif and together with p9 forms the nucleoid core. The retroviral core contains two copies of the single-stranded HIV-1 genomic RNA that is associated with the various preformed viral enzymes, including the reverse transcriptase, integrase, ribonuclease, and protease.

The AIDS virus is acquired by direct exposure of a person's bloodstream to body fluids (blood, semen, vaginal secretions) containing the virus, through sexual contact, or perinatally from an infected mother to her fetus. It also is possible that a newborn can be infected through breast-feeding. Once inside the body, the virus gp120 envelope protein (figure 38.8) binds to the CD4 glycoprotein plasma membrane receptor on $CD4^+$ T cells, macrophages, dendritic cells, and monocytes (**figure 38.9**). (Dendritic cells are present throughout the body's mucosal surfaces and bear the CD4 protein. Thus it is possible that these are the first cells infected by HIV in sexual transmission.) Recent evidence shows that the virus requires a coreceptor in addition to the CD4 receptor. Macrophage-tropic strains, which seem to predominate early in the disease and infect both macrophages and T cells, require the CCR5 (CC-CKR-5) chemokine receptor protein as well as CD4. A second chemokine coreceptor, called CXCR-4 or fusin, is T cell–tropic and used by an HIV strain that is active at later stages of the infection. This strain induces the formation of syncytia, as described later. Individuals with two defective copies of the *CCR5* gene do not seem to get AIDS; apparently the virus cannot infect their T cells. People with one good copy of the *CCR5* gene do get AIDS but survive several years longer than those with no mutation. Host cell receptors and virion adsorption (pp. 399–403); Replication and transcription in retroviruses (p. 407).

Entry into the host cell begins when the envelope fuses with the plasma membrane, and the virus releases its core and two RNA strands into the cytoplasm. Inside the infected cell, the core protein remains associated with the RNA as it is copied into a single strand of DNA by the RNA/DNA-dependent DNA polymerase activity of the reverse transcriptase enzyme. The RNA is next degraded by another reverse transcriptase component, ribonuclease H, and the DNA strand is duplicated to form a double-stranded DNA copy of the original RNA genome. A complex of the double-stranded DNA (the provirus) and the integrase enzyme moves into the nucleus. Then the proviral DNA is integrated into the cell's DNA through a complex sequence of reactions catalyzed by the integrase (figure 38.9). The integrated provirus can remain latent, giving no sign of its presence. Alternatively the provirus can force the cell to synthesize viral mRNA. Some of the RNA is translated to produce viral proteins by the cell's own ribosomes. Viral proteins and the complete HIV-1 RNA genome are then assembled into new virions that bud from the infected host cell (*see figure 18.10*). Eventually the host cell lyses.

The precise mechanism of AIDS pathogenesis still is not known, and many hypotheses exist. Many believe that AIDS is caused primarily by depletion of T cells and disruption of their function, although the exact mechanisms are unclear. The cytopathic effect may be due to the disruption of plasma membrane permeability and function by excessive virus budding. Free gp120 proteins may bind to CD4 proteins on uninfected cells, making them targets for attack by immune system cells. Infected cells do fuse with other cells to form large, multinucleate syncytia that eventually die, and this may contribute greatly to cell destruction. Possibly, insertion of the provirus DNA into the cell's genome and the transposition of the integrated provirus disrupt cell function and destroy the host T cell. Recent research shows that the virus replicates at a furious pace, about a billion virus particles a day. The immune system often manages to hold it off for years but eventually succumbs in almost all cases.

Once a human's $CD4^+$ cells are infected with HIV-1, four types of pathological changes may ensue. First, a mild form of AIDS may develop with symptoms that include fever, malaise, headache, macular rash, weight loss, lymph node enlargement (lymphadenopathy), oral candidiasis (**figure 38.10*a***), and the presence of antibodies to HIV-1 (**figure 38.11**). These symptoms may occur in the first few months after infection, last for 1 to 3 weeks, and recur. This is known as **AIDS-related complex (ARC)**. ARC develops into a full-blown case of AIDS in an undetermined proportion of cases.

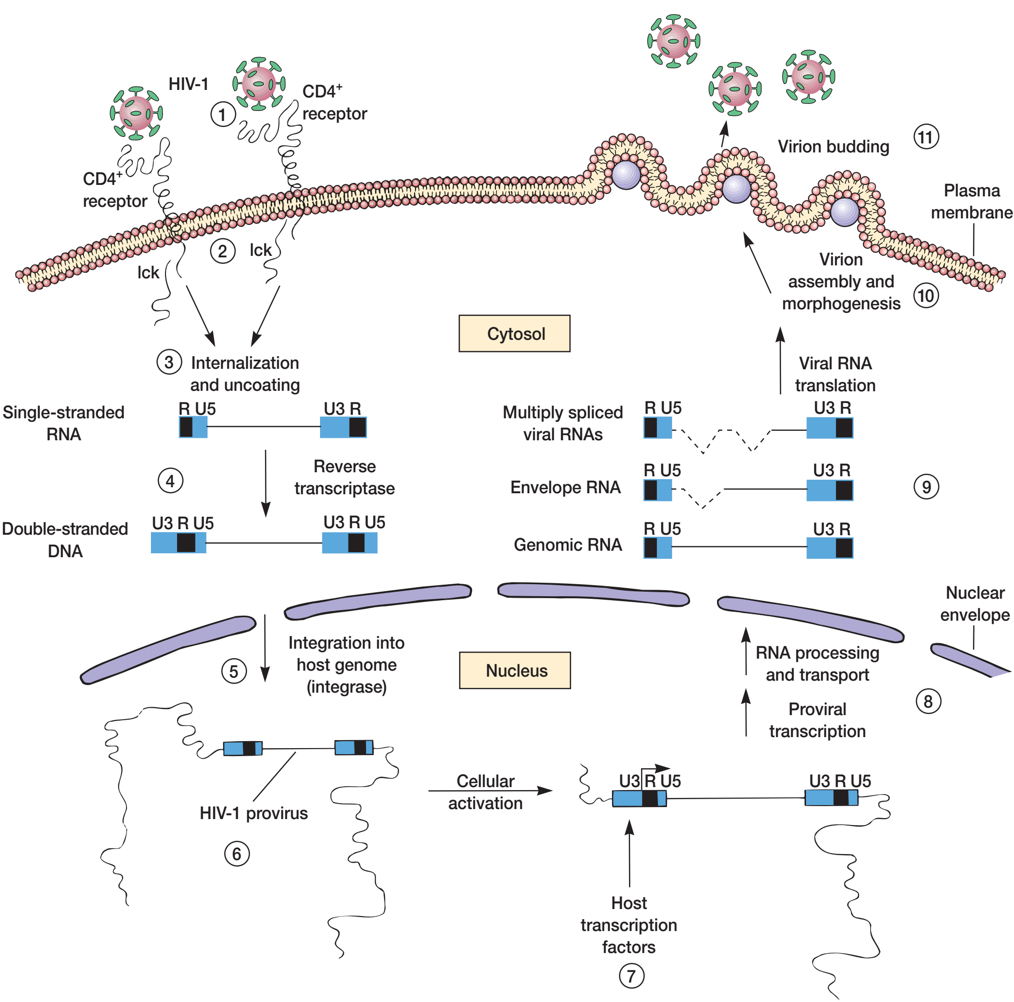

Figure 38.9 **Life Cycle of HIV-1.** (*1*) After interaction of gp120 with the $CD4^+$ cell plasma membrane receptor, gp41-mediated membrane fusion occurs. (*2*) This leads to the entry of HIV-1 into the cell. The lck denotes a lymphoid-specific tyrosine kinase that binds to CD4. (*3*) After internalization and uncoating, reverse transcription of viral RNA begins. (*4*) The double-stranded DNA form of the virus genome is produced in the presence of appropriate host factors. (*5*) The HIV-1 integrase promotes the insertion of this viral DNA duplex into the CD4 cell's genome after the DNA has entered the nucleus. (*6*) This gives rise to the HIV-1 provirus. (*7*) The expression of the HIV-1 gene is stimulated initially by the action of specific inducible and constitutive host transcription factors with binding sites in the long terminal repeat. Their binding leads to the sequential production of various viral mRNAs. (*8*) The first mRNAs produced correspond to the multiply spliced species of approximately 2.0 kilobases encoding *tat, rev,* and *nef* regulatory proteins. (*9*) Subsequently the viral structural proteins are produced, allowing the (*10*) assembly and morphogenesis of the virions. (*11*) The new HIV-1 virions that are produced by viral budding from the host $CD4^+$ cell can then reinitiate the retroviral life cycle by infecting other $CD4^+$ target cells.

(b)

Figure 38.10 Some Diseases Associated with AIDS. (**a**) Candidiasis of the oral cavity and tongue (thrush) caused by *Candida albicans.* (**b**) Kaposi's sarcoma on the arm of an AIDS patient. The flat purple tumors can occur in almost any tissue and are frequently multiple.

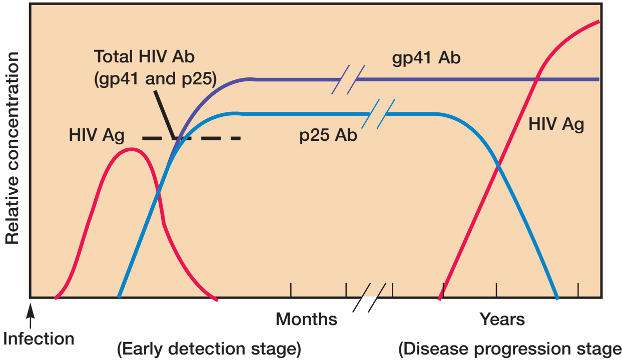

Figure 38.11 The Typical Serological Pattern in an HIV-1 Infection. HIV-1 antigen (HIV Ag) is detectable as early as 2 weeks after infection and typically declines at seroconversion. Seroconversion occurs when HIV-1 antibodies have risen to detectable levels. This usually takes place several weeks to months after the HIV-1 infection. The period between HIV-1 infection and seroconversion often is associated with an acute illness. Whether or not the individual has flulike symptoms, the appearance of circulating HIV-1 antigens typically occurs before IgG antibodies against gp41 and gp25 develop. HIV-1 antigen then usually disappears following seroconversion but reappears in the latter stages of the disease. The reappearance of antigen usually indicates impending clinical deterioration. An asymptomatic HIV-1 antigen-positive individual is six times more likely to develop AIDS within 3 years than a similar individual who is HIV-1 antigen negative. Thus testing for the presence of the HIV-1 antigen assists clinicians in monitoring the progression of the disease.

Second, a true case of AIDS can develop directly upon infection. The mean interval between HIV infection and the onset of AIDS appears to be about 8 to 10 years, although it varies considerably with each individual. At first, a person's immune system responds to the HIV-1 infection by manufacturing HIV-1 antibodies, but not in sufficient quantities to stop the viral attack. The virus becomes established within primarily $CD4^+$ T-helper cells, and HIV accumulates in lymphoid organs in large quantities even before symptoms appear. Initially, $CD4^+$ T-helper cells proliferate abnormally in the lymph nodes. Thereafter the lymph nodes' internal structure collapses due to viral replication. This leads to a decline in the number of lymphocytes within the lymph nodes and results in a selective depletion of the $CD4^+$ T-cell subset that is critical to the propagation of the entire T-cell pool. When this $CD4^+$ population declines, interleukin-2 (IL-2) production also decreases. Because IL-2 stimulates the production of T cells in general, the whole T-cell population may decline. This leaves the infected person open to opportunistic infections: invasion by pathogens that proliferate widely only because the immune system is defective.

It should be noted that factors other than direct T-cell destruction also may be involved in AIDS pathogenesis. HIV may reduce the immune response by destroying or disabling dendritic cells, which present foreign antigens to T cells. HIV also mutates exceptionally rapidly and thus could evade and eventually overwhelm the immune system. HIV may disrupt the balance between different types of T-helper cells and consequently decrease the killer T-cell population. It is possible that several different mechanisms contribute to T-cell destruction.

New findings suggest still another potential mechanism for the depletion of $CD4^+$ cells (**figure 38.12**). In HIV-infected individuals the loss of $CD4^+$ cells is associated with lymphocyte activation; however, this activation does not result in cell proliferation, as it does normally, but rather in cell death by a mechanism known as programmed cell death [**apoptosis;** Greek "a falling off" from *apo,* off, and *ptosis,* fall].

In 1993 the CDC revised its definition of AIDS to include all HIV-infected persons who have fewer than 200 $CD4^+$ cells per μl or a $CD4^+$ cell percentage of total lymphocytes of less than 14. The reason for this definition is that the development of a particular opportunistic infection is related to the concentration of $CD4^+$ cells in

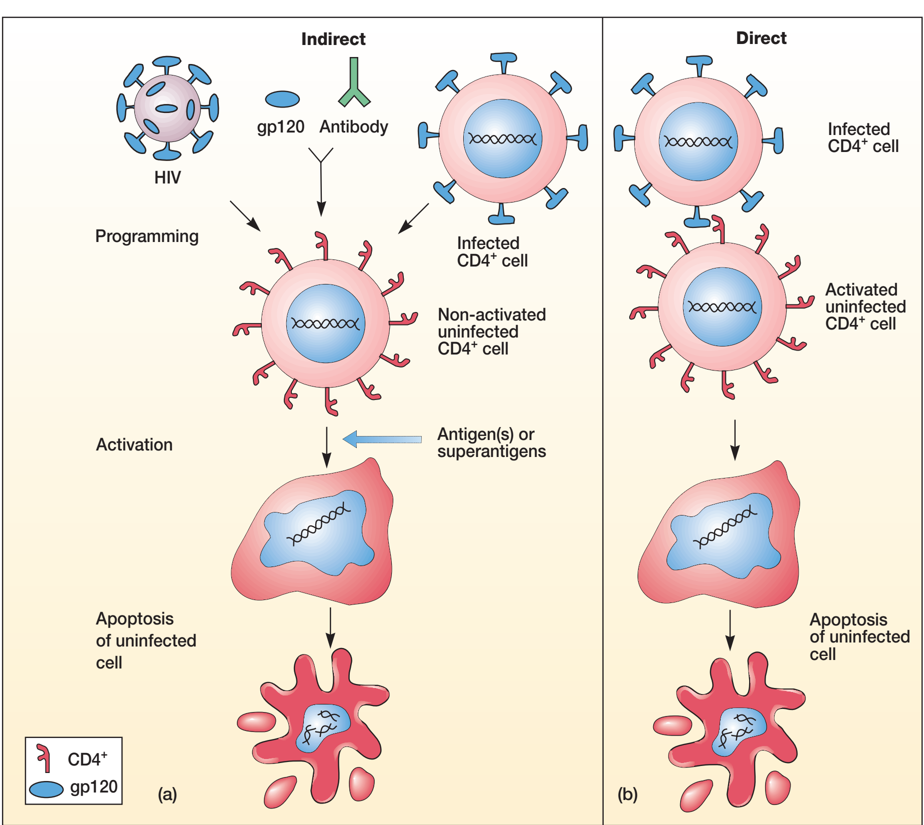

Figure 38.12 Apoptosis and AIDS. Apoptosis is a homeostatic physiological suicide mechanism in which cell death occurs naturally during normal tissue turnover. Usually apoptosis occurs after activation of a calcium-dependent endogenous endonuclease. Cells undergoing apoptosis display profound structural changes such as a decrease in cell volume, blebbing of the plasma membrane, and nuclear fragmentation. The nuclear DNA is cleaved into short oligonucleosomal length DNA fragments. The dying cell sheds small membrane-bound apoptotic bodies, which are phagocytosed and digested. (**a**) There may be several ways in which an HIV infection can indirectly trigger apoptosis. In all cases an initial event would program or prime the target cell so that apoptosis would be triggered by the binding of antigens or superantigens to the cell's T-cell receptors. Possibly the external gp120 envelope glycoprotein of the HIV virion binds to the CD4 protein on lymphocytes and programs the lymphocyte. A combination of free gp120 and antibodies to gp120 also could stimulate programmed cell death. First, the gp120 would bind to CD4 receptors. Then antibodies would attach to the gp120 and cause clustering of the receptors, thus priming the uninfected $CD4^+$ cell. It also is possible that binding of the infected cell's surface gp120 proteins to the CD4 receptors on an uninfected cell will program the uninfected cell for apoptosis in response to antigens. (**b**) Apoptosis may be directly triggered in an uninfected cell. The gp120 envelope proteins on the surface of an infected cell may combine with the CD4 proteins of an uninfected cell and directly stimulate programmed cell death without activation by antigens.

the blood. Healthy individuals have about 1,000 such cells in every μl of blood. In HIV-1 infected individuals, the number declines by an average of about 40 to 80 cells per μl each year. When the $CD4^+$ cell count falls to between 400 and 200 per μl, the first opportunistic infections and disease processes usually appear (**table 38.3**). Examples of such opportunistic infections and diseases include *Pneumocystis carinii* pneumonia; *Mycobacterium avium-intracellulare* pneumonia (*see pp. 902–3*); toxoplasmosis; herpes zoster infection (figure 38.2*b*); chronic diarrhea caused by *Cyclospora;* cryptococcal meningitis; *Histoplasma capsulatum* infection; and tuberculosis (*see figure 39.7*).

The third main type of disease caused by HIV-1 involves the central nervous system since virus-infected macrophages can cross the blood-brain barrier. The classical symptoms of central nervous system disease in AIDS patients are headaches, fevers, subtle cognitive changes, abnormal reflexes, and ataxia (irregularity of muscular action). Dementia and severe sensory and motor changes characterize more advanced stages of the disease. Autoimmune neuropathies, cerebrovascular disease, and brain tumors also are common. Histological changes include inflammation of neurons, nodule formation, and demyelination. All evidence indicates that these neurological changes are correlated with higher levels of HIV-1

Table 38.3 Disease Processes Associated with AIDS

Candidiasis of bronchi, trachea, or lungs
Candidiasis, esophageal
Cervical cancer, invasive
Coccidioidomycosis, disseminated or extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month's duration)
Cyclospora, diarrheal disease
Cytomegalovirus disease (other than liver, spleen, or lymph nodes)
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy, HIV-related
Herpes simplex: chronic ulcer(s) (>1 month's duration); or bronchitis, pneumonitis, or esophagitis
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (>1 month's duration)
Kaposi's sarcoma
Lymphoma, Burkitt's (or equivalent term)
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary, of brain
Mycobacterium avium complex or *M. kansasii*
Mycobacterium tuberculosis, any site
Mycobacterium, other species or unidentified species
Pneumocystis carinii pneumonia
Pneumonia, recurrent
Progressive multifocal leukoencephalopathy
Salmonella septicemia, recurrent
Toxoplasmosis of brain
Wasting syndrome due to AIDS

antigen (figure 38.11) and/or the HIV-1 genome in central nervous system tissue. In AIDS dementia, macrophages and glial cells (supporting cells of the nervous system) are primarily infected and bud new viruses. However, it is unlikely that direct infection of these cells by HIV-1 is responsible for the symptoms. More probably the symptoms arise through either the secretion of viral proteins or viral induction of cytokines that bind to glial cells and neurons. HIV-1 induction of interleukin-1 and tumor necrosis factor-α (TNF-α) may stimulate further viral reproduction and the induction of other cytokines (e.g., interleukin-6, granulocyte-macrophage colony-stimulating factor [GMCSF]). IL-1 and TNF-α in combination with IL-6 and GMCSF could account for the many clinical and histopathological findings in the central nervous system of AIDS individuals.

The fourth result of an HIV infection is cancer. Individuals infected with HIV-1 have an increased risk of three types of tumors: (1) Kaposi's sarcoma (figure 38.10*b*), (2) carcinomas of the mouth and rectum, and (3) B-cell lymphomas or lymphoproliferative disorders. It seems likely that the depression of the initial immune response enables secondary tumor-causing agents to initiate the cancers.

In 1994 it was discovered that Kaposi's sarcoma–associated herpesvirus (KSHV, also known as human herpesvirus 8, or HHV-8) is a virus that is consistently present in Kaposi's sarcoma and in primary effusion (body cavity–based) lymphomas. These cancers occur most frequently in AIDS patients. KSHV is a gamma herpesvirus with homology to herpesvirus saimiri and Epstein-Barr virus, both of which can transform lymphocytes.

The laboratory diagnosis of AIDS can be by viral isolation and culture or by using assays for viral reverse transcriptase activity or viral antigens (figure 38.11). However, diagnosis is best accomplished through the detection of specific anti-HIV antibodies in the blood. These antibodies may be detected by GENIE or HIVAG-1 (Abbott) rapid tests, the SUDS (Murex) 10 minute assay, enzyme-linked immunoabsorbent assay, indirect immunofluorescence, immunoblot (Western Blot), and radioimmunoprecipitation methods. The most sensitive HIV assay employs the polymerase chain reaction (*see pp. 326–27*). PCR can be used to amplify and detect tiny amounts of viral RNA and cDNA in virions or infected host cells. With proper procedures quantitative PCR assays will provide an estimate of a patient's viral load. This is particularly significant because the level of virions in the blood, as well as the concentration of $CD4^+$ cells, is very predictive of the clinical course of the infection. The probable time to development of AIDS can be estimated from the patient's blood virion level and $CD4^+$ cell count.

At present there is no complete cure for AIDS. Primary treatment is directed at reducing the viral load and disease symptoms, and at treating opportunistic infections and malignancies. The antivirals currently approved for use in HIV disease are of three types. (1) Most reverse transcriptase inhibitors are nucleoside analogues that inhibit the enzyme reverse transcriptase as it synthesizes DNA. Examples include AZT or zidovudine (Retrovir), didanosine (Videx), ddC or zalcitabine (HIVID), stavudine (Zerit), and lamivudine or 3TC (Epivir). (2) The nonnucleoside inhibitors of reverse transcriptase include delavirdine (Rescriptor) and nevirapine (Viramune). (3) The protease inhibitors work by blocking the activity of the HIV protease and thus interfere with virion assembly. Examples include indinavir (Crixivan), ritonavir (Norvir), nelfinavir (Viracept), and saquinavir (Invirase). The most successful treatment approach is to use drug combinations. An effective combination is a cocktail of AZT, lamivudine, and a protease inhibitor such as ritonavir. In many patients the virus disappears from the patient's blood with proper treatment and drug-resistant strains do not seem to arise. Recently it has been discovered that HIV is dormant in the memory T cells, survives the drug cocktail, and is capable of reactivation. Thus patients cannot be completely cured with this drug treatment protocol. It should be noted that side effects can be very severe, and not everyone can tolerate the drugs. If the treatment is not started soon enough, the immune system does not fully recover after HIV levels have fallen.

Another avenue of current research is the development of a vaccine that can (1) stimulate the production of neutralizing antibodies which can bind to the virus envelope and prevent it from entering host cells, and (2) promote the destruction of those cells already infected with the virus. The production of an effective vaccine, if possible, is not yet in sight. One difficulty is that the envelope proteins of the virus (figure 38.8) continually change their antigenic properties.

Prevention and control of AIDS involves screening of blood and heat treatment of blood products to destroy the virus. Education and protected sexual behavior and practices, including the use of

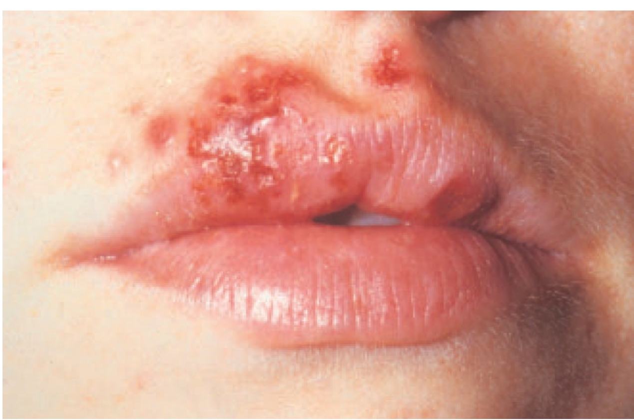

Figure 38.13 **Cold Sores.** Herpes simplex fever blisters on the lip, caused by herpes simplex type 1 virus.

condoms, are keys to comprehensive community-based prevention programs. Education of intravenous drug users concerning the need to avoid sharing needles and syringes is also very important in prevention programs. It must be emphasized that protected sexual behavior and the use of condoms is safer but not totally safe. The only absolute protection against AIDS and other sexually transmitted diseases is abstinence and completely monogamous relationships.

Cold Sores

Cold sores or **fever blisters (herpes labialis)** are caused by the herpes simplex virus type 1 (HSV-1). Like all herpesviruses, it is a double-stranded DNA virus with an enveloped, icosahedral capsid. The term herpes is derived from the Greek word meaning "to creep," and clinical descriptions of herpes labialis (lips) go back to the time of Hippocrates (circa 400 B.C.). Transmission is through direct contact of epithelial tissue surfaces with the virus (*see figure 18.5*). A blister(s) develops at the inoculation site (**figure 38.13**) because of host- and viral-mediated tissue destruction. Most blisters involve the epidermis and surface mucous membranes of the lips, mouth, and gums (**gingivostomatitis**). The blisters generally heal within a week. However, after a primary infection, the virus travels to the trigeminal nerve ganglion, where it remains in a latent state for the lifetime of the infected person. Stressful stimuli such as excessive sunlight, fever, trauma, chilling, emotional stress, and hormonal changes can reactivate the virus. Once reactivated, the virus moves from the trigeminal ganglion down a peripheral nerve to the border of the lip or other parts of the face to produce another fever blister. Primary and recurring infections also may occur in the eyes, causing **herpetic keratitis** (inflammation of the cornea)—currently a major cause of blindness in the United States. The drugs vidarabine (Vira-A) and acyclovir (Zovirax) are effective against cold sores. By adulthood, 70 to 90% of all people in the United States have been infected and have type 1 herpes antibodies. The "gold standard" for the detection of herpes is cell culture. However, cell culture requires up to 14 days for results. The rapid detection of herpes simplex virus (HSV) antigen is by several enzyme immunoassay kits (HERPCHEK, VIDAS, IDEIA, SureCell). This rapid test is especially useful in cases of pregnant women with genital infections and individuals who are particularly susceptible to severe infections.

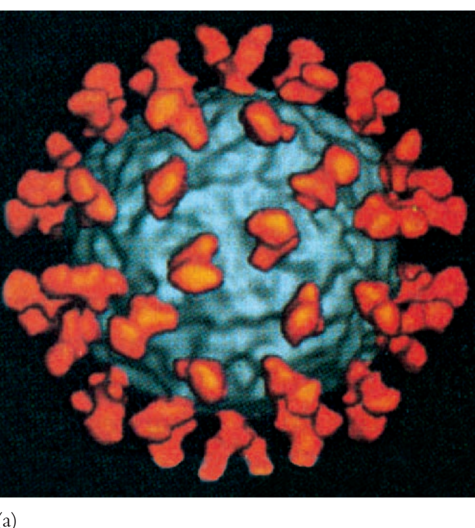
Common Cold

The **common cold** [**coryza:** Greek *koryza,* discharge from the nostrils] is one of the most frequent infections experienced by humans of all ages. About 50% of the cases are caused by rhinoviruses [Greek *rhinos,* nose], single-stranded RNA viruses in the family *Picornaviridae* (*see figure 16.10*k). There are over 115 distinct serotypes, and each of these antigenic types has a varying capacity to infect the nasal mucosa and to cause a cold. In addition, immunity to many of them is transitory. Several other respiratory viruses are also associated with colds (e.g., coronaviruses and parainfluenza viruses). Thus colds are common because of the diversity of rhinoviruses, the involvement of other respiratory viruses, and the lack of a durable immunity.

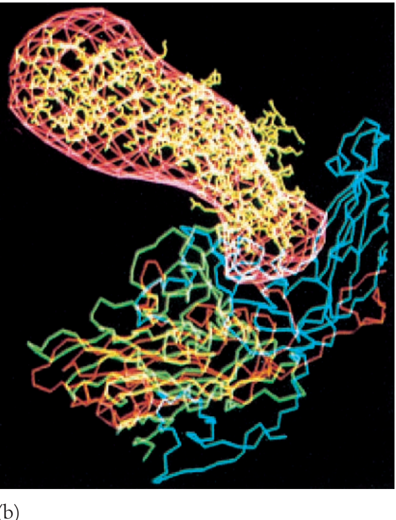
Rhinoviruses provide an excellent example of the medical relevance of research on virus morphology. The complete rhinovirus capsid structure has recently been elucidated with the use of X-ray diffraction techniques. The results help explain rhinovirus resistance to human immune defenses. Human antibodies against the virus combine with four types of surface proteins. Unfortunately there are at least 89 variants of these four antigens, making the production of a cold vaccine from them unlikely. The structural studies have shown that the site that recognizes and binds to cell surface molecules during infection lies at the bottom of a surface cleft about 250 nm deep and 1.2 to 3 nm wide. Thus the binding site is well protected from the immune system while it carries out its functions, and the preparation of a vaccine directed against the binding site is not feasible. Possibly drugs that could fit in the cleft and interfere with virus attachment can be designed.

Viral invasion of the upper respiratory tract is the basic mechanism in the pathogenesis of a cold. The virus enters the body's cells by binding to the adhesion molecule ICAM-1 (**figure 38.14**). The clinical manifestations include the familiar nasal stuffiness and/or partial obstruction, sneezing, scratchy throat, and a watery discharge from the nose. The discharge becomes thicker and assumes a yellowish appearance over several days. General malaise is commonly present. The disease usually runs its course in about a week. Diagnosis of the common cold is made from observations of clinical symptoms. There are no procedures for direct examination of clinical specimens or for serological diagnosis.

The source of the cold viruses may be infected individuals excreting viruses in nasal secretions, airborne transmission over short distances by way of moisture droplets, or transmission on contaminated hands or fomites. Epidemiological studies of rhinovirus colds have shown that the familiar explosive, noncontained sneeze (*see figure 37.6*) may not play an important role in virus spread. Rather, hand-to-hand contact between a rhinovirus "donor" and a susceptible "recipient" is more likely. The common cold occurs worldwide with two main seasonal peaks, spring and early autumn. Infection is most common early in life and generally decreases with an increase in age. Nothing is available for



(a)



(b)

Figure 38.14 Role of an Integrin (Intercellular Adhesion Molecule-1) in Rhinovirus Uptake Into Cells of the Upper Respiratory Tract. Rhinoviruses are a large family of viruses that are the single major cause of acute respiratory infections in humans. ICAM-1 (intercellular adhesion molecule-1) has been identified as the cell surface receptor for the majority of these rhinoviruses. (**a**) In this computer-generated model, the virus-binding portion of ICAM-1 is shown in orange-red attaching to a rhinovirus (gray icosahedral protein capsid in the center). (**b**) This diagram indicates how the rhinovirus surface proteins (shown in blue-green) bind to the ICAM-1 molecule (red-yellow).

treating the common cold except additional rest, extra fluids, and the use of aspirin for alleviating local and systemic discomfort.

Cytomegalovirus Inclusion Disease

Cytomegalovirus inclusion disease is caused by the human cytomegalovirus (HCMV), a member of the family *Herpesviridae.* The virus contains a core with double-stranded DNA, an icosahedral capsid, and a phospholipid-rich envelope. Most people become infected with this virus at some time during their life; in the United States, as many as 80% of individuals older than 35 years have been exposed to this virus and carry a lifelong infection. Although most HCMV infections are asymptomatic, certain patient groups are at risk to develop serious illness and long-term effects from an HCMV infection. For example, this virus remains the leading cause of congenital virus infection in the United States, a significant cause of transfusion-acquired infections, and a frequent contributor to morbidity and mortality among organ transplant recipients and immunocompromised individuals (especially AIDS patients). Because the virus persists in the body, it is shed for several years in saliva, urine, semen, and cervical secretions.

The HCMV can infect any cell of the body, where it multiplies slowly and causes the host cell to swell in size—hence the prefix cytomegalo, which means "an enlarged cell." Infected cells contain the unique **intranuclear inclusion bodies** and cytoplasmic inclusions (**figure 38.15**). In fatal cases, cell damage is seen in the gastrointestinal tract, lungs, liver, spleen, and kidneys. Normally cytomegalovirus inclusion disease symptoms resemble those of infectious mononucleosis.

Laboratory diagnosis is by viral isolation from urine, blood, lung, semen, or tissue. Serological tests (e.g., immunofluorescence, complement fixation, ELISA, and immunohistologic staining) and a rapid test kit (CMV-vue kit) also are available.

Epidemiologically the virus has a worldwide distribution, especially in developing countries where infection is universal by childhood. The prevalence of this disease increases with a lowering of socioeconomic status and hygienic practices. The only drugs available, ganciclovir (Cytovene-IV) and cidofovir (Vistide), are used only for high-risk patients. Infection can be prevented by avoiding close personal contact (including sexual) with an actively infected individual. Transmission by blood transfusion or organ transplantation can be avoided by using blood or organs from seronegative donors.

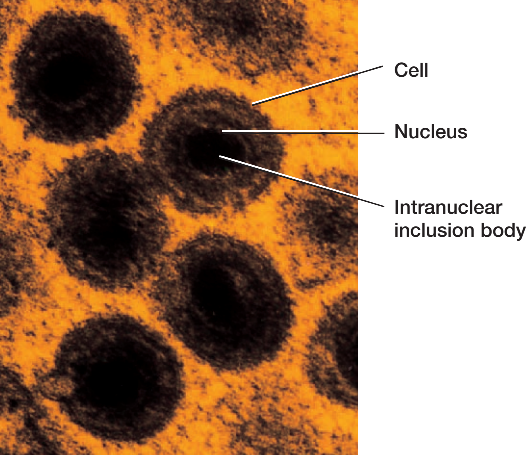


Figure 38.15 Cytomegalovirus Inclusion Disease. Electron micrograph of a single animal cell infected with the cytomegalovirus (×66,000). The intranuclear inclusion body has a typical "owl-eyed" appearance.

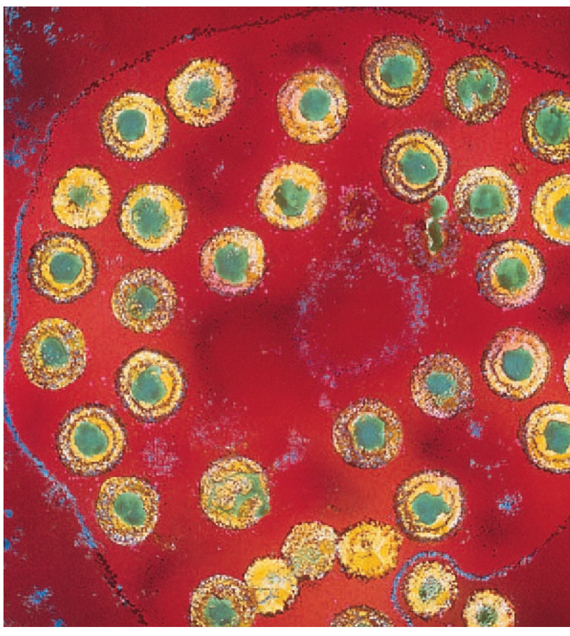
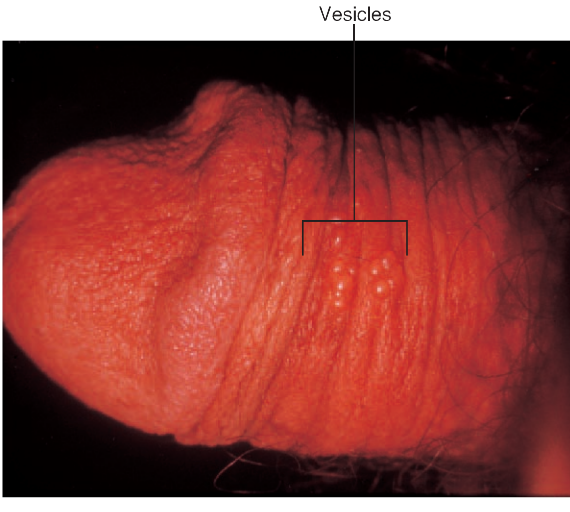
Genital Herpes

Genital herpes is caused by the herpes simplex virus type 2 (HSV-2). The HSV-2 virus (**figure 38.16*a***) is classified in the alphaherpes subfamily of the family *Herpesviridae.* All members



(a)



(b)

Figure 38.16 Genital Herpes. (**a**) Herpes simplex virus type 2 (yellow and green) inside an infected cell (*see also figure 16.17e*). (**b**) Herpes vesicles on the penis. The vesicles contain fluid that is infectious.

of this subfamily have a very short replication cycle. The core DNA is linear and double stranded. The HSV-2 envelope contains at least eight glycoproteins. HSV-2 is most frequently transmitted by sexual contact (*see table 39.4, p. 927 for a summary of all the sexually transmitted diseases covered in this textbook*). Infection begins when the virus is introduced into a break in the skin or mucous membranes. The virus infects the epithelial cells of the external genitalia, the urethra, and the cervix. Rectal and pharyngeal herpes are also caused by sexual contact.

The HSV-2 genome must first enter an epithelial cell for the initiation of infection. The initial association is between the proteoglycans of the epithelial cell surface and viral glycoprotein C. This is followed by a specific interaction with one of several cellular receptors collectively termed HVEMs for "herpesvirus entry mediators." The association also requires the specific interaction with glycoprotein D. Fusion with the epithelial cell plasma membrane follows. This requires the action of a number of other viral glycoproteins. The viral capsid along with some viral tegument proteins then migrates to nuclear envelope pores along the cellular microtubule transport machinery. This "docking" is thought to result in the viral DNA being injected through the nuclear envelope pores while the capsid remains in the cytoplasm. Some tegument proteins also enter the nucleus with the viral genome.

In the infected person, there is an active and latent phase. After an incubation period of about a week, the active phase begins. During the active phase, the virus multiplies explosively—between 50,000 and 200,000 new virions are produced from each infected cell. During this replication cycle, HSV-2 inhibits its host cell's metabolism and degrades its DNA. As a result, the cell dies. Such an active infection may be symptom-free, or painful blisters in the infected tissue (figure 38.16*b*) may occur. The blisters are the result of cell lysis and the development of a local inflammatory response; they contain fluid and infectious viruses. A fever, headache, muscle aches and pains, a burning sensation, and genital soreness are frequently present during the active phase. Although blisters generally heal spontaneously in a few weeks, the viruses retreat to nerve cells in the sacral plexus, where they remain in a latent form. During the latent phase, the viral genome becomes incorporated into the nucleus of the host cell. During this phase, the host cell does not die. Because the viral genes are not expressed, the infected person is symptom-free. However, periodically the viruses multiply and migrate down nerve fibers to the skin or mucous membranes that the nerve supplies, where they produce new blisters. Activation may be due to sunlight, sexual activity, illness accompanied by fever, hormones, or stress. It should be noted that both the primary infection and reactivation can occur without any symptoms and apparently healthy people can transmit HSV-2 to their sexual partners or their newborns.

Besides being transmitted by sexual contact, herpes can be spread to an infant during vaginal delivery, leading to **congenital (neonatal) herpes.** Congenital herpes is one of the most life-threatening of all infections in newborns, affecting approximately 1,500 to 2,200 babies per year in the United States. It can result in neurological involvement as well as blindness. As a result any female who has had genital herpes should have a caesarean section instead of delivering vaginally. For unknown reasons, the HSV-2 virus is also associated with a higher-than-normal rate of cervical cancer and miscarriages.

Although there is no cure for genital herpes, oral use of the antiviral drugs acyclovir (Zovirax or Valtrex) and famciclovir (Famvir) has proven to be effective in ameliorating the recurring blister outbreaks. Topical acyclovir is also effective in reducing virus shedding, the time until the crusting of blisters occurs, and new lesion formation. Idoxuridine and trifluridine are used to treat herpes infections of the eye.

In the United States the incidence of genital herpes has increased so much during the past decade that it is now a very common sexually transmitted disease. It is estimated that over 25 million Americans (20% of adults) are infected with the herpes simplex virus type 2.

Human Herpesvirus 6 Infections

Human herpesvirus 6 (HHV-6) is the etiologic agent of **exanthem subitum** [Greek *exanthema,* rash] in infants. HHV-6 is a unique member of the family *Herpesviridae* that is distinct serologically and genetically from the other herpesviruses. The virus envelope encloses an icosahedral capsid and a core containing double-stranded DNA. The disease caused by HHV-6 was originally termed **roseola infantum** and then given the ordinal designation **sixth disease** to differentiate it from other exanthems and roseolas. Exanthem subitum is a short-lived disease characterized by a high fever of 3 to 4 days' duration, after which the temperature suddenly drops to normal and a macular rash appears on the trunk and then spreads to other areas of the body. HHV-6 infects over 95% of the United States infant population, and most children are seropositive for HHV-6 by 3 years of age. $CD4^+$ T cells are the main site of viral replication, whereas monocytes are in an infected, latent state. The tropism of HHV-6 appears to be wide, including $CD8^+$ T cells, natural killer cells, and probably epithelial cells. In adults HHV-6 is commonly found in peripheral-blood mononuclear cells and saliva, suggesting that the infection is lifelong. Since the salivary glands are the major site of latent infection, transmission is probably by way of saliva.

HHV-6 also produces latent and chronic infections and is occasionally reactivated in immunocompromised hosts leading to pneumonitis. Furthermore, HHV-6 has been implicated in several other diseases (lymphadenitis, multiple sclerosis, and infectious mononucleosis-like syndrome or chronic fatigue syndrome) in immunocompetent adults. Diagnosis is either by immunofluorescence or enzyme immunoassay. To date, there is no antiviral therapy or prevention.

Human Parvovirus B19 Infections

Since its discovery in 1975, **human parvovirus B19** (family *Parvoviridae,* genus *Parvovirus*) has emerged as a significant human pathogen. B19 virions are uniform, icosahedral, unenveloped particles approximately 23 nm in diameter. The genome of B19 is a single-stranded DNA. There is a spectrum of disease caused by parvovirus B19 infection, ranging from mild symptoms (fever, headache, chills, malaise) in normal persons, **erythema infectiosum** in children (**fifth disease**), and a joint disease syndrome in adults; to more serious diseases such as aplastic crisis in persons with sickle cell disease and autoimmune hemolytic anemia, and pure red cell aplasia due to persistent B19 virus infection in immunocompromised individuals. The B19 parvovirus can also infect the fetus, resulting in anemia and fetal hydrops (the accumulation of fluid in tissues). It is assumed that the natural mode of infection is by the respiratory route. A variety of techniques are available for the detection of the B19 virus. Antiviral antibodies appear to represent the principal means of defense against B19 parvovirus infection and disease. The treatment of individuals suffering from acute and persistent B19 infections with commercial immunoglobins containing anti-B19 and human monoclonal antibodies to B19 have shown to be effective therapy. Most of the time infection is followed by lifelong immunity.

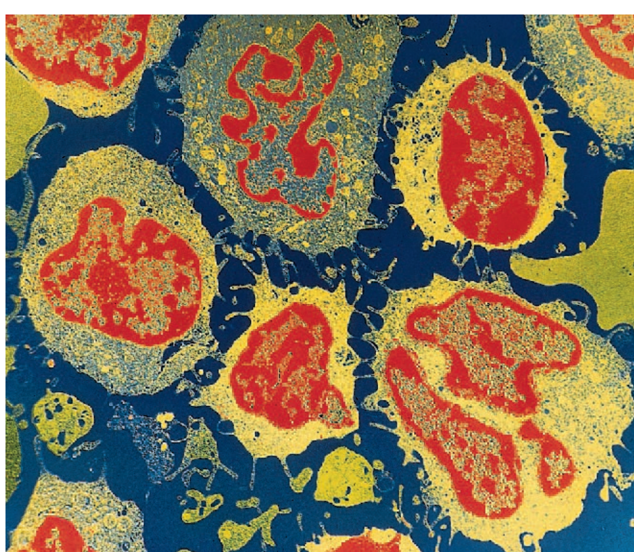


Figure 38.17 Hairy-Cell Leukemia. False-color transmission electron micrograph (×3,100) of abnormal B lymphocytes. Notice that the lymphocytes are covered with characteristic hairlike membrane-derived protrusions.

Leukemia

Certain **leukemias** in humans are caused by two retroviruses: human T-cell lymphotropic virus I (HTLV-I) and HTLV-II. HTLV-I and HTLV-II are members of the family *Retroviridae.* They have a nuclear core containing two positive-sense single-stranded RNA genomes. Once a cell is infected, the RNA genome is converted by reverse transcriptase to DNA and integrates into the host's genome. The viruses are transmitted by transfusions of contaminated blood, among drug addicts sharing needles, by sexual contact, across the placenta, from the mother's milk, or by mosquitoes. Retroviruses and their replication (p. 407); Viruses and cancer (pp. 411–12)

HTLV-1 causes **adult T-cell leukemia.** Once within the body the HTLV-I virus enters white blood cells and integrates into the cellular genome, where it activates the growth-promoting genes. The transformed cell proliferates extensively, and death generally results from the explosive proliferation of the leukemia cells or from opportunistic infections. To date, no effective treatment exists.

In 1982 the second human retrovirus (HTLV-II) was shown to be the agent responsible for hairy-cell leukemia. This virus shares the same disease-causing) mechanism as HTLV-I. Hairy-cell leukemia gets its name from the many membrane-derived protrusions that give white blood cells the appearance of being "hairy" (**figure 38.17**). This leukemia is a chronic, progressive lymphoproliferative disease. The malignancy is believed to originate in a

stage of B-cell development. The bone marrow, spleen, and liver become infiltrated with malignant cells. This lowers the person's immunity. The primary cause of mortality is bacterial and other opportunistic infections. IFN-α n3 (Alferon N) has shown some promise for treatment in certain cases.

Mononucleosis (Infectious)

The Epstein-Barr virus (EBV), a member of the family *Herpesviridae.* As a member of the family *Herpesviridae,* EBV has the characteristic 120 nm enveloped morphology, with 162 capsomeres in icosahedral arrangement. Its double-stranded DNA exists both as a linear form in the mature viron and a circular episomal form in latently infected cells. EBV is the etiologic agent of **infectious mononucleosis** (**mono**), a disease whose symptoms closely resemble those of cytomegalovirus-induced mononucleosis. Because the Epstein-Barr virus occurs in oropharyngeal secretions, it can be spread by mouth-to-mouth contact (hence the terminology infectious and kissing disease) or shared drinking bottles and glasses. Once a person has contracted mono, the virus enters lymphatic tissue, multiplies, and infects B cells. Infected B cells rapidly proliferate and take on an atypical appearance (Downey cells) that is useful in diagnosis. The disease is manifested by enlargement of the lymph nodes and spleen, sore throat, headache, nausea, general weakness and tiredness, and a mild fever that usually peaks in the early evening. The disease lasts for 1 to 6 weeks and is self-limited. Like other herpesviruses, EBV does become latent, probably in the B-cell population.

Treatment of mononucleosis is largely supportive and includes plenty of rest. Diagnosis of mononucleosis is made with a serological test for nonspecific (heterophile) antibodies. Several rapid tests are on the market.

The peak incidence of mononucleosis occurs in people 15 to 25 years of age. Collegiate populations, particularly those in the upper-socioeconomic class, have a high incidence of the disease. About 50% of college students have no immunity, and approximately 15% of these can be expected to contract mononucleosis. People in lower-socioeconomic classes tend to acquire immunity to the disease because of early childhood infection. The Epstein-Barr virus may well be the most common virus in humans as it infects 80 to 90% of all adults worldwide. EBV infections are associated with the cancers Burkitt's lymphoma in tropical Africa and nasopharyngeal carcinoma in Southeast Asia, East and North Africa, and in Eskimos.

Rabies

Rabies [Latin *rabere,* rage or madness] has been the object of human fascination, torment, and fear since the disease was first recognized. Prior to Pasteur's development of an antirabies vaccine, few words were more terrifying than the cry of "mad dog!" Improvements in prevention during the past 50 years have led to the almost complete elimination of indigenously acquired rabies in the United States. Worldwide, virtually all cases of human rabies are attributable to dog bites in developing countries where canine rabies is still endemic.

Rabies is caused by a number of different strains of highly neurotropic viruses. Most belong to a single serotype in the genus *Lyssavirus* [Greek *lyssa,* rage or rabies], family *Rhabdoviridae.* The bullet-shaped virion (**figure 38.18*a;*** *see also figure 16.17*c) contains a single-stranded, negative-sense RNA genome.

As previously noted, in the United States rabies is primarily a disease of animals. Most wild animals can become infected with rabies, but susceptibility varies according to species. Foxes, coyotes, and wolves are the most susceptible; intermediate are skunks, raccoons, insectivorous bats, and bobcats; and opossums are quite resistant.

The virus multiplies in the salivary glands of an infected host. It is transmitted to humans or other animals by the bite of an infected animal whose saliva contains the virus; by aerosols of the virus that can be spread in caves where bats roost; or by contamination of scratches, abrasions, open wounds, and mucous membranes with saliva from an infected animal.

After inoculation, a region of the virions' glycoprotein envelope spike attaches to the plasma membrane of nearby skeletal muscle cells, the virus enters the cells, and multiplication of the virus occurs. When the concentration of the muscle virus is sufficient, the virus enters the nervous system through unmyelinated sensory and motor terminals; the reported binding site is the nicotinic acetylcholine receptor. Since the virus is sequestered from the immune system, infection can no longer be halted by immunization. The virus spreads by retrograde axonal flow at 8 to 20 mm per day until it reaches the spinal cord, when the first specific symptoms of the disease—pain or paresthesia at the wound site—may occur. A rapidly progressive encephalitis develops as the virus quickly disseminates through the central nervous system. The virus then spreads throughout the body along the peripheral nerves, including those in the salivary glands, where it is shed in the saliva.

Within brain neurons the virus produces characteristic **Negri bodies,** masses of viruses or unassembled viral subunits that are visible in the light microscope. In the past the diagnosis of rabies consisted solely of examining nervous tissue for the presence of these bodies. Today diagnosis is based on direct immunofluorescent-antibody (dIFA) of brain tissue, virus isolation, detection of Negri bodies, and a rapid rabies enzyme-mediated immunodiagnosis test.

Symptoms of rabies usually begin 2 to 16 weeks after viral exposure and include anxiety, irritability, depression, fatigue, loss of appetite, fever, and a sensitivity to light and sound. The disease quickly progresses to a stage of paralysis. In about 50% of all cases, intense and painful spasms of the throat and chest muscles occur when the victim swallows liquids. The mere sight, thought, or smell of water can set off spasms. Consequently rabies has been called hydrophobia (fear of water). Death results from destruction of the regions of the brain that regulate breathing.

Safe and effective vaccines (human diploid-cell rabies vaccine HDCV [Imovax Rabies] or rabies vaccine adsorbed [RVA]) against rabies are available; however, to be effective they must be given soon after the person has been infected. Veterinarians and laboratory personnel, who have a high risk of exposure to rabies, usually are immunized every 2 years and tested for the presence of suitable antibody titer. About 30,000 people annually receive this treatment. In the United States fewer than 10 cases of rabies

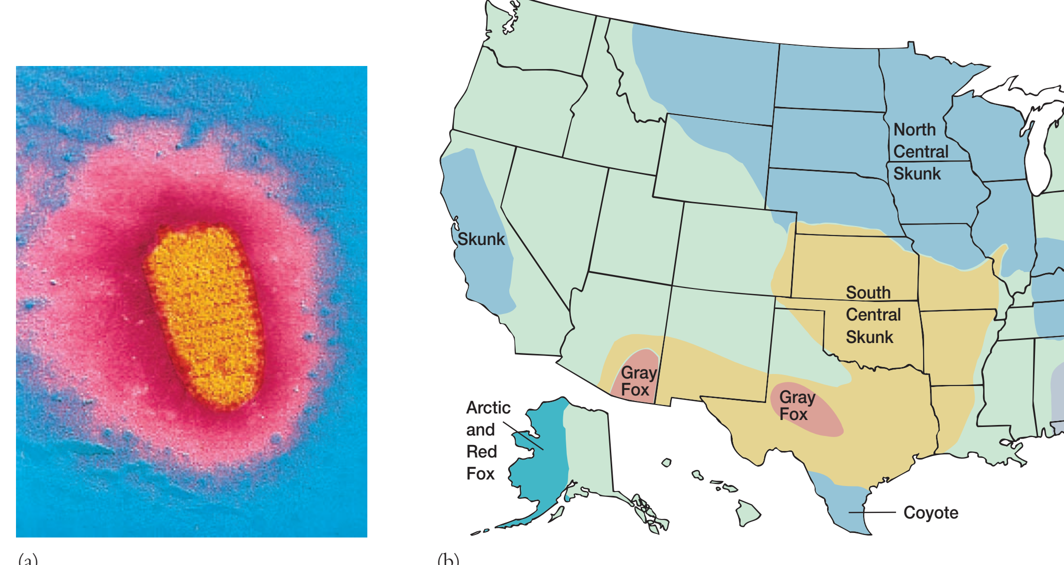

Figure 38.18 **Rabies.** (**a**) Electron micrograph of the rabies virus (yellow) (×36,700). Note the bullet shape. The external surface of the virus contains spikelike glycoprotein projections that bind specifically to cellular receptors. (**b**) In the United States rabies is found in terrestrial animals in 10 distinct geographic areas. In each area a particular species is the reservoir and one of five antigenic variants of the virus predominates as illustrated by the five different colors. Although not shown, another eight viral variants are found in insectivorous bats and cause sporadic cases of rabies in terrestrial animals throughout the country. Absence of a strain does not imply absence of rabies.

occur yearly in humans; about 8,000 cases of animal rabies are reported each year from various sources (figure 38.18*b*). Prevention and control involves preexposure vaccination of dogs and cats, postexposure vaccination of humans, and preexposure vaccination of humans at special risk (persons spending a month or more in countries where rabies is common in dogs).

Viral Hepatitides

Any infection that results in inflammation of the liver is called **hepatitis** [pl., hepatitides] [Greek *hepaticus,* liver]. Currently nine viruses are recognized as causing hepatitis. Two are herpesviruses (cytomegalovirus [CMV] and Epstein-Barr virus [EBV]) and seven are hepatotropic viruses.

EBV and CMV cause mild, self-resolving forms of hepatitis with no permanent hepatic damage. Both viruses cause the typical infectious mononucleosis syndrome of fatigue, nausea, and malaise.

Of the eight human hepatotropic viruses, only five are well characterized; hepatitis F, G, and TTV (transfusion-transmitted virus) are newly discovered viruses (**table 38.4**). Hepatitis A (sometimes called infectious hepatitis), and hepatitis E (formerly enteric-transmitted NANB hepatitis), are transmitted by fecal-oral contamination and discussed in the section on food- and waterborne diseases (section 38.4). The other major types include hepatitis B (sometimes called serum hepatitis), hepatitis C (formerly non-A, non-B hepatitis), and hepatitis D (formerly delta hepatitis).

Hepatitis B (serum hepatitis) is caused by the hepatitis B virus (HBV), a double-stranded circular DNA virus of complex structure. HBV is classified as an *Orthohepadnavirus* within the family *Hepadnaviridae.* Serum from individuals infected with hepatitis B contains three distinct antigenic particles: a spherical 22 nm particle, a 42 nm spherical particle (containing DNA and DNA polymerase) called the **Dane particle,** and tubular or filamentous particles that vary in length (**figure 38.19**). The small spherical and tubular particles are the unassembled components of the Dane particle—the infective form of the virus. The unassembled particles contain **h**epatitis **B** **s**urface **a**nti**g**en (HBsAg) whose presence in the blood is (1) an indicator of hepatitis B infection, (2) the basis for the large-scale screening of blood for the hepatitis B virus, and (3) the basis for the first vaccine for human use developed by recombinant DNA technology.

The hepatitis B virus is normally transmitted through blood transfusions, contaminated equipment, drug users' unsterile needles, or any body secretion (saliva, sweat, semen [*see table 39.4, p. 927*], breast milk, urine, feces). The virus also can pass from the blood of an infected mother through the placenta to infect the fetus. Each year an estimated 300,000 people in the United States are infected with HBV. About 5,000 persons die yearly from hepatitis-related cirrhosis and about 1,000 die from HBV-related liver cancer. (HBV is second only to tobacco as a known cause of human cancer.) Worldwide, HBV infects over 200 million people.

Table 38.4 Characteristics of Hepatitides Caused by Hepatotropic Viruses[a]

Disease (Virus)	Genome	Classification	Transmission	Outcome	Prevention
Hepatitis A (Hepatitis A)	RNA	*Picornaviridae, Hepatovirus*	Fecal-oral	Subclinical, acute infection	Killed HAV (Havrix vaccine)
Hepatitis B (Hepatitis B)	DNA	*Hepadnaviridae, Orthohepadnavirus*	Blood, needles, body secretions, placenta, sexually	Subclinical, acute chronic infection; cirrhosis; primary hepatocarcinoma	Recombinant HBV vaccines
Hepatitis C (Hepatitis C)	RNA	*Flaviviridae, Pestivirus, or Flavivirus* (?)	Blood, sexually	Subclinical, acute chronic infection; primary hepatocarcinoma	Routine screening of blood
Hepatitis D (Hepatitis D)	RNA	Unclassified	Blood, sexually	Superinfection or coinfection with HBV	HBV vaccine
Hepatitis E (Hepatitis E)	RNA	*Caliciviridae* (?)	Fecal-oral	Subclinical, acute infection (but high mortality in pregnant women)	Improve sanitary conditions

[a]Hepatitis F, G, and TTV have been discovered but not well characterized. Thus they are not included in this table.

Filamentous form (22 nm diameter)
Dane particle (42 nm diameter)
Spherical particle (22 ± 2 nm diameter)

Figure 38.19 Hepatitis B Virus in Serum. Electron micrograph (×210,000) showing the three distinct types of hepatitis B antigenic particles. The spherical particles and filamentous forms are small spheres or long filaments without an internal structure, and only two of the three characteristic viral envelope proteins appear on their surface. Dane particles are the complete, infectious virion.

The clinical signs of hepatitis B vary widely. Most cases are asymptomatic. However, sometimes fever, loss of appetite, abdominal discomfort, nausea, fatigue, and other symptoms gradually appear following an incubation period of 1 to 3 months. The virus infects liver hepatic cells and causes liver tissue degeneration and the release of liver-associated enzymes (transaminases) into the bloodstream. This is followed by jaundice, the accumulation of bilirubin (a breakdown product of hemoglobin) in the skin and other tissues with a resulting yellow appearance. Chronic hepatitis B infection also causes the development of primary liver cancer, hepatocellular carcinoma (hepatitis B is second in importance only to tobacco as a known human carcinogen).

General measures for prevention and control involve (1) excluding contact with HBV-infected blood and secretions, and minimizing needle-sticks by scrupulous technique; (2) passive prophylaxis with intramuscular injection of hepatitis B immune globulin within 7 days of exposure; and (3) active prophylaxis with two recombinant vaccines: Engerix-B, and Recombivax HB. These vaccines are widely used by health professionals who are at increased risk of contacting the hepatitis B virus. Other individuals who should be vaccinated include:

1. Contacts of HBV carriers (e.g., household members, sex partners, institutional inmates)
2. International travelers (*see table 37.5*)
3. Sexually active homosexual males
4. Hemodialysis patients
5. Recipients of blood and related products that are possibly HBV contaminated

Another form of hepatitis is called **hepatitis C.** The virion has an 80 nm diameter, has a lipid coat, contains a single strand of linear ssRNA, and has been designated the hepatitis C virus (HCV) within the family *Flaviviridae.* HCV has recently been classified into multiple genotypes. This virus is transmitted by intimate contact with virus-contaminated blood, by the fecal-oral route, by in utero transmission from mother to fetus, sexually, or through organ transplantation. Diagnosis is made by a first-generation enzyme-linked immunosorbent assay (ELISA), which detects serum antibody to a recombinant antigen of HCV. Hepatitis C is found worldwide. In recent years hepatitis C has accounted for more than 90% of hepatitis cases developing after a blood transfusion. Worldwide, hepatitis C has reached epidemic proportions, with more than 1 million new cases reported annually. In the United States alone, nearly 4 million persons are infected and 30,000 new cases occur annually. Currently, HCV is responsible for 8,000 to 10,000 deaths

annually in the United States, and without effective intervention, that number is predicted to triple in the next 10 years. Furthermore, HCV is the leading reason for liver transplantation in the United States. Treatment is with recombinant IFN-α 2b or IFN-α 2a (Intron A, Roferon-A) three times weekly for 6 months.

In 1977 a cytopathic hepatitis agent termed the **Delta agent** was discovered. Later it was called the hepatitis D virus (HDV) and the disease **hepatitis D** designated. HDV is a unique agent in that it is dependent on the hepatitis b virus to provide the envelope protein (HBsAg) for its RNA genome. Thus HDV only replicates in liver cells in which the HBV also is actively replicating. Furthermore, the RNA of the HDV is smaller than the RNA of the smallest picornaviruses and its circular conformation differs from the linear structure typical of animal RNA viruses. (The nearest relatives of the HDV are in the plant kingdom—the viroids, virusoids, and satellite RNAs [*see chapter 18*].) HDV is spread only to persons who are already infected with HBV (superinfection) or to individuals who get both viruses at once (coinfection). The primary laboratory tools for the diagnosis of an HDV infection are serological tests for anti-delta antibodies. Treatment of patients with chronic HDV remains difficult. Early studies indicate that some positive results can be obtained with alpha interferon for 3 months to 1 year. Worldwide, there are approximately 300 million HBV carriers, and available data indicate that no fewer than 5% of these are infected with HDV. Thus because of the propensity of HDV to cause fulminant as well as chronic liver disease, continued incursion of HDV into areas of the world where persistent hepatitis B infection is endemic will have serious implications. Prevention and control involves the widespread use of the hepatitis B vaccine.

Recently the presence of two other forms of hepatitis have been identified: **hepatitis F** (causing fulminant, post-transfusion hepatitis) and a syncytial giant-cell hepatitis (**hepatitis G**) with viruslike particles resembling the measles virus (*Paramyxovirus*). Further virologic, epidemiological, and molecular efforts to clone and characterize these new agents and their diseases are currently being undertaken.

1. Describe the AIDS virus and how it cripples the immune system. How is the virus transmitted? What types of pathological changes can result?
2. Why do people periodically get cold sores? Describe the causative agent.
3. Why do people get the common cold so frequently? How are cold viruses spread?
4. Give two major ways in which herpes simplex virus type 2 is spread. Why do herpes infections become active periodically?
5. What two types of leukemias are caused by viruses?
6. Describe the causative agent and some symptoms of mononucleosis and exanthem subitum.
7. How does the rabies virus cause death in humans?
8. What are the different causative viruses of hepatitis and how do they differ from one another? How can one avoid hepatitis? Do you know anyone who is a good candidate for infection with these viruses?

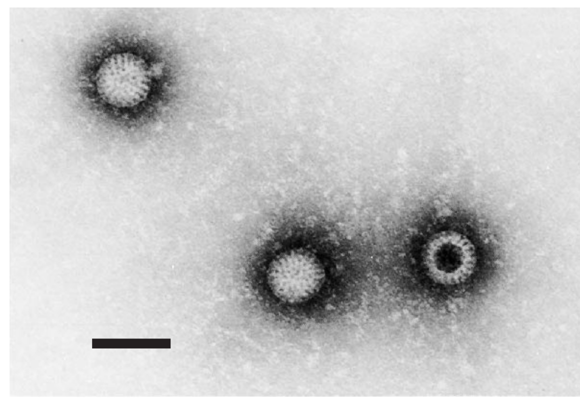

Figure 38.20 Viral Gastroenteritis. Electron micrograph of rotaviruses (reoviruses) in a human gastroenteritis stool filtrate. Note the spokelike appearance of the icosahedral capsids that surround double-stranded RNA within each virion. Bar = 100 nm.

38.4 Food-Borne and Waterborne Diseases

Food and water have been recognized as potential carriers of disease since the beginning of recorded history. Collectively more infectious diseases occur by these two routes than any other. A few human viral diseases that are food- and waterborne are now discussed. Water-based diseases (section 29.5); Diseases and food (section 41.4)

Gastroenteritis (Viral)

Acute viral gastroenteritis (inflammation of the stomach or intestines) is caused by four major categories of viruses: rotaviruses (**figure 38.20**), Norwalk and Norwalk-like viruses, other caliciviruses, and astroviruses. The medical importance of these viruses is summarized in **table 38.5.**

The viruses responsible for gastroenteritis are probably transmitted by the fecal-oral route. Infection is most common during the cooler months in contrast to bacteria-caused diarrheal diseases, which usually occur in the warmer months of the year. Diarrheal diseases are the leading cause of childhood deaths (5 to 10 million deaths per year) in developing countries where malnutrition is common. Current estimates are that viral gastroenteritis produces 30 to 40% of the cases of infectious diarrhea in the United States, far outnumbering documented cases of bacterial and parasitic diarrhea (the cause of approximately 40% of presumed cases of diarrhea remains unknown). In the United States rotaviruses account for about 3.5 million cases of illness, resulting in 35% of the hospitalizations for gastroenteritis, and 75 to 150 deaths each year.

Viral gastroenteritis is seen most frequently in infants 1 to 11 months of age, where the virus attacks the upper intestinal epithelial cells of the villus, causing malabsorption, impairment of

© The McGraw–Hill Companies, 2002

Table 38.5 Medically Important Gastroenteritis Viruses

Virus	Epidemiological Characteristics	Clinical Characteristics
Rotaviruses		
Group A	Endemic diarrhea in infants worldwide	Dehydrating diarrhea for 5–7 days; fever, abdominal cramps, nausea, and vomiting common
Group B	Large outbreaks in adults and children in China	Severe watery diarrhea for 3–5 days
Group C	Sporadic cases in children in Japan	Similar to group A
Norwalk and Norwalk-like viruses	Epidemics of vomiting and diarrhea in older children and adults; occurs in families, communities, and nursing homes; often associated with shellfish, other food, or water and infected food handlers	Acute vomiting, fever, myalgia, and headache lasting 1–2 days
Caliciviruses other than the Norwalk group	Pediatric diarrhea; associated with shellfish and other foods in adults	Rotavirus-like illness in children; Norwalk-like in adults
Astroviruses	Pediatric diarrhea; reported in nursing homes	Watery diarrhea for 1–3 days

sodium transport, and diarrhea. The clinical manifestations range from asymptomatic to a relatively mild diarrhea with headache and fever to a severe and occasionally fatal dehydrating disease. Vomiting is almost always present.

Viral gastroenteritis is usually self-limited. Treatment is designed to provide relief through the use of oral fluid replacement with isotonic liquids, analgesics, and antiperistaltic agents.

Hepatitis A

Hepatitis A (infectious hepatitis) usually is transmitted by fecal-oral contamination of food, drink, or shellfish that live in contaminated water and contain the virus in their digestive system. The disease is caused by the hepatitis A virus (HAV). HAV has recently been reclassified as the type species of a new genus (*Hepatovirus*) in the family *Picornaviridae.* The hepatitis A virus is an icosahedral, single-stranded linear, positive-sense RNA virus that lacks an envelope. Once in the digestive system, the viruses multiply within the intestinal epithelium. Usually only mild intestinal symptoms result. Occasionally viremia (the presence of viruses in the blood) occurs and the viruses may spread to the liver. The viruses reproduce in the liver, enter the bile, and are released into the small intestine. This explains why feces are so infectious. Symptoms last from 2 to 20 days and include anorexia, general malaise, nausea, diarrhea, fever, and chills. If the liver becomes infected, jaundice ensues. Laboratory diagnosis is by detection of the hepatitis A antibody. About 30,000 cases are reported annually in the United States. Fortunately the mortality rate is low (less than 1%), and infections in children are usually asymptomatic. Most cases resolve in 4 to 6 weeks and yield a strong immunity. Approximately 40 to 80% of the United States population have serum antibodies though few have been aware of the disease. Control of infection is by simple hygienic measures, the sanitary disposal of excreta, and the killed HAV vaccine (Havrix). This vaccine is recommended for travelers (*see table 37.5*) going to regions with high evidence rates of hepatitis A.

Hepatitis E

Hepatitis E is implicated in many epidemics in certain developing countries in Asia, Africa, and Central and South America. The virus has been cloned and sequenced. The genomic organization suggests it is the prototype human pathogen for a new class of single-stranded linear RNA viruses or perhaps a separate genus within the family *Caliciviridae.* Infection usually is associated with feces-contaminated drinking water. Presumably HEV enters the blood from the gastrointestinal tract, replicates in the liver, is released from hepatocytes into the bile, and is subsequently excreted in the feces. Like hepatitis A, an HEV infection usually runs a benign course and is self-limiting. One exception is that at least 10% of women infected in their last 3 months of pregnancy die of fulminant hepatic failure. Antibody assay systems are under development using HEV cDNA products. There are no specific measures for preventing HEV infections other than those aimed at improving the level of health and sanitation in affected areas. There are only a few documented cases of hepatitis E in the United States and all of them imported.

Poliomyelitis

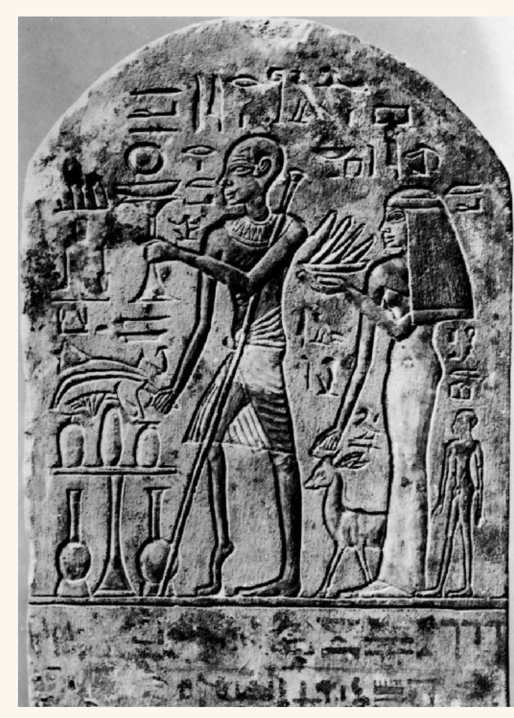
Poliomyelitis [Greek *polios,* gray, and *myelos,* marrow or spinal cord], **polio,** or **infantile paralysis** is caused by the poliovirus, a member of the family *Picornaviridae* (**Box 38.3**). The poliovirus is a plus-stranded RNA virus with three different serotypes—1, 2, and 3. The virus is very stable and can remain infectious for relatively long periods in food and water—its main routes of transmission. Once ingested, the virus multiplies in the mucosa of the throat and/or small intestine. From these sites the virus invades the tonsils and lymph nodes of the neck and terminal portion of the small intestine. Generally, there are either no symptoms or a brief illness characterized by fever, headache, sore throat, vomiting, and loss of appetite. The virus sometimes enters the bloodstream and causes a viremia. In most cases (more than 99%), the viremia is transient and clinical disease does not result. In the minority of cases (less than 1%), the viremia persists and the virus enters the central nervous system and causes paralytic polio. The virus has a high affinity

Box 38.3

A Brief History of Polio

Like many other infectious diseases, polio is probably of ancient origin. Various Egyptian hieroglyphics dated approximately 2000 B.C. depict individuals with wasting, withered legs and arms (see **Box figure**). In 1840 the German orthopedist Jacob von Heine described the clinical features of poliomyelitis and identified the spinal cord as the problem area. Little further progress was made until 1890, when Oskar Medin, a Swedish pediatrician, portrayed the natural history of the disease as epidemic in form. He also recognized that a systemic phase, characterized by minor symptoms and fever, occurred early and was complicated by paralysis only occasionally. Major progress occurred in 1908, when Karl Landsteiner and William Popper successfully transmitted the disease to monkeys. In the 1930s much public interest in polio occurred because of the polio experienced by Franklin D. Roosevelt. This led to the founding of the March of Dimes campaign in 1938; the sole purpose of the March of Dimes was to collect money for research on polio. In 1949 John Enders, Thomas Weller, and Frederick Robbins discovered that the poliovirus could be propagated in vitro in cultures of human embryonic tissues of non-neural origin. This was the keystone that later led to the development of vaccines.

In 1952 David Bodian recognized that there were three distinct serotypes of the poliovirus. Jonas Salk successfully immunized humans with formalin-inactivated poliovirus in 1953, and this vaccine (IPV) was licensed in 1955. In 1962 Albert Sabin and others developed the live attenuated poliovirus vaccines (oral polio vaccines, OPV). Both the Salk and Sabin vaccines led to a dramatic decline of paralytic poliomyelitis in most developed countries and, as such, have been rightfully hailed as two of the great accomplishments of medical science.



Ancient Egyptian with Polio. Note the withered leg.

for anterior horn motor nerve cells of the spinal cord. Once inside these cells, it multiplies and destroys the cells; this results in motor and muscle paralysis. Since the arrival of the formalin-inactivated Salk vaccine (1954) and the attenuated virus Sabin vaccine (1962), the incidence of polio has decreased markedly. There are fewer than 10 cases per year, and no endogenous reservoir of polioviruses exists in the United States. However, there is a continuing need for vaccination programs in all population groups to limit the spread of poliovirus when it is introduced from other countries. In developing countries, 4 of every 1,000 children born annually have paralytic disease caused by the poliovirus. Prevention and control is by vaccination; global eradication of polio is possible in the next few years (see the quote at the beginning of this chapter).

1. What two virus groups are associated with acute viral gastroenteritis? How do they cause the disease's symptoms?
2. Describe some symptoms of hepatitis A.
3. Why was hepatitis A called infectious hepatitis?
4. At what specific sites within the body can the poliomyelitis virus multiply? What is the usual outcome of an infection?

38.5 Slow Virus and Prion Diseases

An introduction to slow diseases caused by viruses and prions appears on pp. 410 and 416–17. A **slow virus disease** can be defined as a progressive pathological process caused by a transmissible agent—virus or prion—that remains clinically silent during a prolonged incubation period of months to years, after which progressive clinical disease becomes apparent. This usually ends months later in disability or death. It is probably inappropriate to say that a slow virus disease or slow disease is caused by a slow virus for two reasons. First, the causative agent of some of these diseases does not fit the conventional definition of a virus. Second, even in those diseases caused by viruses, it is the disease process and not the virus that is slow. Six of these diseases are summarized in **table 38.6.** From this list, the first four diseases are caused by prions and they will now be briefly discussed.

Prion diseases, also called **spongiform encephalopathies,** are fatal neurodegenerative disorders that have attracted enormous attention not only for their unique biological features but also for their impact on public health. This group of diseases includes

Table 38.6 Slow Virus and Prion Diseases of Humans

Disease	Agent	Incubation Period	Nature of Disease
Creutzfeldt-Jakob disease (CJD) (sporadic, familial, new-variant)	Prion	Months to years	Spongiform encephalopathy (degenerative changes in the central nervous system)
Kuru	Prion	Months to years	Spongiform encephalopathy
Gerstmann-Sträussler-Scheinker Syndrome (GSS)	Prion	Months to years	Genetic neurodegenerative disease
Fatal familial insomnia (FFI)	Prion	Months to years	Genetic neurodegenerative disease with progressive, untreatable insomnia
Progressive multifocal leukoencephalopathy	Papovavirus	Years	Central nervous system demyelination
Subacute sclerosing panencephalitis (SSPE)	Measle virus variant	2–20 years	Chronic sclerosing (hard tissue) panencephalitis (involving both white and gray matter of the brain)

kuru, Creutzfeldt-Jakob disease (CJD), Gerstmann-Sträussler syndrome (GSS), and fatal familial insomnia (FFI). The primary symptom of the human disorders is dementia, usually accompanied by manifestations of motor dysfunction such as cerebral ataxia (inability to coordinate muscle activity) and myoclonus (shocklike contractions of muscle groups). FFI is also characterized by dysautonomia (abnormal functioning of the autonomic nervous system) and sleep disturbances. These symptoms appear insidiously in middle to late adult life and last from months (CJD, FFI, and kuru) to years (GSS) prior to death. Neuropathologically, these disorders produce a characteristic spongiform degeneration of the brain, as well as deposition of amyloid plaques. Prion diseases thus share important clinical, neuropathological, and cell biological features with another, more common cerebral amyloidosis, Alzheimer's disease.

Recently a new variant form of CJD (vCJD) has arisen. It is transmitted from cattle that have bovine spongiform encephalopathy (mad cow disease) as described in section 41.4.

38.6 Other Diseases

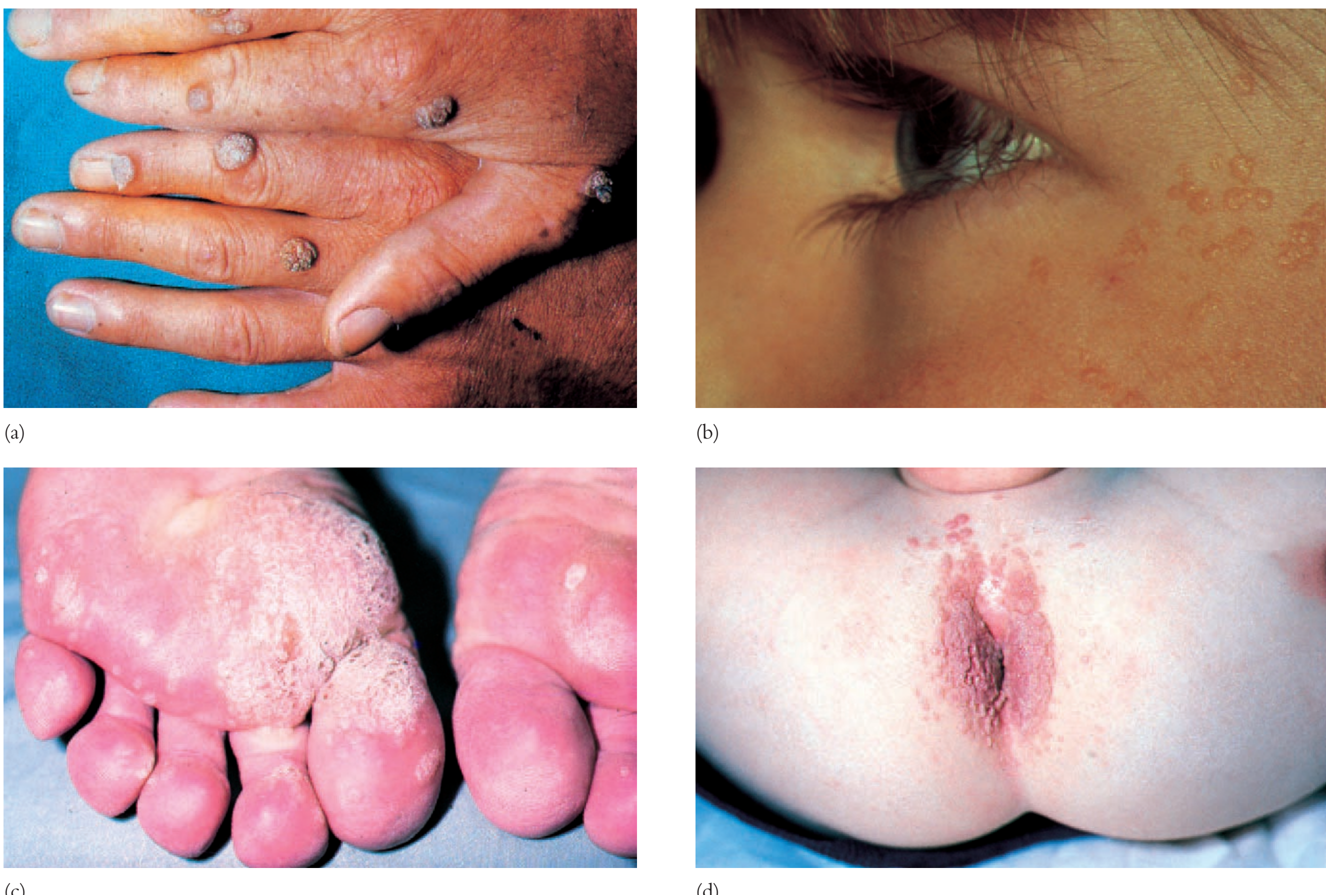
Several other human diseases (e.g., diabetes mellitus, viral arthritis) have been associated with viruses but do not fit into any of the previous categories. Another example is warts.

Warts

Warts or verrucae [Latin *verruca,* wart] are horny projections on the skin caused by the human papillomaviruses (*see figure 16.12*d). The papillomaviruses are placed in the family *Papillomaviridae* (formerly they were in the *Papovaviridae*). These viruses have naked icosahedral capsids with a double-stranded, supercoiled, circular DNA genome. At least eight distinct genotypes produce benign epithelial tumors that vary in respect to their location, clinical appearance, and histopathologic features. Warts occur principally in children and young adults and are limited to the skin and mucous membranes. The viruses are spread between people by direct contact; autoinoculation occurs through scratching. Four major kinds of warts are **plantar warts, verrucae vulgaris, flat** or **plane warts,** and **anogenital condylomata** (**venereal warts**) (**figure 38.21**). Treatment includes physical destruction of the wart(s) by electrosurgery, cryosurgery with liquid nitrogen or solid CO_2, laser fulguration (drying), direct application of the drug podophyllum to the wart(s), or injection of IFN-α (Intron A, Alferon N).

Anogenital condylomata (venereal warts) are sexually transmitted and caused by types 6, 11, and 42 **h**uman **p**apilloma**v**irus (HPV). Once the virus enters the body, the incubation period is 1 to 6 months. The warts (figure 38.21*d*) are soft, pink, cauliflowerlike growths that occur on the external genitalia, in the vagina, on the cervix, or in the rectum. They often are multiple and vary in size. In addition to being a common sexually transmitted disease (*see table 39.4, p. 927*), genital infection with HPV is of considerable importance because specific types of genital HPV play a major role in the pathogenesis of epithelial cancers of the male and female genital tracts. Over the last decade many studies have convincingly demonstrated that specific types of HPV are the causal agents of at least 90% of cervical cancers. The most common types conferring a high risk for cervical cancer include HPV types 16, 18, 31, 33, 35, 45, 51, 52, and 56. There is also a possible link between papillomaviruses and nonmelanoma squamous and basal cell cancers. Thirty percent of humans with a rare syndrome of persistent warts (not common warts, but a particular type of warty growth) eventually develop skin cancer, and HPV viral DNA is found in the malignant cells. However, the epidemiology, molecular biology, and role of HPV in the development of such cancers are largely unknown.

1. Name six slow virus diseases of humans.
2. What kind of viruses cause the formation of warts? Describe venereal warts or anogenital condylomata.



(a) (b) (c) (d)

Figure 38.21 Warts. (**a**) Common warts on fingers. (**b**) Flat warts on the face. (**c**) Plantar warts on the feet. (**d**) Perianal condyloma acuminata.

Summary

1. More than 400 different viruses can infect humans. These viruses can be grouped and discussed according to their mode of acquisition/transmission.
2. Most airborne viral diseases involve either directly or indirectly the respiratory system. Examples include chickenpox (varicella, **figure 38.1**), shingles (zoster, **figure 38.2**), rubella (German measles, **figure 38.5**), influenza (flu), measles (rubeola, **figure 38.3**), mumps (**figure 38.4**), the acute respiratory viruses such as the respiratory syncytial virus, the extinct smallpox (variola, **figure 38.6**), and viral pneumonia.
3. The arthropod-borne viral diseases are transmitted by arthropod vectors from human to human or animal to human (**table 38.2**). Examples include California encephalitis; Colorado tick fever; St. Louis encephalitis; eastern, western, and Venezuelan equine encephalitis; West Nile virus; and yellow fever. All these diseases are characterized by fever, headache, nausea, vomiting, and the characteristic encephalitis.
4. Person-to-person contact is another way of acquiring or transmitting a viral disease. Examples of such diseases include AIDS, cold sores (**figure 38.13**), the common cold, cytomegalovirus inclusion disease, genital herpes (**figure 38.1*b***), human herpesvirus 6 infections, human parvovirus B19 infection, certain leukemias, infectious mononucleosis, rabies, and the five types of hepatitis (**table 38.4**): hepatitis A (infectious hepatitis); hepatitis B (serum hepatitis); hepatitis C (post-transfusion NANB hepatitis); hepatitis D (delta hepatitis); and hepatitis E (enteric-transmitted NANB hepatitis).
5. The viruses that are transmitted in food and water usually grow in the intestinal system and leave the body in the feces (**table 38.5**). Acquisition is generally by the oral route. Examples of diseases caused by these viruses include acute viral gastroenteritis (rotavirus and others), infectious hepatitis A, and poliomyelitis.
6. A slow virus or prion disease is a pathological process caused by a transmissible agent (a prion or virus) that remains clinically silent for a prolonged period, after which the clinical disease becomes apparent. Examples include (**table 38.6**) Creutzfeldt-Jakob disease, kuru, subacute sclerosing panencephalitis, Gerstmann-Sträussler-Scheinker syndrome, fatal familial insomnia, and progressive multifocal leukoencephalopathy. These diseases are chronic infections of the central nervous system that result in progressive degenerative changes and eventual death.
7. Common skin warts (**figure 38.21**) are caused by viruses and can be spread by autoinoculation through scratching or by direct or indirect contact. Anogenital condylomata (venereal warts) are sexually transmitted.

Key Terms

acute viral gastroenteritis *891*
adult T-cell leukemia *887*
AIDS (acquired immune deficiency syndrome) *878*
AIDS-related complex (ARC) *879*
anogenital condylomata (venereal warts) *894*
apoptosis *881*
chickenpox (varicella) *871*
cold sore *884*
Colorado tick fever *878*
common cold *884*
congenital (neonatal) herpes *886*
congenital rubella syndrome *876*
coryza *884*
cytomegalovirus inclusion disease *885*
Dane particle *889*
Delta agent *891*
Ebola virus hemorrhagic fever *877*
erythema infectiosum *887*
exanthem subitum *887*
fever blister *884*
fifth disease *887*
flat or plane warts *894*
genital herpes *885*
gingivostomatitis *884*
Guillain-Barré syndrome (French Polio) *874*
hantavirus pulmonary syndrome *877*
hemorrhagic fevers *877*
hepatitis *889*
hepatitis A *892*
hepatitis B *889*
hepatitis C *890*
hepatitis D *891*
hepatitis E *892*
hepatitis F *891*
hepatitis G *891*
herpes labialis *884*
herpetic keratitis *884*
human herpesvirus 6 *887*
human immunodeficiency virus (HIV) *878*
human parvovirus B19 *887*
infantile paralysis *892*
infectious mononucleosis (mono) *888*
influenza or flu *872*
intranuclear inclusion body *885*
Koplik's spots *874*
Korean hemorrhagic fever *877*
leukemia *887*
Marburg viral hemorrhagic fever *877*
measles (rubeola) *873*
mumps *875*
Negri bodies *888*
orchitis *875*
plantar warts *894*
polio *892*
poliomyelitis *892*
postherpetic neuralgia *872*
pulmonary syndrome hantavirus *877*
rabies *888*
respiratory syncytial virus (RSV) *875*
Reye's syndrome *874*
roseola infantum *887*
rubella (German measles) *875*
shingles (zoster) *872*
sixth disease *887*
slow virus disease *893*
smallpox (variola) *876*
spongiform encephalopathies *893*
subacute sclerosing panencephalitis *874*
verrucae vulgaris *894*
wart *894*
yellow fever *878*

Questions for Thought and Review

1. Briefly describe each of the major or most common viral diseases in terms of its causative agent, signs and symptoms, the course of infection, mechanism of pathogenesis, epidemiology, and prevention and/or treatment.
2. Which virus is responsible for each of the following: shingles, German measles, influenza, measles, mumps, and smallpox?
3. What are respiratory syndromes?
4. From an epidemiological perspective, why are most arthropod-borne viral diseases hard to control?
5. In terms of molecular genetics, why is the common cold such a prevalent viral infection in humans?
6. What are the differences between the five types of hepatitis?
7. Which viral diseases can be transmitted by sexual contact?
8. Why are the herpesviruses called persistent viruses?
9. What viruses specifically attack the nervous system?
10. Why is rabies such a feared disease?
11. Which viruses can cause encephalitis? Hepatitis?
12. What are two types of mononucleosis?
13. Will it be possible to eradicate many viral diseases in the same way as smallpox? Why or why not?

Critical Thinking Questions

1. Explain why antibiotics are not effective against viral infections. Advise a person about what he or she can do to relieve symptoms of a viral infection and recover most quickly. Address your advice to (a) someone who has had only a basic course in high school biology, and (b) a third-grade student.
2. Several characteristics of AIDS render it particularly difficult to detect, prevent, and treat effectively. Discuss two of them. Contrast the disease with polio and smallpox.

CHAPTER 39

Human Diseases Caused by Bacteria

The toll of tetanus. The bacterial genus *Clostridium* contains many pathogenic species, including the species responsible for tetanus (*C. tetani*). Sir Charles Bell's portrait (c. 1821) of a soldier wounded in the Peninsular War in Spain shows the suffering from generalized tetanus.

Outline

39.1 Airborne Diseases 900
- Diphtheria 900
- Legionnaires' Disease and Pontiac Fever 901
- Meningitis 902
- *Mycobacterium avium–M.intracellulare* Pneumonia 902
- Pertussis 903
- Streptococcal Diseases 903
- Tuberculosis 906

39.2 Arthropod-Borne Diseases 908
- Ehrlichiosis 909
- Epidemic (Louse-Borne) Typhus 909
- Endemic (Murine) Typhus 909
- Lyme Disease 910
- Plague 911
- Q Fever 912
- Rocky Mountain Spotted Fever 913

39.3 Direct Contact Diseases 913
- Anthrax 913
- Bacterial Vaginosis 914
- Cat-Scratch Disease 914
- Chancroid 914
- Chlamydial Pneumonia 914
- Gas Gangrene or Clostridial Myonecrosis 915
- Genitourinary Mycoplasmal Diseases 915
- Gonorrhea 915
- Inclusion Conjunctivitis 916
- Leprosy 916
- Lymphogranuloma Venereum 917
- Mycoplasmal Pneumonia 917
- Nongonococcal Urethritis 918
- Peptic Ulcer Disease and Gastritis 918
- Psittacosis (Ornithosis) 919
- Staphylococcal Diseases 919
- Syphilis 923
- Tetanus 924
- Trachoma 925
- Tularemia 926
- Sexually Transmitted Diseases 926

39.4 Food-Borne and Waterborne Diseases 926
- Botulism 929
- *Campylobacter jejuni* Gastroenteritis 929
- Cholera 930
- Listeriosis 931
- Salmonellosis 931
- Shigellosis 931
- Staphylococcal Food Poisoning 932
- Traveler's Diarrhea and *Escherichia coli* Infections 932
- Typhoid Fever 933

39.5 Sepsis and Septic Shock 933

39.6 Dental Infections 933
- Dental Plaque 933
- Dental Decay (Caries) 936
- Periodontal Disease 936

Concepts

1. Bacterial diseases of humans can be discussed according to their mode of acquisition/transmission.
2. Most of the airborne diseases caused by bacteria involve the respiratory system. Examples include diphtheria, Legionnaires' disease and Pontiac fever, *Mycobacterium avium–M. intracellulare* pneumonia, pertussis, streptococcal diseases, and tuberculosis. Other airborne bacteria can cause skin diseases, including cellulitis, erysipelas, and scarlet fever, or systemic diseases such as meningitis, glomerulonephritis, and rheumatic fever.
3. Although arthropod-borne bacterial diseases are generally rare, they are of interest either historically (plague) or because they have been newly introduced into humans (Lyme disease). Most of the rickettsial diseases are arthropod-borne. The rickettsias found in the United States can be divided into the typhus group (epidemic typhus caused by *R. prowazekii* and murine typhus caused by *R. typhi*) and the spotted fever group (Rocky Mountain spotted fever caused by *R. rickettsii* and ehrlichiosis caused by *Ehrlichia chaffeensis*), with Q fever (caused by *Coxiella burnetti*) being an exception because it forms endosporelike structures and does not have to use an insect vector as with other rickettsias.
4. Most of the direct contact bacterial diseases involve the skin, mucous membranes, or underlying tissues. Examples include anthrax, bacterial vaginosis, cat-scratch disease, chancroid, gas gangrene, leprosy, peptic ulcer disease and gastritis, staphylococcal diseases, and syphilis. Others can become disseminated throughout specific regions of the body—for example, gonorrhea, staphylococcal diseases, syphilis, tetanus, and tularemia. Three chlamydial species cause direct contact disease: *Chlamydia pneumoniae* causes chlamydial pneumonia; *Chlamydia trachomatis* causes inclusion conjunctivitis, lymphogranuloma venereum, nongonococcal urethritis, and trachoma; and *C. psittaci* causes psittacosis. Three species of mycoplasmas are human pathogens: *Mycoplasma hominis* and *Ureaplasma urealyticum* cause genitourinary tract disease, whereas *M. pneumoniae* is a major cause of acute respiratory disease and pneumonia.
5. The food-borne and waterborne bacterial diseases are contracted when contaminated food or water is ingested. These diseases are essentially of two types: infections and intoxications. An infection occurs when a pathogen enters the gastrointestinal tract and multiplies. Examples include *Campylobacter* gastroenteritis, salmonellosis, listerosis, shigellosis, traveler's diarrhea, *Escherichia coli* infections, and typhoid fever. An intoxication occurs because of the ingestion of a toxin produced outside the body. Examples include botulism, cholera, and staphylococcal food poisoning.
6. Some microbial diseases and their effects cannot be categorized under a specific mode of transmission. Two important examples are sepsis and septic shock. Gram-positive bacteria, fungi, and endotoxin-containing gram-negative bacteria can initiate the pathogenic cascade of sepsis leading to septic shock.
7. Several bacterial odontopathogens are responsible for the most common bacterial diseases in humans—tooth decay and periodontal disease. Both are the result of plaque formation and the production of lactic and acetic acids by the odontopathogens.

Soldiers have rarely won wars. They more often mop up after the barrage of epidemics. And typhus, with its brothers and sisters—plague, cholera, typhoid, dysentery—has decided more campaigns than Caesar, Hannibal, Napoleon, and all the . . . generals of history. The epidemics get the blame for the defeat, the generals the credit for victory. It ought to be the other way around. . . .

—*Hans Zinsser*

The first four parts of this textbook cover the general biology of bacteria. Chapters 19 through 24 specifically review bacterial morphology and taxonomy. Chapter 39 continues the coverage of bacteria by discussing some of the more important gram-positive and gram-negative bacteria, chlamydiae, mycoplasmas, and rickettsias that are pathogenic to humans. The microorganisms involved in dental infections are also described.

Table 39.1 Some Examples of Human Bacterial Diseases Recognized Since 1973

Year	Bacterium	Disease
1977	*Legionella pneumophila*	Legionnaires' disease
1977	*Campylobacter jejuni*	Enteric disease (gastroenteritis)
1981	*Staphylococcus aureus*	Toxic shock syndrome
1982	*Escherichia coli* O157:H7	Hemorrhagic colitis; hemolytic uremic syndrome
1982	*Borrelia burgdorferi*	Lyme disease
1982	*Helicobacter pylori*	Peptic ulcer disease
1986	*Ehrlichia chaffeensis*	Human ehrlichiosis
1992	*Vibrio cholerae* O139	New strain associated with epidemic cholera in Asia
1992	*Bartonella henselae*	Cat-scratch disease; bacillary angiomatosis
1993	*Enterococcus faecium;* vancomycin-resistant enterococci	Colitis and enteritis
1994	*Ehrlichia* spp.	Human granulocytic ehrlichiosis
1995	*Neisseria meningitidis*	Meningococcal supraglottitis
1997	*Kingella kingae*	Pediatric infections

Of all the known bacterial species, only a few are pathogenic to humans. Some human diseases have been only recently recognized (**table 39.1**); others have been known since antiquity. In the following sections the more important disease-causing bacteria are discussed according to their mode of acquisition/transmission.

39.1 Airborne Diseases

Most airborne diseases caused by bacteria involve the respiratory system. Other airborne bacteria can cause skin diseases. Some of the better known of these diseases are now discussed.

Diphtheria

Diphtheria [Greek *diphthera,* membrane, and *ia,* condition] is an acute contagious disease caused by the gram-positive *Corynebacterium diphtheriae* (*see figure 24.8*). *C. diphtheriae* is well adapted to airborne transmission by way of nasopharyngeal secretions and is very resistant to drying. Diphtheria mainly affects poor people living in crowded conditions. Once within the respiratory system, bacteria that carry the prophage β containing the *tox* gene (*see section 17.5*) produce diphtheria toxin, an exotoxin that causes an inflammatory response and the formation of a grayish pseudomembrane on the respiratory mucosa (**figure 39.1**). The pseudomembrane consists of dead host cells and cells of *C. diphtheriae.* The exotoxin is also absorbed into the circulatory system and distributed throughout the body,

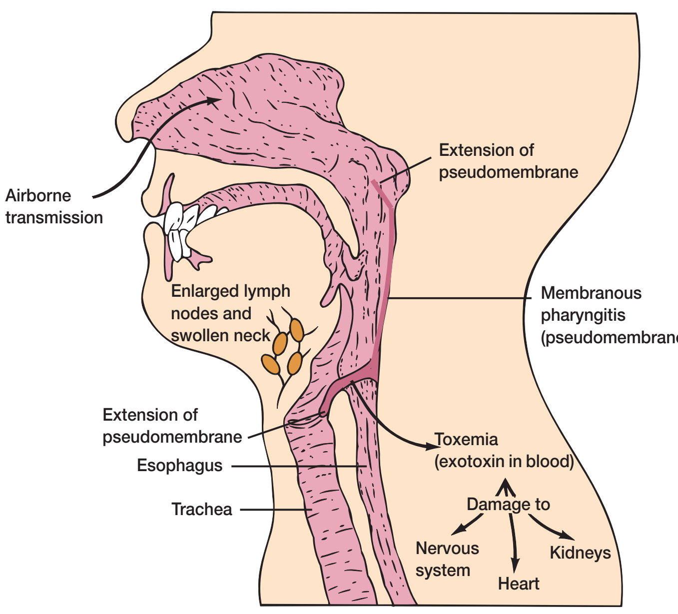

Figure 39.1 Diphtheria Pathogenesis. Diphtheria is a well-known exotoxin-mediated infectious disease caused by *Corynebacterium diphtheriae.* The disease is an acute, contagious, febrile illness characterized by local oropharyngeal inflammation and pseudomembrane formation. If the exotoxin gets into the blood, it is disseminated and can damage the peripheral nerves, heart, and kidneys.

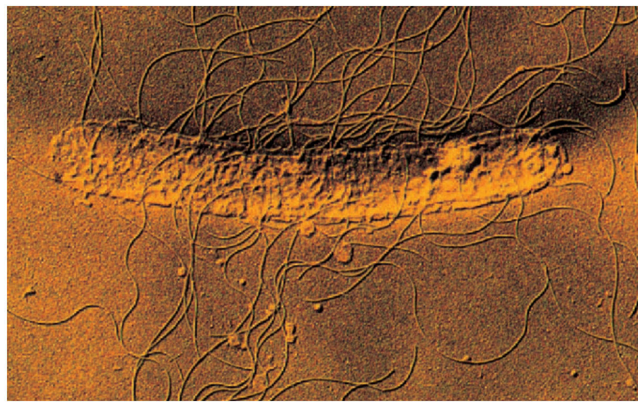

Figure 39.2 Legionnaires' Disease. *Legionella pneumophila,* the causative agent of Legionnaires' disease, with many lateral flagella; SEM (×10,000).

where it may cause destruction of cardiac, kidney, and nervous tissues by inhibiting protein synthesis (*see table 34.6 and figure 34.5*).

Typical symptoms of diphtheria include a thick mucopurulent (containing both mucus and pus) nasal discharge, fever, and cough. Diagnosis is made by observation of the pseudomembrane in the throat and by bacterial culture. Diphtheria antitoxin is given to neutralize any unabsorbed exotoxin in the patient's tissues; penicillin and erythromycin are used to treat the infection. Prevention is by active immunization with the **DPT** (**d**iphtheria-**p**ertussis-**t**etanus) **vaccine** (*see table 33.1*).

C. diphtheriae can also infect the skin, usually at a wound or skin lesion, causing a slow-healing ulceration termed **cutaneous diphtheria.** Most cases involve people over 30 years of age who have a weakened immunity to the diphtheria toxin and live in tropical areas.

Fewer than 100 diphtheria cases are reported annually in the United States, and most occur in nonimmunized individuals. Since 1990, a massive and expanding epidemic of diphtheria has been underway in 14 of the 15 new independent states of the former Soviet Union with approximately 50,000 new cases reported each year.

Legionnaires' Disease and Pontiac Fever

In 1976 the term **Legionnaires' disease,** or **legionellosis,** was coined to describe an outbreak of pneumonia that occurred at the Pennsylvania State American Legion Convention in Philadelphia. The bacterium responsible for the outbreak was described as *Legionella pneumophila,* a nutritionally fastidious aerobic gram-negative rod (**figure 39.2**). It is now known that this bacterium is part of the natural microbial community of soil and aquatic ecosystems, and it has been found in large numbers in air-conditioning systems and shower stalls.

An increasing body of evidence suggests that environmental protozoa are the most important factor for the survival and growth of *Legionella* in nature (*see p. 608*). A variety of free-living amoebae and ciliated protozoa that contain *Legionella* spp. have been isolated from water sites suspected as sources of *Legionella* infections. *Legionella* spp. multiply intracellularly within the amoebae, just as they do within human monocytes and macrophages. This might explain why there is no human-to-human spread of legionellosis.

Infection with *L. pneumophila* results from the airborne spread of bacteria from an environmental reservoir to the human respiratory system. Males over 50 years of age most commonly contract the disease, especially if their immune system is compromised by heavy smoking, alcoholism, or chronic illness. The bacteria reside within the phagosomes of alveolar macrophages, where they multiply and produce localized tissue destruction through export of a cytotoxic exoprotease. Symptoms include a high fever, nonproductive cough (respiratory secretions are not brought up during coughing), headache, neurological manifestations, and severe bronchopneumonia. Diagnosis depends on isolation of the bacterium, documentation of a rise in antibody titer over time, or a rapid test kit using urine to detect antigens. Treatment begins with supportive measures and the administration of erythromycin or rifampin.

Prevention of Legionnaires' disease depends on the identification and elimination of the environmental source of *L. pneumophila* contamination. Chlorination, the heating of water, and the cleaning of water-containing devices can help control the multiplication and spread of *Legionella.* These control measures are effective because the pathogen does not appear to be spread from person to person.

Table 39.2 Causative Agents of Meningitis by Diagnostic Category

Type of Meningitis	Causative Agent
Bacterial (Septic) Meningitis	*Streptococcus pneumoniae*
	Neisseria meningitidis
	Haemophilus influenzae type b
	Gram-negative bacilli
	Group B streptococci
	Listeria monocytogenes
	Mycobacterium tuberculosis
	Nocardia asteroides
	Staphylococcus aureus
	Staphylococcus epidermidis
Aseptic Meningitis Syndrome	
Agents Requiring Antimicrobials	Fungi
	Amoebae
	Syphilis
	Mycoplasmas
	Leptospires
Agents Requiring Other Treatments	Viruses
	Cancers
	Parasitic cysts
	Chemicals

Since the initial outbreak of this disease in 1976, many outbreaks during summer months have been recognized in all parts of the United States. About 1,000 to 1,400 cases are diagnosed each year, and about 30,000 or more additional mild or subclinical cases are thought to occur. It is estimated that 3 to 6% of all nosocomial pneumonias are due to *L. pneumophila,* especially among immunocompromised patients.

L. pneumophila also causes an illness called **Pontiac fever.** This disease, which resembles an allergic disease more than an infection, is characterized by an abrupt onset of fever, headache, dizziness, and muscle pains. It is indistinguishable clinically from the various respiratory syndromes caused by viruses. Pneumonia does not occur. The disease resolves spontaneously within 2 to 5 days. No deaths from Pontiac fever have been reported.

Pontiac fever was first described from an outbreak in a county health department in Pontiac, Michigan. Ninety-five percent of the employees became ill and eventually showed elevated serum titers against *L. pneumophila.* These bacteria were later isolated from the lungs of guinea pigs exposed to the air of the building. The likely source was water from a defective air conditioner.

Meningitis

Meningitis [Greek *meninx,* membrane, and *-itis,* inflammation] is an inflammation of the brain or spinal cord meninges (membranes). Based on the specific cause, it can be divided into **bacterial (septic) meningitis** and the **aseptic meningitis syndrome** (**table 39.2**). As shown by the table, there are many causes of the aseptic meningitis syndrome, only some of which can be treated with antimicrobials. Thus accurate identification of the causative agent is essential to proper treatment of the disease. The immediate sources of the bacteria responsible for meningitis are respiratory secretions from carriers or active cases. The bacteria initially colonize the nasopharynx after which they cross the mucosal barrier and enter the bloodstream and cerebrospinal fluid, where they produce inflammation of the meninges.

The usual symptoms of meningitis include an initial respiratory illness or sore throat interrupted by one of the meningeal syndromes: vomiting, headache, lethargy, confusion, and stiffness in the neck and back. Bacterial meningitis can be diagnosed by a Gram stain and culture of the bacteria from cerebrospinal fluid or rapid tests (*see table 36.3*). Once meningitis is suspected, specific antibiotics (penicillin, chloramphenicol, cefotaxime, ceftriaxone, ofloxacin) are administered immediately. A sharp reduction in the incidence of *H. influenzae* serotype b infections began in the mid-1980s due to vaccine administration, rifampin prophylaxis of disease contacts, and the availability of more efficacious therapeutic agents. From 1987 through 1999, the incidence of invasive infection among U.S. children less than 5 years of age declined by 95%. Currently, all children at the age of 2 months should be vaccinated with the *H. influenzae* type b conjugate vaccine.

A person may have meningitis symptoms, but show no microbial agent in Gram-stained specimens, and have negative cultures. In such a case the diagnosis often is aseptic meningitis syndrome. Aseptic meningitis is more difficult to treat, and the prognosis is usually poor.

Mycobacterium avium–M. intracellulare Pneumonia

During the past decade it has been discovered that there is an extremely large group of mycobacteria that are normal inhabitants of soil, water, and house dust. Two of these have become noteworthy pathogens in the United States. The two, *Mycobacterium avium* and *Mycobacterium intracellulare,* are so closely related that they are referred to as the *M. avium* complex (MAC).

These mycobacteria are found worldwide and infect a variety of insects, birds, and animals. Both the respiratory and the gastrointestinal tract have been proposed as the portal of entry for the *M. avium* complex. The gastrointestinal tract is thought to be the most common site of colonization and dissemination in AIDS patients. MAC causes a pulmonary infection in humans similar to *M. tuberculosis.* Pulmonary MAC is more common in non-AIDS patients, particularly in elderly persons with preexisting pulmonary disease.

Shortly after the recognition of AIDS and the associated opportunistic infections (*see table 38.3*), it became apparent that one of the more common infections was caused by MAC. Disseminated infection with MAC occurs in 15 to 40% of persons with AIDS in the United States with $CD4^+$ cell counts of less than 100 per cubic millimeter. Disseminated infection with MAC produces disabling symptoms, including fever, malaise, weight loss, night sweats, and diarrhea. Carefully controlled epidemiological studies have shown that MAC shortens survival by 5 to 7 months among persons with AIDS. With more effective antiviral therapy for AIDS and with prolonged survival, the number of cases of disseminated MAC is likely to increase substantially, and its contribution to AIDS mortality will increase.

MAC can be isolated from sputum, blood, and aspirates of bone marrow. Acid-fast stains are of value in making a diagnosis. The most sensitive method for detection is the commercially available lysis-centrifugation blood culture system (Wampole Laboratories). Although no drugs are currently approved by the FDA for the therapy of MAC, every regimen should contain either azithromycin or clarithromycin or ethambutol as a second drug, and one or more of the following: closfazimine, rifabutin, rifampin, ciprofloxacin, and amikacin.

Pertussis

Pertussis [Latin *per,* intensive, and *tussis,* cough], sometimes called "whooping cough," is caused by the gram-negative bacterium *Bordetella pertussis.* (*B. parapertussis* is a closely related species that causes a milder form of the disease.) Pertussis is a highly contagious disease that primarily affects children. It has been estimated that over 95% of the world's population has experienced either mild or severe symptoms of the disease. Around 500,000 die from the disease each year. However, there are less than around 5,000 cases and less than 10 deaths annually in the United States.

Transmission occurs by inhalation of the bacterium in droplets released from an infectious person. The incubation period is 7 to 14 days. Once inside the upper respiratory tract, the bacteria attach to the ciliated epithelial cells by producing adhesins such as the factor called filamentous hemagglutinin, which recognizes a complementary molecule on the cells. After attachment, the bacteria synthesize several toxins (*see table 34.6*) that are responsible for the symptoms. The most important toxin is pertussis toxin, which causes increased tissue susceptibility to histamine and serotonin, and an increased lymphocyte response. *B. pertussis* also produces an extracytoplasmic invasive adenylate cyclase, and tracheal cytotoxin and dermonecrotic toxin, which destroy epithelial tissue. In addition, the secretion of a thick mucus impedes ciliary action, and often, ciliated epithelial cells die.

Pertussis is divided into three stages. (1) The catarrhal stage, so named because of the mucous membrane inflammation, which is insidious and resembles the common cold. (2) Prolonged coughing sieges characterize the paroxysmal stage. During this stage the infected person tries to cough up the mucous secretions by making 5 to 15 rapidly consecutive coughs followed by the characteristic whoop—a hurried deep inspiration. The catarrhal and paroxysmal stages last about 6 weeks. (3) Final recovery may take several months (the convalescent stage).

Laboratory diagnosis of pertussis is by culture of the bacterium, fluorescent antibody staining of smears from nasopharyngeal swabs, and serological tests. The development of a strong, lasting immunity takes place after an initial infection. Treatment is with erythromycin, tetracycline, or chloramphenicol. Treatment ameliorates clinical illness when begun during the catarrhal phase and may also reduce the severity of the disease when begun within 2 weeks of the onset of the paroxysmal cough. Prevention is with the DPT vaccine (*see p. 765*); vaccination of children is recommended when they are 2 to 3 months old (*see table 33.1*).

Streptococcal Diseases

Streptococci, commonly called strep, are a heterogeneous group of gram-positive bacteria. In this group *Streptococcus pyogenes* (group A β-hemolytic streptococci; *see pp. 530–33*) is one of the most important bacterial pathogens. The different serotypes produce (1) extracellular enzymes that break down host molecules; (2) streptokinases, enzymes that activate a host-blood factor that dissolves blood clots; (3) the cytolysins streptolysin O and streptolysin S, which kill host leukocytes; and (4) capsules and M protein that help retard phagocytosis.

S. pyogenes is widely distributed among humans, but usually people are asymptomatic carriers. Individuals with acute infections may spread the pathogen, and transmission can occur through respiratory droplets, direct, or indirect contact. When highly virulent strains appear in schools, they can cause sharp outbreaks of sore throats and scarlet fever. Due to the cumulative buildup of antibodies to many different *S. pyogenes* serotypes over the years, outbreaks among adults are less frequent.

Diagnosis of a streptococcal infection is based on both clinical and laboratory findings. Several rapid tests are available (*see table 36.3*). Treatment is with penicillin or erythromycin. Vaccines are not available for streptococcal diseases other than streptococcal pneumonia because of the large number of serotypes.

The best control measure is prevention of bacterial transmission. Individuals with a known infection should be isolated and treated. Personnel working with infected patients should follow standard aseptic procedures.

In the following sections some of the more important human streptococcal diseases are discussed (**figure 39.3**).

Cellulitis and Erysipelas

Cellulitis is a diffuse, spreading infection of subcutaneous skin tissue. The resulting inflammation is characterized by a defined area of redness (erythema) and the accumulation of fluid (edema).

The most frequently diagnosed skin infection caused by *S. pyogenes* is **impetigo** (impetigo also can be caused by *S. aureus* [figure 39.19*e*]). Impetigo is a superficial cutaneous infection, most commonly seen in children, usually located on the face, and characterized by crusty lesions and vesicles surrounded by a red border. Impetigo is most common in late summer and early fall. The drugs of choice for impetigo are penicillin or erythromycin in those individuals who are allergic to penicillin.

Erysipelas [Greek *erythros,* red, and *pella,* skin] is an acute infection and inflammation of the dermal layer of the skin. It occurs primarily in infants and people over 30 years of age with a history of streptococcal sore throat. The skin often develops painful reddish patches that enlarge and thicken with a sharply defined edge (**figure 39.4**). Recovery usually takes a week or longer if no treatment is given. The drugs of choice for the treatment of erysipelas are erythromycin and penicillin. Erysipelas may recur periodically at the same body site for years.

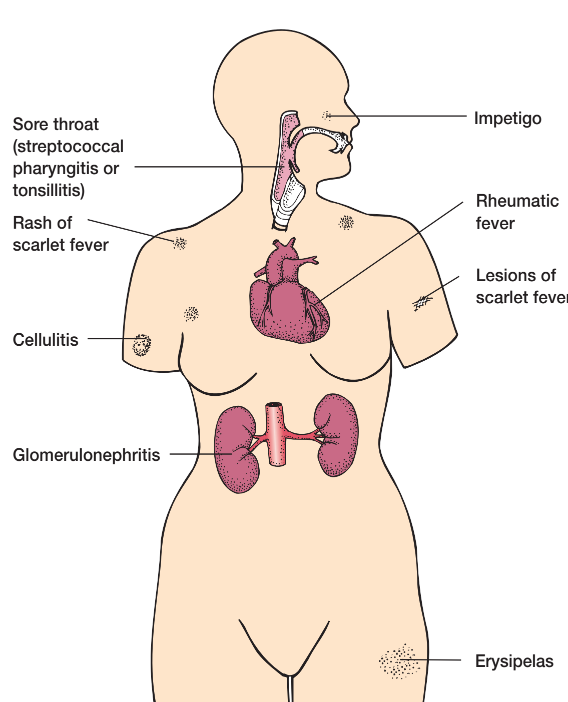

Figure 39.3 Streptococcal Diseases. Some of the more prominent diseases associated with group A streptococcal infections, and the body sites affected.

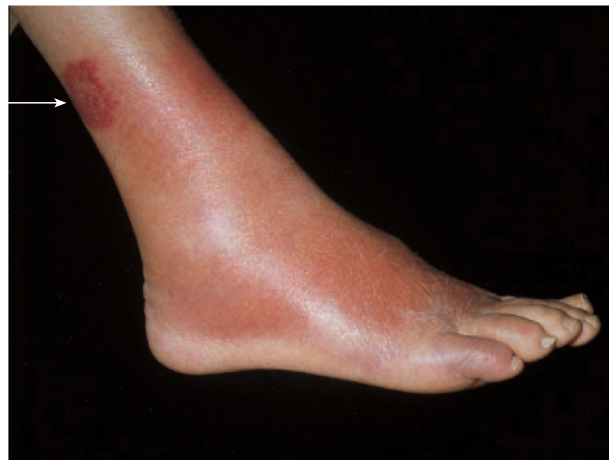

Figure 39.4 Erysipelas. Notice the bright, raised, rubbery lesion at the site of initial entry (white arrow) and the spread of the inflammation to the foot. The reddening is caused by toxins produced by the streptococci as they invade new tissue.

Invasive Streptococcus A Infections

In the nineteenth century invasive *Streptococcus pyogenes* infections were a major cause of morbidity and mortality. However, during this century the incidence of severe group A streptococcal infections has declined, especially since the arrival of antibiotic therapy. In the mid-1980s there was a worldwide increase in group A streptococcal sepsis; clusters of rheumatic fever were reported from locations within the United States, and a streptococcal toxic shock–like syndrome emerged. (A virulent strep A infection killed *Sesame Street* Muppeteer Jim Henson in 1990, and in 1994 the press made headlines with articles on "the flesh-eating invasive disease.")

The development of invasive strep A disease appears to depend on the presence of specific virulent strains (M-1 and M-3 serotypes) and predisposing host factors (surgical or nonsurgical wounds, diabetes, and other underlying medical problems). A life-threatening infection begins when invasive strep A strains penetrate a mucous membrane or take up residence in a skin lesion such as a bruise. This infection can quickly lead either to **necrotizing fasciitis** [Greek *nekrosis,* deadness, Latin *fascis,* band or bandage, and *itis,* inflammation] that destroys the sheath covering skeletal muscles or to **myositis** [Greek *myos,* muscle, and *itis*], the inflammation and destruction of skeletal muscle and fat tissue. Because necrotizing fasciitis and myositis arise and spread so quickly, they have been colloquially called "galloping gangrene."

Rapid treatment is necessary to reduce the risk of death, and penicillin G remains the treatment of choice. In addition, surgical removal of dead and dying tissue usually is needed in more advanced cases of necrotizing fasciitis. It is estimated that 10,000 to 15,000 cases of invasive strep A infections occur annually in the United States, and between 5 and 10% of them are associated with necrotizing conditions.

One reason invasive strep A strains are so deadly is that about 85% of them carry the genes for the production of **s**treptococcal **p**yrogenic **e**xotoxins A and B (Spe exotoxins). Exotoxin A acts as a superantigen. This superantigen quickly stimulates T cells to begin producing abnormally large quantities of cytokines. These cytokines damage the endothelial cells that line blood vessels, causing fluid loss and rapid tissue death from a lack of oxygen. Another pathogenic mechanism involves the secretion of exotoxin B (cysteine protease). Cysteine protease is an enzyme that rapidly destroys tissue by breaking down proteins.

Since 1986 it has been recognized that invasive strep A infections can also trigger a ***t*****oxic *s*****hock–*l*****ike *s*****yndrome (TSLS),** characterized by a precipitous drop in blood pressure, failure of multiple organs, and a very high fever. TSLS is caused by an invasive strep A that produces one or more of the streptococcal pyrogenic exotoxins. TSLS has a mortality rate of over 30%.

Because group A streptococci are less contagious than cold or flu viruses, infected individuals do not pose a major threat to people around them. The best preventive measures are simple ones such as covering food, washing hands, and cleansing and medicating wounds.

Poststreptococcal Diseases

The poststreptococcal diseases are glomerulonephritis and rheumatic fever. They occur 1 to 4 weeks after an acute streptococcal infection (hence the term post). Today these two diseases are the

most serious problems associated with streptococcal infections in the United States.

Glomerulonephritis or **Bright's disease** is an inflammatory disease of the renal glomeruli, membranous structures within the kidney where blood is filtered. Damage probably results from the deposition of antigen-antibody complexes, possibly involving the streptococcal M protein, in the glomeruli. Thus the disease arises from a type III hypersensitivity reaction (*see figure 33.6*). The complexes cause destruction of the glomerular membrane, allowing proteins and blood to leak into the urine. Clinically the affected person exhibits edema, fever, hypertension, and hematuria (blood in the urine). The disease occurs primarily among school-age children. Diagnosis is based on the clinical history, physical findings, and confirmatory evidence of prior streptococcal infection. The incidence of glomerulonephritis in the United States is less than 0.5% of streptococcal infections. Penicillin G or erythromycin can be given for any residual streptococci. However, there is no specific therapy once kidney damage has occurred. About 80 to 90% of all cases undergo slow spontaneous healing of the damaged glomeruli, whereas the others develop a chronic form of the disease. The latter may require a kidney transplant or lifelong renal dialysis.

Rheumatic fever is an autoimmune disease characterized by inflammatory lesions involving the heart valves, joints, subcutaneous tissues, and central nervous system. It usually results from a prior streptococcal sore throat infection. The exact mechanism of rheumatic fever development remains unknown. The disease occurs most frequently among children 6 to 15 years of age and manifests itself through a variety of signs and symptoms, making diagnosis difficult. In the United States rheumatic fever has become very rare (less than 0.05% of streptococcal infections), but it occurs 100 times more frequently in tropical countries. Therapy is directed at decreasing the inflammation and fever and controlling cardiac failure. Salicylates and corticosteroids are the mainstays of treatment. Though rheumatic fever is rare, it is still the most common cause of permanent heart valve damage in children.

Scarlet Fever

Scarlet fever (scarlatina) results from a throat infection with a strain of *S. pyogenes* that carries a lysogenic bacteriophage. This codes for the production of an erythrogenic or rash-inducing toxin that causes shedding of the skin. Scarlet fever is a communicable disease spread by inhalation of infective respiratory droplets. After a 2-day incubation period, a scarlatinal rash appears on the upper chest and then spreads to the remainder of the body. This rash represents the skin's generalized reaction to the circulating toxin. Along with the rash, the infected individual experiences a sore throat, chills, fever, headache, and a strawberry-colored tongue (**figure 39.5**). Treatment is with penicillin.

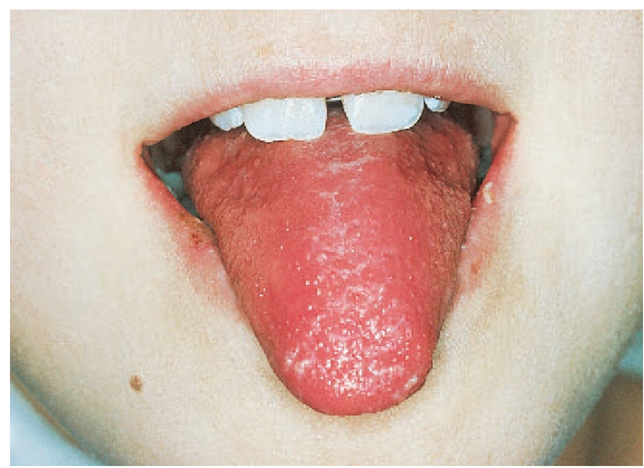

Figure 39.5 Scarlet Fever. The strawberry-colored tongue of this streptococcal disease.

Streptococcal Sore Throat

Streptococcal sore throat is one of the most common bacterial infections of humans and is commonly called strep throat. The β-hemolytic group A streptococci are spread by droplets of saliva or nasal secretions. The incubation period in humans is 2 to 4 days. The incidence of sore throat is greater during the winter and spring months.

The action of the strep bacteria in the throat (**pharyngitis**) or on the tonsils (**tonsillitis**) stimulates an inflammatory response and the lysis of leukocytes and erythrocytes. An inflammatory exudate consisting of cells and fluid is released from the blood vessels and deposited in the surrounding tissue. This is accompanied by a general feeling of discomfort or malaise, fever (usually above 101°F), and headache. Prominent physical manifestations include redness, edema, and lymph node enlargement in the throat. Several common rapid test kits are available for diagnosing strep throat. In the absence of complications, the disease is self-limited and disappears within a week. However, treatment with penicillin G benzathine (or erythromycin for penicillin-allergic people) can shorten the infection and clinical syndromes, and is especially important in children for the prevention of complications such as rheumatic fever and glomerulonephritis. Infections in older children and adults tend to be milder and less frequent due in part to the immunity they have developed against the many serotypes encountered in early childhood. Prevention and control measures include proper disposal or cleansing of objects (e.g., facial tissue, handkerchiefs) contaminated by discharges from the infected individual.

Streptococcal Pneumonia

Streptococcal pneumonia is now considered an **endogenous infection**—that is, it is contracted from one's own normal microbiota (*see figure 31.2*). It is caused by the gram-positive *Streptococcus pneumoniae,* found in the upper respiratory tract (**figure 39.6**). However, disease usually occurs only in those individuals with predisposing factors such as viral infections of the respiratory tract, physical injury to the tract, alcoholism, or diabetes. About 60 to 80% of all respiratory diseases known as pneumonia are caused by *S. pneumoniae.* An estimated 150,000 to 300,000

 © The McGraw–Hill Companies, 2002

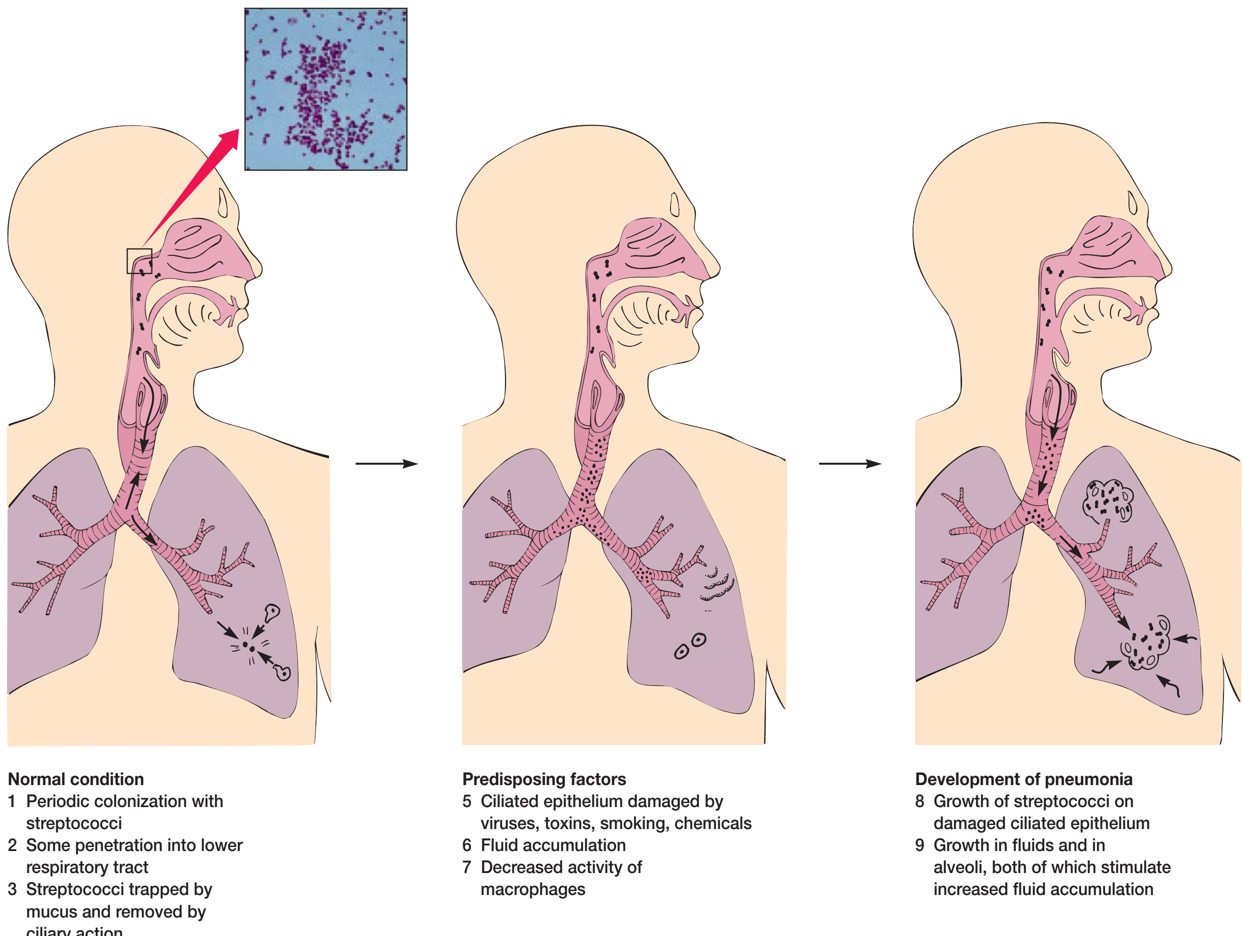

Figure 39.6 Predisposition to and the Development of Streptococcal Pneumonia. The insert shows the morphology of *Streptococcus pneumoniae* (× 1,000). Streptococci are gram-positive bacteria of spherical to ovoid shape that characteristically form chains when grown in liquid media or as diplococci on solid media.

people in the United States contract this form of pneumonia annually, and between 13,000 to 66,000 deaths result.

The primary virulence factor of *S. pneumoniae* is its capsular polysaccharide. The capsular polysaccharide is composed of hyaluronic acid. It is the production of large amounts of hyaluronic capsular polysaccharide that plays an important role in protecting the organism from ingestion and killing by phagocytes (*see chapter 34 opener*). The pathogenesis is due to the rapid multiplication of the bacteria in alveolar spaces. The bacteria also produce the toxin pneumolysin that destroys host cells. The alveoli fill with blood cells and fluid and become inflamed. The sputum is often rust colored because of blood coughed up from the lungs. The onset of clinical symptoms is usually abrupt, with chills, hard labored breathing, and chest pain. Diagnosis is by chest X ray, biochemical tests, and culture. Penicillin G, cefotaxime, ofloxacin, and ceftriaxone have contributed to a greatly reduced mortality rate. For individuals who are sensitive to penicillin, erythromycin, or tetracycline can be used. Recently a penicillin- and tetracyline-resistant strain of *S. pneumoniae* has appeared in the United States. Pneumococcal vaccines (Pneumovax 23, Pnu-Imune 23) are available for people who are debilitated (e.g., people in chronic-care facilities). The efficacy of the Pneumovax vaccines (pooled collections of 23 different *S. pneumoniae* capsular polysaccharides) is that they generate antibodies to the capsule. When these antibodies are deposited on the surface of the capsule, they become opsonic and enhance phagocytosis. Preventive and control measures include immunization and adequate treatment of infected persons.

Tuberculosis

Over a century ago Robert Koch (*see figure 1.4*) identified *Mycobacterium tuberculosis* as the causative agent of **tuberculosis (TB).** At the time, TB was rampant, causing 1/7 of all deaths in Europe and 1/3 of deaths among productive young adults. Today TB remains a global health problem of enormous dimension. It is estimated that there are 1 billion (20% of the world's human pop-

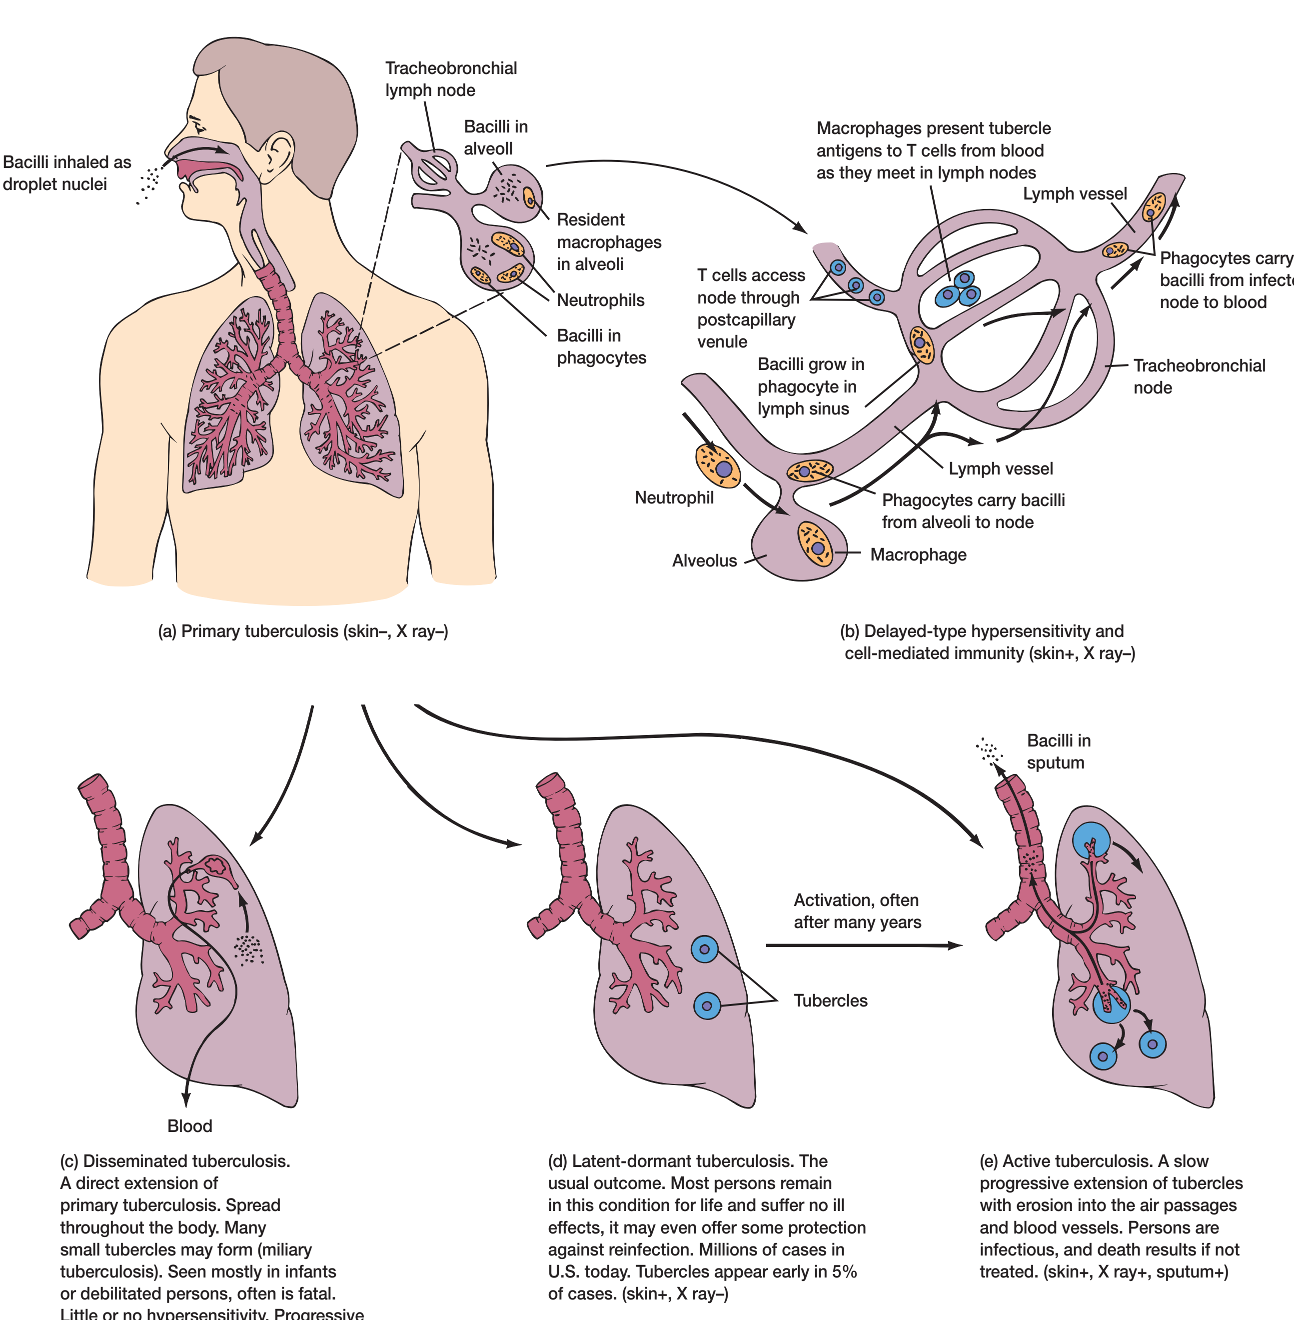

Figure 39.7 Tuberculosis. The history of untreated tuberculosis in the human body.

ulation) infected worldwide, with 10 million new cases and over 3 million deaths per year.

In the United States this disease occurs most commonly among the homeless, elderly, malnourished, or alcoholic poor males, minorities, immigrants, prison populations, and Native Americans. More than 26,000 new cases of tuberculosis and over 12,000 deaths are reported annually. Most cases in the United States are caused by the acid-fast *Mycobacterium tuberculosis,* acquired from other humans through droplet nuclei and the respiratory route (**figure 39.7**). It appears that about 1/4 to 1/3 of active TB cases in the United States may be due to recent transmission. The majority of active cases result from the reactivation of old dormant infections. Worldwide, *M. bovis* and *M. africanum* also cause TB. Transmission to humans from susceptible animal species and their products (e.g., milk) is also possible. Recently there has been a steady yearly increase in the number of TB cases

as a result of the AIDS epidemic. Available statistics indicate that a close association exists between AIDS and TB. Therefore further spread of HIV infection among the population with a high prevalence of TB infection is resulting in dramatic increases in TB.

Once in the lungs the bacteria are phagocytosed by macrophages and a hypersensitivity response forms small, hard nodules called **tubercles,** which are characteristic of tuberculosis and give the disease its name. The disease process usually stops at this stage, but the bacteria often remain alive within macrophage phagosomes. Resistance to oxidative killing, inhibition of phagosome-lysosome fusion, and inhibition of diffusion of lysosomal enzymes are some of the mechanisms that may explain the survival of *M. tuberculosis* inside macrophages. In time the tubercle may change to a cheeselike consistency and is then called a **caseous lesion.** If such lesions calcify, they are termed **Ghon complexes,** which show up prominently in a chest X ray. (Often the primary lesion is called the Ghon's tubercle or Ghon's focus.) Sometimes the tubercle lesions liquefy and form air-filled **tuberculous cavities.** From these cavities the bacteria can spread to new foci of infections throughout the body. This spreading is often called **miliary tuberculosis** due to the many tubercles the size of millet seeds that are formed in the infected tissue. It also may be called **reactivation tuberculosis** because the bacteria have been reactivated in the initial site of infection.

Persons infected with *M. tuberculosis* develop a cell-mediated immunity due to the bacteria being phagocytosed by macrophages. This immunity involves sensitized T cells (figure 39.7*b*) and is the basis for the tuberculin skin test (*see figure 33.7*a). In this test a purified protein derivative (PPD) of *M. tuberculosis* is injected intracutaneously (the Mantoux test). If the person has had tuberculosis, sensitized T cells react with these proteins, and a delayed hypersensitivity reaction occurs within 48 hours. This positive skin reaction appears as an induration (hardening) and reddening of the area around the injection site. Multiple puncture tests such as the Tine test are more convenient but not as accurate.

In a young person a positive skin test possibly indicates active tuberculosis. In older persons it may result from previous disease, vaccination, or a false-positive test. In both cases X rays and bacterial isolation should be completed.

The incubation period is about 4 to 12 weeks, and the disease develops slowly. The symptoms of tuberculosis are fever, fatigue, and weight loss. A cough, which is characteristic of pulmonary involvement, may result in expectoration of bloody sputum.

Laboratory diagnosis of tuberculosis is by isolation of the acid-fast bacterium, chest X ray, commercially available DNA probes, the BACTEC NAP test, and the Mantoux or tuberculin skin test. Both chemotherapy and chemoprophylaxis are carried out by administering isoniazid (INH), plus rifampin, ethambutol, and pyrazinamide. These drugs are administered simultaneously for 12 to 24 months as a way of decreasing the possibility that the patient develops drug resistance.

Recently, new ***m*ulti-*d*rug-*r*esistant strains of *tu*berculosis (MDR-TB)** have developed and are spreading. A multi-drug-resistant strain is defined as *M. tuberculosis* resistant to isoniazid and rifampin, with or without resistance to other drugs. Within the United States drug resistance has increased from 2 to 9% in the past three decades, and similar increases have occurred in many other countries. This has resulted in many cases of marginally treatable, often fatal, disease. Inadequate therapy is the most common means by which resistant bacteria are acquired, and patients who have previously undergone therapy should be presumed to harbor MDR-TB until proved otherwise.

The way in which MDR-TB arises is now known. Tubercle bacilli have spontaneous, predictable rates of chromosomally born mutations that confer resistance to drugs. These mutations are unlinked; hence resistance to one drug is not associated to resistance to an unrelated drug. The emergence of drug resistance represents the survival of random preexisting mutations, not a change caused by exposure to the drug—that the mutations are not linked is the cardinal principle underlying TB chemotherapy. For example, mutations causing resistance to isoniazid or rifampin occur roughly 1 in 10^8 replications of *M. tuberculosis.* The likelihood of spontaneous mutations causing resistance to both isoniazid and rifampin is the sum of these probabilities, or 1 in 10^{16}. However, these biological mechanisms of resistance break down when chemotherapy is inadequate. In the circumstances of monotherapy, erratic drug ingestion, omission of one or more drugs, suboptimal dosage, poor drug absorption, or an insufficient number of active drugs in a regimen, a susceptible strain on *M. tuberculosis* may become resistant to multiple drugs within a matter of months.

Prevention and control of tuberculosis requires rapid specific therapy to interrupt infectious spread. Retreatment of patients who have multi-drug-resistant tuberculosis should be carried out in programs with comprehensive microbiological, pharmacokinetic, psychosocial, and nutritional support systems. In many countries individuals, especially infants and children, are vaccinated with **b**acille **C**almette-**G**uérin (BCG) vaccine to prevent complications such as meningitis. The BCG vaccine appears to protect about half of those inoculated. Tuberculosis rates also can be lowered by better public health measures and social conditions, for example, a reduction in homelessness and drug abuse.

1. What causes the typical symptoms of diphtheria and how are individuals protected against this disease?
2. What is the environmental source of the bacterium that causes Legionnaires' disease? Pontiac fever?
3. What are the two major types of meningitis? Why is it so important to determine which type a person has?
4. Name the three stages of pertussis.
5. Name the most important human diseases caused by *Streptococcus pyogenes.* How do they differ from one another?
6. How is tuberculosis diagnosed? Describe the various types of lesions and how they are formed. How do multi-drug-resistant strains of tuberculosis develop?

39.2 Arthropod-Borne Diseases

Although arthropod-borne bacterial diseases are generally rare, they are of interest either historically (plague, typhus [*see chapter opener quote*]) or because they have been newly introduced into

Box 39.1

The Hazards of Microbiological Research

The investigation of human pathogens often is a very dangerous matter, and several microbiologists have been killed by the microorganisms they were studying. The study of typhus fever provides a classic example. In 1906 Howard T. Ricketts (1871–1910), an associate professor of pathology at the University of Chicago, became interested in Rocky Mountain spotted fever, a disease that had decimated the Nez Percé and Flathead Indians of Montana. By infecting guinea pigs, he established that a small bacterium was the disease agent and was transmitted by ticks. In late 1909 Ricketts traveled to Mexico to study Mexican typhus.

He discovered that a microorganism similar to the Rocky Mountain spotted fever bacillus could cause the disease in monkeys and be transmitted by lice. Despite his careful technique, he was bitten while transferring lice in his laboratory and died of typhus fever on May 3, 1910. The causative agent of typhus fever was fully described in 1916 by the Brazilian scientist H. da Roche-Lima and named *Rickettsia prowazekii* in honor of Ricketts and Stanislaus von Prowazek, a Czechoslovakian microbiologist who died in 1915 while studying typhus.

Today modern equipment to control microorganisms, such as laminar airflow hoods, have greatly reduced the risks of research on microbial pathogens.

humans (ehrlichiosis, Q fever, Lyme disease). In the following sections, only diseases that occur in the United States are discussed.

Ehrlichiosis

In 1986 the first case of **ehrlichiosis** was diagnosed in the United States and shown to be caused by a new bacterial species (table 39.1), *Ehrlichia chaffeensis.* Members of the genus *Ehrlichia* are related to the genus *Rickettsia* and placed in the order *Rickettsiales* of the α-proteobacteria. Since the initial discovery, more than 400 cases have been reported in the United States. *E. chaffeensis* is transmitted from unknown animal vectors to humans by the Lone Star tick (*Amblyomma americanum*). Once inside the human body, *E. chaffeensis* infects circulating monocytes causing a nonspecific febrile illness (**h**uman **m**onocytic **e**hrlichiosis, HME) that resembles Rocky Mountain spotted fever. Diagnosis involves serological tests and tetracycline is the drug of choice.

In 1994 a new form of ehrlichiosis was discovered. **H**uman **g**ranulocytic **e**hrlichiosis (HGE) is transmitted by deer ticks (*Ixodes scapularis*) and possibly dog ticks (*Dermacentor variabilis*), and has been found in 30 states, particularly in the southeastern and south central United States. The causative agent is an *Ehrlichia* species different from *E. chaffeensis.* The disease is characterized by the rapid onset of fever, chills, headaches, and muscle aches. Treatment is with doxycycline.

Epidemic (Louse-Borne) Typhus

Epidemic (louse-borne) typhus is caused by the rickettsia *Rickettsia prowazekii,* which is transmitted from person to person by the body louse (**Box 39.1**). In the United States a reservoir of *R. prowazekii* also exists in the southern flying squirrel. When a louse feeds on an infected rickettsemic person, the rickettsias infect the insect's gut and multiply, and large numbers of organisms appear in the feces in about a week. When a louse takes a blood meal, it defecates. The irritation causes the affected individual to scratch the site and contaminate the bite wound with rickettsias. The rickettsias then spread by way of the bloodstream and infect the endothelial cells of the blood vessels, causing a **vasculitis** (inflammation of the blood vessels). This produces an abrupt headache, fever, and muscle aches. A rash begins on the upper trunk, and spreads. Without treatment, recovery takes about 2 weeks, though mortality rates are very high (around 50%), especially in the elderly. Recovery from the disease gives a solid immunity and also protects the person from murine typhus.

Diagnosis is by the characteristic rash, symptoms, and the Weil-Felix reaction (**Box 39.2**). Chloramphenicol and tetracycline are effective against typhus. Control of the human body louse (*Pediculus humanus corporis*) and the conditions that foster its proliferation are mainstays in the prevention of epidemic typhus, although a typhus vaccine is available for high-risk individuals. The importance of louse control and good public hygiene is shown by the prevalence of typhus epidemics during times of war and famine when there is crowding and little attention to the maintenance of proper sanitation. For example, around 30 million cases of typhus fever and 3 million deaths occurred in the Soviet Union and Eastern Europe between 1918 and 1922. The bacteriologist Hans Zinsser believes that Napoleon's retreat from Russia in 1812 may have been partially provoked by typhus and dysentery epidemics that ravaged the French army. Fewer than 25 cases of epidemic typhus are reported in the United States each year.

Endemic (Murine) Typhus

The etiologic agent of **endemic (murine) typhus** is the rickettsia *Rickettsia typhi.* It occurs in isolated areas around the world, including southeastern and Gulf Coast states, especially Texas. The disease occurs sporadically in individuals who come into contact with rats and their fleas (*Xenopsylla cheopi*). The disease is nonfatal in the rat and is transmitted from rat to rat by fleas. When an infected flea takes a human blood meal, it defecates. Its feces are heavily laden with rickettsias, which infect humans by contaminating the bite wound.

Box 39.2

The Weil-Felix Reaction

During World War I Austrian bacteriologists Edmond Weil (1880–1922) and Arthur Felix (1887–1956) were in charge of diagnosing typhus in the Austrian Army. In 1916 they developed the agglutination test for typhus that now bears their names.

The **Weil-Felix reaction** is based on the detection of heterophilic antibodies—that is, cross-reactive antibodies. In this test, antibodies produced in response to a particular rickettsial infection agglutinate bacterial strains of *Proteus,* designated OX–19, OX–2, and OX–K. These cross-reactions occur because rickettsial strains possess cell wall antigens that are similar to polysaccharide O antigens of the *Proteus* strains. The results are considered to give presumptive diagnosis of rickettsial diseases. However, it should be kept in mind that *Proteus* species are indigenous to humans and may cause urinary tract infections. Therefore the presence of antibodies to *Proteus* OX strains is not of itself an absolute criterion for the presence of rickettsial disease.

The clinical manifestations of murine [Latin *mus, muris,* mouse or rat] typhus are similar to those of epidemic typhus except that they are milder in degree and the mortality rate is much lower: less than 5%. Diagnosis and treatment also are the same. Rat control and avoidance of rats are preventive measures for the disease. Fewer than 100 cases of endemic typhus are reported in the United States each year.

Lyme Disease

Lyme disease (LD, Lyme borreliosis) was first observed and described in 1975 among people of Old Lyme, Connecticut. It has become the most common tick-borne zoonosis in the United States, with more than 10,000 cases being reported annually. In fact, Lyme disease has reached epidemic proportions, and if it were not for AIDS, Lyme disease would be the most important “new” infectious disease (*table 39.1*) of humans in the United States. The disease is also present in Europe and Asia.

The Lyme spirochetes responsible for this disease comprise at least three species, currently designated *Borrelia burgdorferi* (**figure 39.8*a***), *B. garinii,* and *B. afzelii.* Deer and field mice are the natural hosts. In the northeastern United States, *B. burgdorferi* is transmitted to humans by the bite of the infected deer tick (*Ixodes scapularis;* figure 39.8*b*). On the Pacific Coast, especially in California, the reservoir is a dusky-footed woodrat, and the tick, *I. pacificus.*

Clinically Lyme disease is a complex illness with three major stages. The initial, localized stage occurs a week to 10 days after an infectious tick bite. The illness usually begins with an expanding, ring-shaped, skin lesion with a red outer border and partial central clearing (figure 39.8*c*). This often is accompanied by flulike symptoms (malaise and fatigue, headache, fever, and chills). Often the tick bite is unnoticed, and the skin lesion may be missed due to skin coloration or its obscure location such as on the scalp. Thus treatment, which is usually effective at this stage, may not be given because the illness is passed off as “just a touch of the flu.”

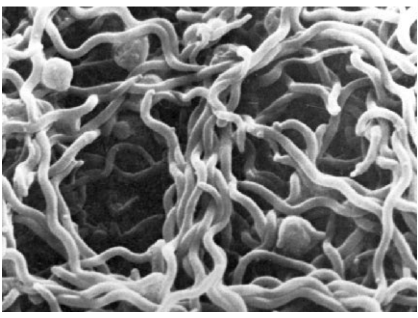
The second, disseminated stage may appear weeks or months after the initial infection. It consists of several symptoms such as neurological abnormalities, heart inflammation, and bouts of arthritis (usually in the major joints such as the elbows or knees). Current research indicates that Lyme arthritis might be an autoimmune response to joint cell HLA molecules that are similar to the bacterial antigens. The inflammation that produces organ damage is initiated and possibly perpetuated by the immune response to one or more spirochetal proteins.

Finally, like syphilis, years later the late stage may appear. Infected individuals may develop demyelination of neurons with symptoms resembling Alzheimer’s disease and multiple sclerosis. Behavioral changes also can occur.

Laboratory diagnosis of Lyme’s disease is based on (1) the recovery of the spirochete from the patient, (2) use of the polymerase chain reaction (*see section 14.3*) for detection of *B. burgdorferi* DNA in urine, or (3) serological testing (Lyme ELISA or Western Blot) for IgM and IgG antibodies to the pathogen. Treatment with amoxicillin or tetracycline early in the illness results in prompt recovery and prevents arthritis and other complications. If nervous system involvement is suspected, ceftriaxone is used since it can cross the blood-brain barrier.

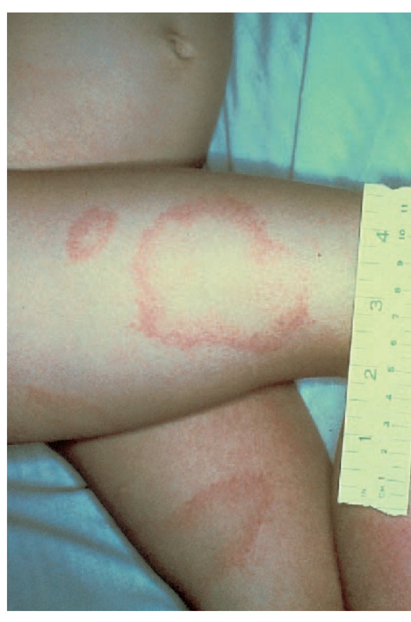
Prevention and control of Lyme disease involves environmental modification (clearing and burning tick habitat) and the application of acaricidal compounds (agents that destroy mites and ticks). An individual’s risk of acquiring Lyme disease may be greatly reduced by education and personal protection. A vaccine, LYMErix, is available for individuals living in areas where Lyme disease is prevalent. The following points should be kept in mind whenever a person is active in an area where Lyme disease or other tick-borne zoonoses occur:

1. It takes a minimum of 24 hours of attachment and feeding for transmission to occur; thus prompt removal of attached ticks will greatly reduce the risk of infection. To remove an embedded tick, one should use tweezers to grasp the tick as close as possible to the skin and then pull with slow, steady pressure in a direction perpendicular to the skin.
2. Because each deer tick life cycle stage is most abundant at a certain time, there are periods when an individual should be most aware of the risk of infection. The most dangerous times are May through July, when the majority of nymphal deer ticks are present and the risk of transmission is greatest.



(a)

(b)



(c)

Figure 39.8 Lyme Disease. (**a**) The etiological agent is the spirochete *Borrelia burgdorferi;* SEM. (**b**) The vector in the Northeast is the tick *Ixodes scapularis.* The youngest (nymphal stage, top) is about the size of a poppy seed. An unengorged adult (bottom), and an engorged adult (center) can reach the size of a jelly bean. (**c**) The typical rash (erythema migrans) showing concentric rings around the initial site of the tick bite.

3. If you must be in the woods, dress accordingly. Wear light-colored pants and good shoes. Tuck the cuffs of your pants into long socks to deny ticks easy entry under your clothes. After coming out of the woods, check all clothes for ticks.
4. Repellents containing high concentrations of DEET (diethyltoluamide) or permanone are available over the counter and are very noxious to ticks. Premethrin kills ticks on contact but is approved only for use on clothing.
5. Immediately after being in a high-risk area, examine your body for bites or itches. Taking a shower and using lots of soap aids in this examination. Areas such as the scalp, armpits, and groin are difficult to examine effectively but are preferred sites for tick attachment. Special attention should be given to these parts of the body.

Plague

In the southwestern part of the United States, **plague** [Latin *plaga,* pest] occurs primarily in wild rodents (ground squirrels and prairie dogs). However, massive human epidemics occurred during the Middle Ages, and the disease was known as the Black Death because one of its characteristics is blackish areas on the skin caused by subcutaneous hemorrhages. Infections now occur in humans only sporadically or in limited outbreaks. In the United States approximately 25 cases are reported annually, and the mortality rate is about 15%.

The disease is caused by the gram-negative bacterium *Yersinia pestis.* It is transmitted from rodent to human by the bite of an infected flea, direct contact with infected animals or their products, or inhalation of contaminated airborne droplets (**figure 39.9**). Once in the human body, the bacteria multiply in the blood and lymph. An important factor in the virulence of *Y. pestis* is its ability to survive and proliferate inside phagocytic cells rather than be killed by them. One of the ways this is accomplished is by the YOPS (**y**ersinal plasmid-encoded **o**uter membrane **p**roteins) that are secreted by the bacterium and act as antiphagocytic proteins to counteract natural defense mechanisms and help the bacteria multiply and disseminate in the host (*see figure 34.4*).

Symptoms—besides the subcutaneous hemorrhages—include fever and the appearance of enlarged lymph nodes called **buboes** (hence the old name, **bubonic plague**). In 50 to 70% of the untreated cases, death follows in 3 to 5 days from toxic conditions caused by the large number of bacilli in the blood.

Laboratory diagnosis of plague is by direct microscopic examination, culture of the bacterium, serological tests, the PCR for detection of bacteria in infected fleas, and phage testing. Treatment is with streptomycin, chloramphenicol, or tetracycline, and recovery from the disease gives a good immunity.

Pneumonic plague arises (1) from primary exposure to infectious respiratory droplets from a person or cat with respiratory plague or (2) secondary to hematogenous spread in a patient with bubonic or septicemic plague. Pneumonic plague can also arise from accidental inhalation of *Y. pestis* in the laboratory. The mortality rate for this kind of plague is almost 100% if it is not recognized within 12 to 24 hours. Obviously great care must be taken to prevent the spread of airborne infections to personnel taking care of pneumonic plague patients.

Prevention and control involves ectoparasite and rodent control, isolation of human patients, prophylaxis or abortive therapy of exposed persons, and vaccination (USP Plague vaccine) of persons at high risk.

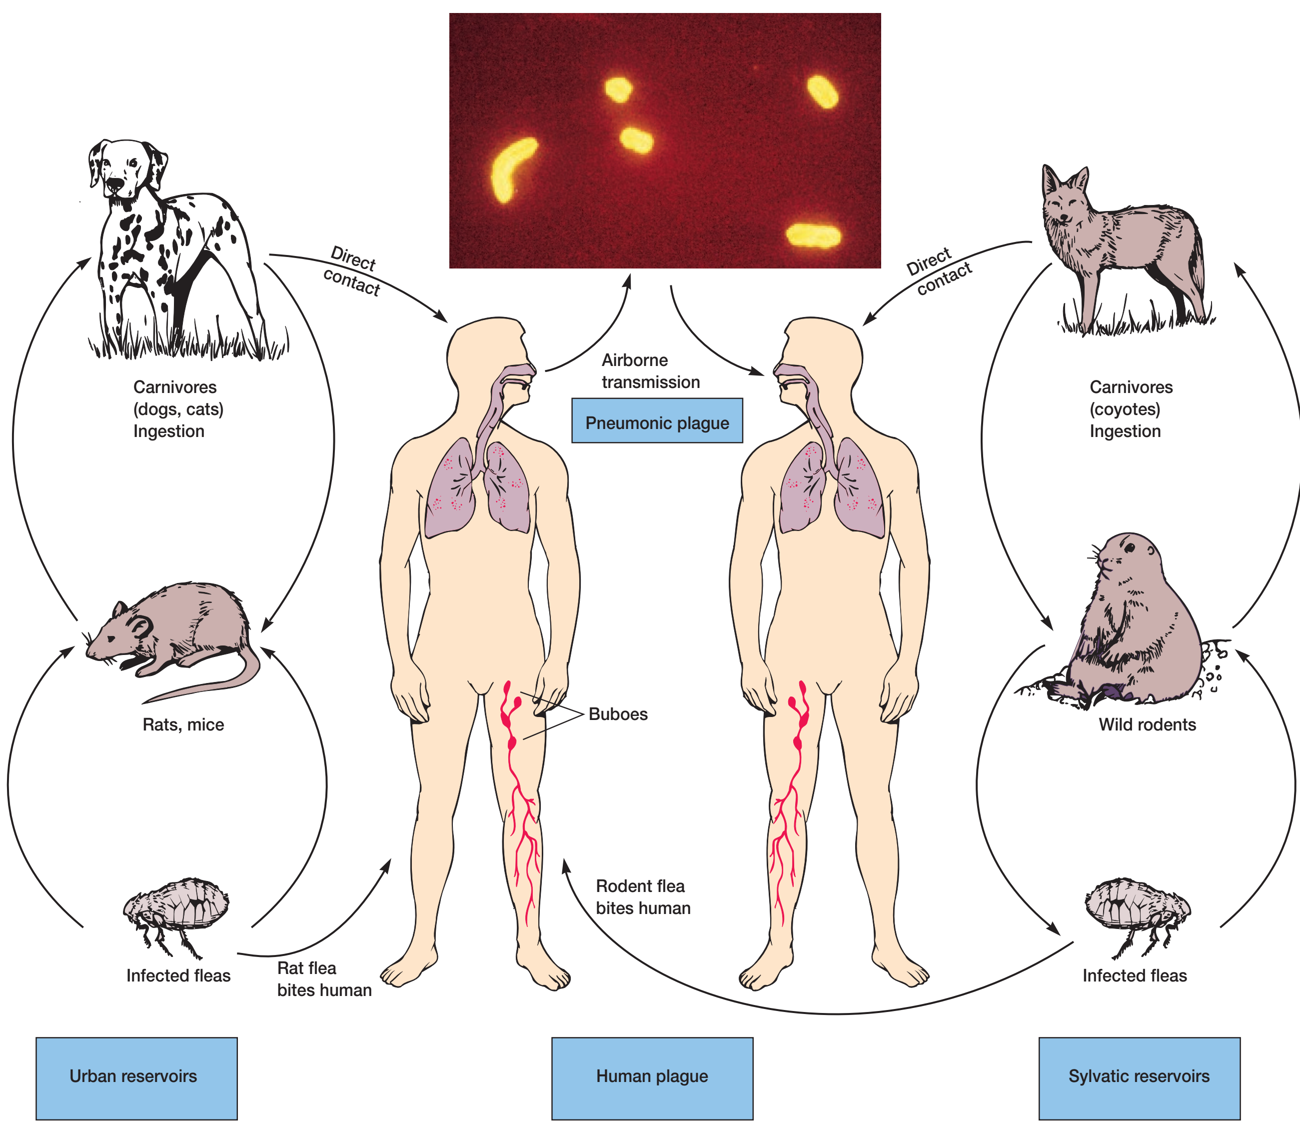


Figure 39.9 Plague. Plague is spread to humans through (1) the urban cycle and rat fleas, (2) the sylvatic cycle centered on wild rodents and their fleas, or (3) by airborne transmission from an infected person leading to pneumonic plague. Dogs, cats, and coyotes can also acquire the bacterium by ingestion of infected animals. The insert shows *Yersinia pestis* stained with fluorescent antibodies.

Q Fever

Q fever (Q for query because the cause of the fever was not known for some time) is an acute zoonotic disease caused by the γ-proteobacterium *Coxiella burnetii,* a strictly intracellular, gram-negative bacterium. *C. burnetii* is different from *Rickettsia* in its ability to survive outside host cells by forming a resistant endosporelike body. This bacterium infects both wild animals and livestock. In animals, ticks (many species) transmit *C. burnetii,* whereas in humans transmission is primarily by inhalation of dust contaminated with bacteria from dried animal feces, urine, or milk. The disease is apt to occur in epidemic form among slaughterhouse workers and sporadically among farmers and veterinarians. Each year, fewer than 100 cases of Q fever are reported in the United States.

In humans, after inhalation of the bacteria, local proliferation occurs in the lungs. This may result in mild respiratory

symptoms similar to those of atypical pneumonia or influenza. Q fever itself is an acute illness characterized by the sudden onset of severe headache, myalgia (muscle pain), and fever, which may remain very high for more than a month if not treated. Unlike rickettsial diseases, Q fever is not accompanied by a rash. It is rarely fatal, but endocarditis—inflammation of the heart muscle—occurs in about 10% of the cases. Five to ten years may elapse between the initial infection and the appearance of the endocarditis. During this interval the bacteria reside in the liver and often cause hepatitis. Diagnosis is most commonly made serologically. Treatment is with chloramphenicol and tetracycline. Prevention and control consists of vaccinating researchers and others at high occupational risk and in areas of endemic Q fever; cow and sheep milk should be pasteurized before consumption.

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever is caused by the rickettsia *Rickettsia rickettsii.* Although originally detected in the Rocky Mountain area, most cases of this disease now occur east of the Mississippi River. The disease is transmitted by ticks and usually occurs in people who are or have been in tick-infested areas. There are two principal vectors: *Dermacentor andersoni,* the wood tick, is distributed in the Rocky Mountain states and is active during the spring and early summer. *D. variabilis,* the dog tick, has assumed greater importance and is almost exclusively confined to the eastern half of the United States. Unlike the other rickettsias discussed, *R. rickettsii* can pass from generation to generation of ticks through their eggs in a process known as **transovarian passage.** No humans or mammals are needed as reservoirs for the continued propagation of this rickettsia in the environment.

When humans contact infected ticks, the rickettsias are either deposited on the skin (if the tick defecates after feeding) and then subsequently rubbed or scratched into the skin, or the rickettsias are deposited into the skin as the tick feeds. Once inside the skin, the rickettsias enter the endothelial cells of small blood vessels, where they multiply and produce a characteristic vasculitis (inflammation of blood vessels).

The disease is characterized by the sudden onset of a headache, high fever, chills, and a skin rash (**figure 39.10**) that initially appears on the ankles and wrists and then spreads to the trunk of the body. If the disease is not treated, the rickettsias can destroy the blood vessels in the heart, lungs, or kidneys and cause death. Usually, however, severe pathological changes are avoided by antibiotic therapy (chloramphenicol, chlortetracycline), the development of immune resistance, and supportive therapy. Diagnosis is made through observation of symptoms and signs such as the characteristic rash and by serological tests. The best means of prevention remains the avoidance of tick-infested habitats and animals (*see preventive methods for Lyme disease,* p. 910). There are approximately 1,000 reported cases of Rocky Mountain spotted fever annually in the United States.

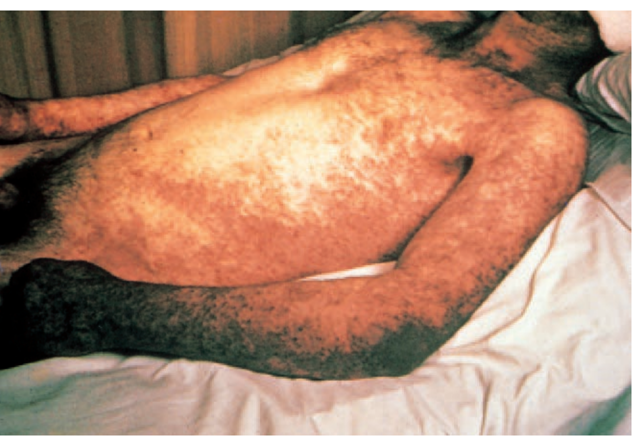

Figure 39.10 Rocky Mountain Spotted Fever. Typical rash occurring on the arms and chest consists of generally distributed, sharply defined macules.

1. What is the causative agent of Lyme disease and how is it transmitted to humans? How does the illness begin? Describe the three stages of Lyme disease.
2. Why is plague sometimes called the Black Death? How is it transmitted? Distinguish between bubonic and pneumonic plague.
3. What two antibiotics are used against most rickettsial infections?
4. How is epidemic typhus spread? Ehrlichiosis? Murine typhus? What are their symptoms?
5. What is unique about *Coxiella burnetii* compared to the other rickettsias?
6. Describe the symptoms of Rocky Mountain spotted fever.
7. How does transovarian passage occur?

39.3 Direct Contact Diseases

Most of the direct contact bacterial diseases involve the skin or underlying tissues. Others can become disseminated through specific regions of the body. Some of the better-known of these diseases are now discussed.

Anthrax

Anthrax [Greek *anthrax,* coal] is a highly infectious animal disease that can be transmitted to humans by direct contact with infected animals (cattle, goats, sheep) or their products. The causative bacterium is the gram-positive *Bacillus anthracis.* Its endospores can remain viable in soil and animal products for decades (*see figure 3.41*). Human infection is usually through a cut or abrasion of the skin, resulting in **cutaneous anthrax;** however, inhaling endospores may result in **pulmonary anthrax,** also known as woolsorter's disease. If endospores reach the intestine, **gastrointestinal anthrax** may result.

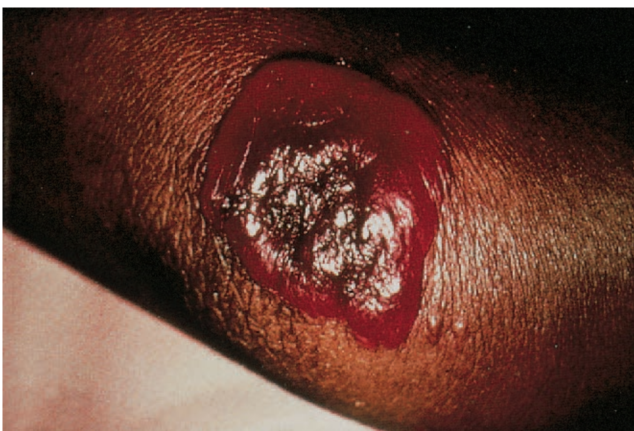

Figure 39.11 **Anthrax.** The malignant (destructive) eschar pustules of anthrax on the arm of an infected person.

In humans the incubation period for cutaneous anthrax is 1 to 15 days. It begins with a skin papule that ulcerates and is called an **eschar** (**figure 39.11**). Headache, fever, and nausea are the major symptoms. Pulmonary anthrax resembles influenza. If the bacteria invade the bloodstream, the disease can be fatal. The signs and symptoms of anthrax are due to anthrax toxins, a complex exotoxin system composed of three proteins. The genes encoding these factors are found on plasmids.

Diagnosis is by direct microscopic examination, culture of the bacterium, and serology; therapy is with penicillin G or penicillin G plus streptomycin. Vaccination of animals, primarily cattle, is an important control measure. However, people with a high occupational risk, such as those who handle infected animals or their products, including hides and wool, should be immunized with the cell-free vaccine obtainable from the Centers for Disease Control and Prevention. Fewer than 10 cases of anthrax occur annually in the United States. Unfortunately, anthrax is one of the major diseases that poses a threat in bioterrorism (*see section 37.10*).

Bacterial Vaginosis

Bacterial vaginosis is considered a sexually transmitted disease (table 39.4). It has a polymicrobic etiology that includes *Gardnerella vaginalis* (a gram-negative to gram-variable, pleomorphic nonmotile rod), *Mobiluncus* spp., *Mycoplasma hominis,* and various anaerobic bacteria. The recent finding that these microorganisms inhabit the rectum of 20 to 40% of healthy women indicates a potential source of autoinfection in addition to sexual transmission. Although a mild disease it is a risk factor for obstetric infections, various adverse outcomes of pregnancy, and pelvic inflammatory disease. The vaginosis is characterized by a copious, frothy, fishy-smelling discharge without pain or itching. Diagnosis is based on this fishy odor and the microscopic observation of clue cells in the discharge. **Clue cells** are sloughed-off vaginal epithelial cells covered with bacteria, mostly *G. vaginalis.* Treatment for bacterial vaginosis is with metronidazole (Flagyl, MetroGel-Vaginal), a drug that kills the anaerobes that are needed for the continuation of the disease.

Cat-Scratch Disease

Cat-scratch disease (CSD) is a loosely defined syndrome, the cause of which eluded microbiologists for decades. Currently the etiology centers on a recently described gram-negative bacillus, *Bartonella henselae* (table 39.1).

The diagnosis of CSD is based on the combination of the clinical history of either a cat scratch or bite at the skin surface (primary lesion) and subsequent swelling of the lymph node(s) that drain the inoculation site, and on detection by PCR techniques. This is accompanied by malaise and fever. The typical case of CSD is self-limiting, with abatement of symptoms over a period of days to weeks, and the resolution of the lymphadenopathy over several months.

Chancroid

Chancroid [French *chancre,* a destructive sore, and Greek *eidos,* to form], also known as **genital ulcer disease,** is a sexually transmitted disease caused by the gram-negative bacillus *Haemophilus ducreyi* (table 39.4). The bacterium enters the skin through a break in the epithelium. After an incubation period of 4 to 7 days, a papular lesion develops within the epithelium, causing swelling and white blood cell infiltration. Within several days a pustule forms and ruptures, producing a painful circumscribed ulcer with a ragged edge; hence the term genital ulcer disease. Most of the ulcers in males are on the penis and in females at the entrance of the vagina. Genital ulcer disease occurs commonly in the tropics; however, in the past decade there have been major outbreaks in the United States. Worldwide, genital ulcer disease is an important cofactor in the transmission of the AIDS virus; thus it could be an important cofactor in the United States as well. Diagnosis is by isolating *H. ducreyi* from the ulcers; treatment is with erythromycin or ceftriaxone. Control is by the use of condoms or abstinence.

Chlamydial Pneumonia

Chlamydial pneumonia is caused by *Chlamydia pneumoniae* (TWAR). Clinically, infections are generally mild; pharyngitis, bronchitis, and sinusitis commonly accompany some lower respiratory tract involvement. Symptoms include fever, a productive cough, sore throat, hoarseness, and pain on swallowing. Infections with *C. pneumoniae* are common but sporadic; about 50% of adults have antibody to the chlamydiae. Evidence suggests that *C. pneumoniae* is primarily a human pathogen directly transmitted from human to human by respiratory secretions. Identification of chlamydial pneumonia is based on symptoms and a microimmunofluorescence test. Tetracycline and erythromycin are used for treatment.

In seroepidemiological studies, *C. pneumoniae* infections have been linked with coronary artery disease as well as vascular disease at other sites. Following a demonstration of *C. pneumoniae*-like particles in artheromatous tissue by electron microscopy, *C. pneumoniae* genes and antigens have been detected in artheromas.

Rarely, the microorganism has been recovered in cultures of atheromatous tissue. As a result of these findings, the possible etiologic role of *C. pneumoniae* in coronary artery disease and systemic atherosclerosis is currently under intense scrutiny.

Gas Gangrene or Clostridial Myonecrosis

Clostridium perfringens, C. novyi, and *C. septicum* are gram-positive spore-forming rods termed the histotoxic clostridia. They can produce a necrotizing infection of skeletal muscle called **gas gangrene** [Greek *gangraina,* an eating sore] or **clostridial myonecrosis** [*myo,* muscles, and *necrosis,* death].

Histotoxic clostridia occur in the soil worldwide and also are part of the normal endogenous microflora of the human large intestine. Contamination of injured tissue with spores from soil containing histotoxic clostridia or bowel flora is the usual means of transmission. Infections are commonly associated with wounds resulting from abortions, automobile accidents, military combat, or frostbite.

If the spores germinate in anaerobic tissue, the bacteria grow and secrete α-toxin, which breaks down muscle tissue. Growth often results in the accumulation of gas (mainly hydrogen as a result of carbohydrate fermentation), and of the toxic breakdown products of skeletal muscle tissue.

Clinical manifestations include severe pain, edema, drainage, and muscle necrosis. The pathology arises from progressive skeletal muscle necrosis due to the effects of α-toxin. Other enzymes produced by the bacteria degrade collagen and tissue, facilitating spread of the disease.

Gas gangrene is a medical emergency. Laboratory diagnosis is through recovery of the appropriate species of clostridia accompanied by the characteristic disease symptoms. Treatment is extensive surgical debridement (removal of all dead tissue), the administration of polyvalent antitoxin, and antimicrobial therapy with penicillin and tetracycline. Hyperbaric oxygen therapy (the use of high concentrations of oxygen at elevated pressures) also is considered effective. The oxygen saturates the infected tissue and thereby prevents the growth of the obligately anaerobic clostridia.

Prevention and control includes debridement of contaminated traumatic wounds plus antimicrobial prophylaxis and prompt treatment of all wound infections. Amputation of limbs often is necessary to prevent further spread of the disease.

Genitourinary Mycoplasmal Diseases

The mycoplasmas *Ureaplasma urealyticum* and *M. hominis* are common parasitic microorganisms of the genital tract and their transmission is related to sexual activity (table 39.4). Both mycoplasmas can opportunistically cause inflammation of the reproductive organs of males and females. Because mycoplasmas are not usually cultured by clinicians, management and treatment of these infections depend on a recognition of clinical syndromes and provision for adequate therapy. Tetracyclines are active against most strains; resistant organisms can be treated with erythromycin.

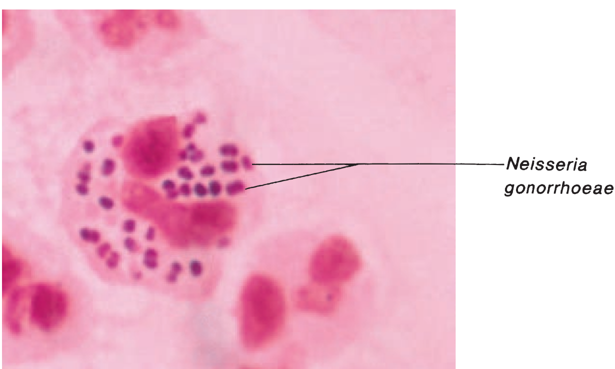

Figure 39.12 Gonorrhea. Gram stain of male urethral exudate showing *Neisseria gonorrhoeae* (diplococci) inside a PMN; light micrograph (× 500). Although the presence of gram-negative diplococci in exudates is a probable indication of gonorrhea, the bacterium should be isolated and identified.

Gonorrhea

Gonorrhea [Greek *gono,* seed, and *rhein,* to flow] is an acute, infectious, sexually transmitted disease of the mucous membranes of the genitourinary tract, eye, rectum, and throat (table 39.4). It is caused by the gram-negative, oxidase-positive, diplococcus, *Neisseria gonorrhoeae.* These bacteria are also referred to as **gonococci** [pl. of gonococcus; Greek *gono,* seed, and *coccus,* berry] and have a worldwide distribution.

Once inside the body the gonococci attach to the microvilli of mucosal cells by means of pili and protein II, which function as adhesins. This attachment prevents the bacteria from being washed away by normal vaginal discharges or by the strong flow of urine. They are then phagocytosed by the mucosal cells and may even be transported through the cells to the intercellular spaces and subepithelial tissue. Phagocytes, such as neutrophils, also may contain gonococci (**figure 39.12**) inside vesicles. Because the gonococci are intracellular at this time, the host's defenses have little effect on the bacteria. Following penetration of the bacteria, the host tissue responds locally by the infiltration of mast cells, more PMNs, and plasma cells. These cells are later replaced by fibrous tissue that may lead to urethral closing, or stricture, in males.

In males the incubation period is 2 to 8 days. The onset consists of a urethral discharge of yellow, creamy pus and frequent, painful urination that is accompanied by a burning sensation. In females the disease is more insidious in that few individuals are aware of any symptoms. However, some symptoms may begin 7 to 21 days after infection. These are generally mild; some vaginal discharge may occur. The gonococci also can infect the uterine tubes and surrounding tissues, leading to ***p*elvic *i*nflammatory *d*isease (PID).** This occurs in 10 to 20% of infected females. Gonococcal PID is a major cause of sterility and ectopic pregnancies because of scar formation in the uterine tubes. Gonococci disseminate most often during menstruation, a time in which there is an increased concentration of free iron available to the bacteria. In both sexes disseminated gonococcal infection with

© The McGraw–Hill Companies, 2002

bacteremia may occur. This can lead to involvement of the joints (gonorrheal arthritis), heart (gonorrheal endocarditis), or pharynx (gonorrheal pharyngitis). Gonorrheal eye infections occur most often in newborns as they pass through an infected birth canal. The resulting disease is called **ophthalmia neonatorum** or **conjunctivitis of the newborn,** which was once a leading cause of blindness in many parts of the world. To prevent this, tetracycline, erythromycin, povidone-iodine, or silver nitrate in dilute solution is placed in the eyes of newborns. This type of treatment is required by law in the United States and many other nations.

Laboratory diagnosis of gonorrhea relies on the successful growth of *N. gonorrhoeae* in culture to determine oxidase reaction, Gram stain reaction, and colony and cell morphology. The performance of confirmation tests also is necessary. Because the gonococci are very sensitive to adverse environmental conditions and survive poorly outside the body, special transport media (e.g., PACE) are necessary. A DNA probe (Gen-Probe Pace) for *N. gonorrhoeae* has been developed and is used to supplement other diagnostic techniques.

The Centers for Disease Control and Prevention consider four treatment regimens to be coequal after sensitivity testing has been done: (1) penicillin G plus probenecid, (2) ampicillin plus probenecid, (3) ceftriaxone or ofloxacin plus doxycycline for 7 days, or (4) spectinomycin.

Penicillin-resistant strains of gonococci have now developed and occur worldwide. Most of these strains carry a plasmid that directs the formation of penicillinase, a β-lactamase enzyme able to inactivate penicillin G and ampicillin. Since 1980 strains of *N. gonorrhoeae* with chromosomally mediated penicillin resistance have developed. Instead of producing a penicillinase, these strains have altered penicillin-binding proteins. Since 1986 tetracycline-resistant *N. gonorrhoeae* also have developed.

The most effective method for control of this sexually transmitted disease is public education, diagnosing and treating the asymptomatic patient, condom use, and treating infected individuals quickly to prevent further spread of the disease. Slightly under a million cases of gonorrhea are reported in the United States each year, but the actual number of cases is thought to be three to four times greater than that. More than 60% of all cases occur in the 15- to 24-year-old age group. Repeated gonococcal infections are common. Protective immunity to reinfection does not arise because of antigenic variation in which a single strain changes its pilin gene by a recombinational event and alters the expression of the various protein II genes by slipped strand mispairing. This can thus be viewed as a programmed evasion technique employed by the bacterium rather than a mere reflection of strain variation.

Inclusion Conjunctivitis

Inclusion conjunctivitis is an acute infectious disease caused by *C. trachomatis* serotypes D–K, and it occurs throughout the world. It is characterized by a copious mucous discharge from the eye, an inflamed and swollen conjunctiva, and the presence of large inclusion bodies in the host cell cytoplasm. In inclusion conjunctivitis of the newborn, the chlamydiae are acquired during passage through an infected birth canal. The disease appears 7 to 12 days after birth. If the chlamydiae colonize an infant's nasopharynx and tracheobronchial tree, pneumonia may result. Adult inclusion conjunctivitis is acquired by contact with infective genital tract discharges.

Without treatment, recovery usually occurs spontaneously over several weeks or months. Therapy involves treatment with tetracycline, erythromycin, or a sulfonamide. The specific diagnosis of *C. trachomatis* can be made by direct immunofluorescence, Giemsa stain, nucleic acid probes, and culture. Genital chlamydial infections and inclusion conjunctivitis are sexually transmitted diseases that are spread by indiscriminate contact with multiple sex partners. Prevention depends upon diagnosis and treatment of all infected individuals.

Leprosy

Leprosy [Greek *Lepros,* scaly, scabby, rough] or **Hansen's disease** is a severely disfiguring skin disease caused by *Mycobacterium leprae* (*see figure 24.9*). The only reservoirs of proved significance are humans. The disease most often occurs in tropical countries, where there are more than 14 million cases. An estimated 4,000 cases exist in the United States, with approximately 200 to 300 new cases reported annually.

Transmission of leprosy is most likely to occur when individuals are exposed for prolonged periods to infected individuals who shed large numbers of *M. leprae.* Nasal secretions probably are the infectious material for family contacts.

The incubation period is about 3 to 5 years but may be much longer, and the disease progresses slowly. The bacterium invades peripheral nerve and skin cells and becomes an obligately intracellular parasite. It is most frequently found in the Schwann cells that surround peripheral nerve axons and in mononuclear phagocytes. The earliest symptom of leprosy is usually a slightly pigmented skin eruption several centimeters in diameter. Approximately 75% of all individuals with this early solitary lesion heal spontaneously because of the cell-mediated immune response to *M. leprae.* However, in some individuals this immune response may be so weak that one of two distinct forms of the disease occurs: tuberculoid or lepromatous leprosy (**figure 39.13**).

Tuberculoid (neural) leprosy is a mild, nonprogressive form of leprosy associated with a delayed-type hypersensitivity reaction (*see section 33.2*) to antigens on the surface of *M. leprae.* It is characterized by damaged nerves and regions of the skin that have lost sensation and are surrounded by a border of nodules (**figure 39.14**). Afflicted individuals who do not develop hypersensitivity have a relentlessly progressive form of the disease, called **lepromatous (progressive) leprosy,** in which large numbers of *M. leprae* develop in the skin cells. The bacteria kill skin tissue, leading to a progressive loss of facial features, fingers, toes, and other structures. Moreover, disfiguring nodules form all over the body. Nerves are also infected, but usually are less damaged than in tuberculoid leprosy.

Because the leprosy bacillus cannot be cultured in vitro, laboratory diagnosis is supported by the demonstration of the bacterium in biopsy specimens and by acid-fast staining. Serodiagnostic methods, such as the fluorescent leprosy antibody absorption test, DNA amplification, and ELISA have recently been developed.

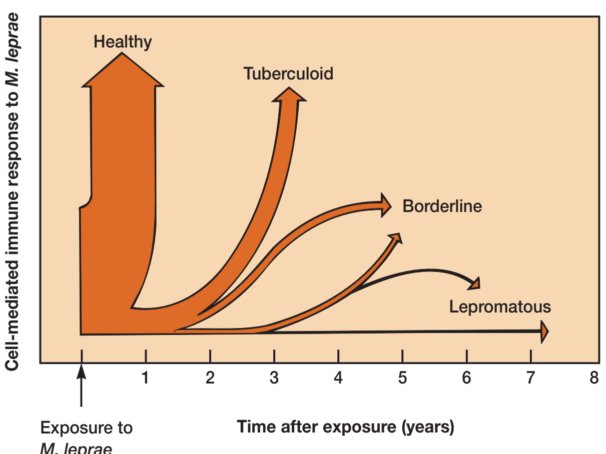

Figure 39.13 Development of Leprosy. A schematic representation of the hypothesis of how the development of subclinical infection and various types of leprosy is related to the time of onset of cell-mediated immune response to *M. leprae* antigens after the initial exposure. The thickness of the lines indicates the proportion of individuals from the exposed population that is likely to fall into each category.

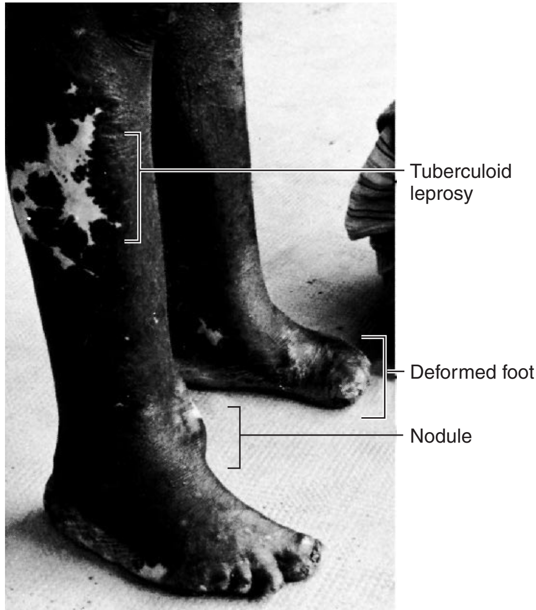

Figure 39.14 Leprosy. In tuberculoid leprosy the skin within the nodule is completely without sensation. The deformed foot is associated with lepromatous leprosy. Note the disfiguring nodule on the ankle.

Treatment is long-term with the sulfone drug diacetyl dapsone and rifampin, with or without clofazimine. Alternative drugs are ethionamide or protionamide. Use of *Mycobacterium w* vaccine in conjunction with the drugs shortens the duration of drug therapy and speeds recovery from the disease.

There is good evidence that the nine-banded armadillo is an animal reservoir for the leprosy bacillus in the United States but plays no role in transmission of leprosy to humans. Identification and treatment of patients with leprosy is the key to control. Children of presumably contagious parents should be given chemoprophylactic drugs until treatment of the parents has made them noninfectious.

1. How can humans acquire anthrax? Gas gangrene? Gonorrhea? Chancroid? Leprosy? Describe the major symptoms of each.
2. Define the following terms: cutaneous anthrax, bacterial vaginosis, pelvic inflammatory disease, ophthalmia neonatorum, tuberculoid and lepromatous leprosy.
3. How does an infant acquire inclusion conjunctivitis?
4. How do humans contract chlamydial pneumonia?

Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV) is a sexually transmitted disease (table 39.4) caused by *Chlamydia trachomatis* serotypes L_1–L_3. It has a worldwide distribution but is more common in tropical climates.

LGV proceeds through three phases. (1) In the primary phase a small ulcer appears several days to several weeks after a person is exposed to the chlamydiae. The ulcer may appear on the penis in males or on the labia or vagina in females. The ulcer heals quickly and leaves no scar. (2) The secondary phase begins 2 to 6 weeks after exposure, when the chlamydiae infect lymphoid cells, causing the regional lymph nodes to become enlarged and tender; such nodes are called buboes (**figure 39.15**). Systemic symptoms such as fever, chills, and anorexia are common. (3) If the disease is not treated, a late phase ensues. This results from fibrotic changes and abnormal lymphatic drainage that produces fistulas (abnormal passages leading from an abscess or a hollow organ to the body surface or from one hollow organ to another) and urethral or rectal strictures (a decrease in size). An untreatable fluid accumulation in the penis, scrotum, or vaginal area may result.

The disease is detected by staining infected cells with iodine to observe inclusions (chlamydia-filled vacuoles), culture of the chlamydiae from a bubo, nucleic acid probes, or by the detection of a high antibody titer to LGV. Treatment in the early phases consists of aspiration of the buboes and administration of drugs: tetracycline, doxycycline, erythromycin, or cefotoxin. The late phase may require surgery. The methods used for the control of LGV are the same as for other sexually transmitted diseases: reduction in promiscuity, use of condoms, and early diagnosis and treatment of infected individuals. About 300 cases of LGV occur annually in the United States.

Mycoplasmal Pneumonia

Typical pneumonia has a bacterial origin. If a bacterial pathogen cannot be isolated, the pneumonia is termed atypical and a virus is usually suspected. If viruses can't be detected, then **mycoplasmal**

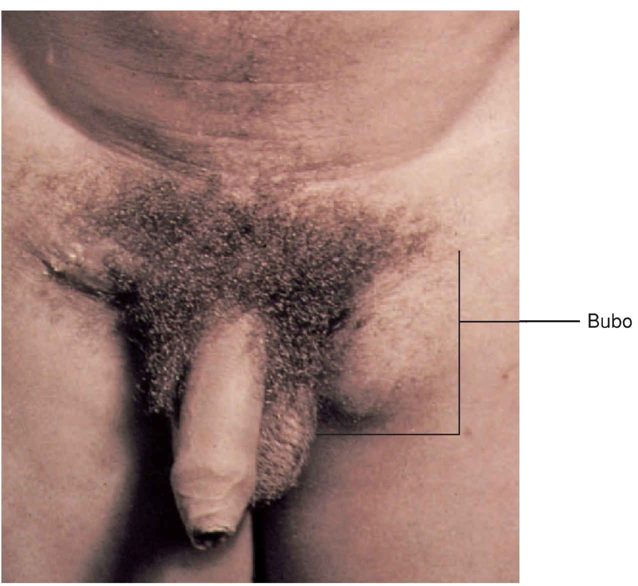

Figure 39.15 Lymphogranuloma Venereum. The bubo in the left inguinal area is draining.

pneumonia can be considered. This pneumonia is caused by *Mycoplasma pneumoniae* (*see figure 23.2*), a mycoplasma with worldwide distribution. Spread involves close contact and sometimes airborne droplets. The disease is fairly common and mild in infants and small children; serious disease is seen principally in older children and young adults.

M. pneumoniae usually infects the upper respiratory tract, and subsequently moves to the lower respiratory tract, where it attaches to respiratory mucosal cells. It then produces peroxide, which may be a toxic factor, but the exact mechanism of pathogenesis is unknown. An alternation in mucosal cell nucleic acid synthesis has been observed. The manifestations of this disease vary in severity from asymptomatic to a serious pneumonia. The latter is accompanied by death of the surface mucosal cells, lung infiltration, and congestion. Initial symptoms include headache, weakness, a low fever, and a predominant cough. The disease and its symptoms usually persist for weeks. The mortality rate is less than 1%.

Several rapid tests using latex agglutination for *M. pneumoniae* antibodies are available for diagnosis of mycoplasmal pneumonia. When isolated from respiratory secretions, the mycoplasmas form distinct colonies with a "fried-egg" appearance (*see figure 23.3*). During the acute stage of the disease, diagnosis must be made by clinical observations. Tetracyclines or erythromycin are effective in treatment. There are no preventive measures.

Nongonococcal Urethritis

Nongonococcal urethritis (NGU) is any inflammation of the urethra not due to the bacterium *Neisseria gonorrhoeae.* This condition is caused both by nonmicrobial factors such as catheters and drugs and by infectious microorganisms. The most important causative agents are *C. trachomatis, Ureaplasma urealyticum, Mycoplasma hominis, Trichomonas vaginalis, Candida albicans,* and herpes simplex viruses. Most infections are acquired sexually (table 39.4), and of these, approximately 50% are *Chlamydia* infections. NGU caused by chlamydia is probably the most common sexually transmitted disease in the United States, with over 10 million Americans infected. It is endemic throughout the world.

Symptoms of NGU vary widely. Males may have few or no manifestations of disease; however, complications can exist. These include a urethral discharge, itching, and inflammation of the male reproductive structures. Females may be asymptomatic or have a severe infection called pelvic inflammatory disease (PID) that often leads to sterility. Chlamydia may account for as many as 200,000 to 400,000 cases of PID annually in the United States. In the pregnant female, a chlamydial infection is especially serious because it is directly related to miscarriage, stillbirth, inclusion conjunctivitis, and infant pneumonia.

Diagnosis of NGU requires the demonstration of a leukocyte exudate and exclusion of urethral gonorrhea by Gram stain and culture. Several rapid tests for detecting *Chlamydia* in urine specimens are also available. Treatment is with tetracycline, doxycycline, erythromycin, or sulfisoxazole.

Peptic Ulcer Disease and Gastritis

A gram-negative, microaerophilic spiral bacillus found in gastric biopsy specimens from patients with histologic **gastritis** [Greek *gaster,* stomach, and *itis,* inflammation] was successfully cultured in Perth, Australia, in 1982 and named *Campylobacter pylori.* In 1993 its name was changed to *Helicobacter pylori.* It now appears that this bacterium is responsible for most cases of chronic gastritis not associated with another known primary cause (e.g., autoimmune gastritis or eosinophilic gastritis), and it is the leading factor in the pathogenesis of **peptic ulcer disease.** In addition, there are strong positive correlations between gastric cancer rates and *H. pylori* infection rates in certain populations.

The evidence for *H. pylori* as a gastrointestinal pathogen is now very strong, if not overwhelming. For example, *H. pylori* has been isolated from the gastric mucosa (**figure 39.16**) of 95% of patients with gastric ulcer disease and virtually 100% of those patients with chronic gastritis, but not from healthy tissue.

H. pylori colonizes only gastric mucus-secreting cells, beneath the gastric mucous layers, and surface fimbriae are believed to be one of the adhesins associated with this process. *H. pylori* binds to Lewis antigens (which are part of the blood group antigens that determine blood group O) and to the monosaccharide sialic acid, also found in the glycoproteins on the surface of gastric epithelial cells. After attachment, the bacterium moves into the mucous layer.

H. pylori is also a strong producer of urease. Urease activity may create an alkaline environment by urea hydrolysis to produce ammonia that protects the bacterium from gastric acid until it colonizes under the layer of mucus in the stomach. The potential virulence factors responsible for epithelial cell damage and inflammation probably include proteases, phospholipases, cytokines, and cytotoxins.

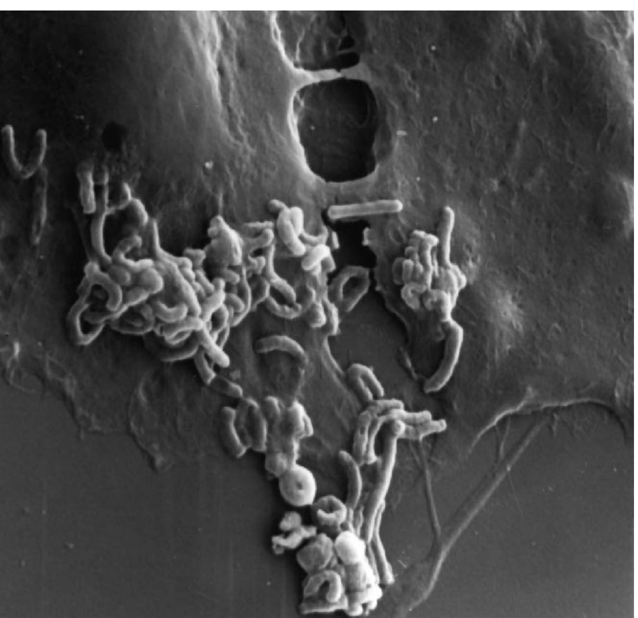

Figure 39.16 Peptic Ulcer Disease. Scanning electron micrograph (× 3,441) of *Helicobacter pylori* adhering to gastric cells.

Approximately 50% of the world's population is estimated to be infected with *H. pylori. H. pylori* is most likely transmitted from person to person, although infection from a common exogenous source cannot be completely ruled out, and some think that it is spread by food or water. Support for the person-to-person transmission comes from evidence of clustering within families and from reports of higher than expected prevalences in residents of custodial institutions and nursing homes.

Laboratory identification of *H. pylori* is by culture of gastric biopsy specimens, examination of stained biopsies for the presence of bacteria, detection of serum IgG (Pyloriset EIA-G, Malakit *Helicobacter pylori*), the urea breath test, urinary excretion of [^{15}N] ammonia, or detection of urease activity in the biopsies. Treatment is with bismuth subsalicylate (Pepto-Bismol) combined with metronidazole and either tetracycline or amoxicillin; clarithromycin (Biaxin), ranitidine, and bismuth citrate; or clarithromycin, amoxicillin, and lansoprazole (Prevacid).

Psittacosis (Ornithosis)

Psittacosis (ornithosis) is a worldwide infectious disease of birds that is transmissible to humans. It was first described in association with parrots and parakeets, both of which are psittacine birds. The disease is now recognized in many other birds—among them, pigeons, chickens, ducks, and turkeys—and the general term ornithosis [Latin *ornis,* bird] is used.

Ornithosis is caused by *Chlamydia psittaci.* Humans contract this disease either by handling infected birds or by inhaling dried bird excreta that contains viable *C. psittaci.* Ornithosis is recognized as an occupational hazard within the poultry industry, particularly to workers in turkey processing plants.

After entering the respiratory tract, the chlamydiae are transported to the cells of the liver and spleen. They multiply within these cells and then invade the lungs, where they cause inflammation, hemorrhaging, and pneumonia.

Laboratory diagnosis is either by isolation of *C. psittaci* from blood or sputum, or by serological studies. Treatment is with tetracycline. Because of antibiotic therapy, the mortality rate has dropped from 20 to 2%. Between 100 and 200 cases of ornithosis are reported annually in the United States. Prevention and control is by chemoprophylaxis (tetracycline) for pet birds and poultry, although this can lead to the development of antibiotic resistance and should be discouraged.

Staphylococcal Diseases

The genus *Staphylococcus* consists of gram-positive cocci, 0.5 to 1.5 μm in diameter, occurring singly, in pairs, and in tetrads, and characteristically dividing in more than one plane to form irregular clusters. The cell wall contains peptidoglycan and teichoic acid. Staphylococci are facultative anaerobes and usually catalase positive.

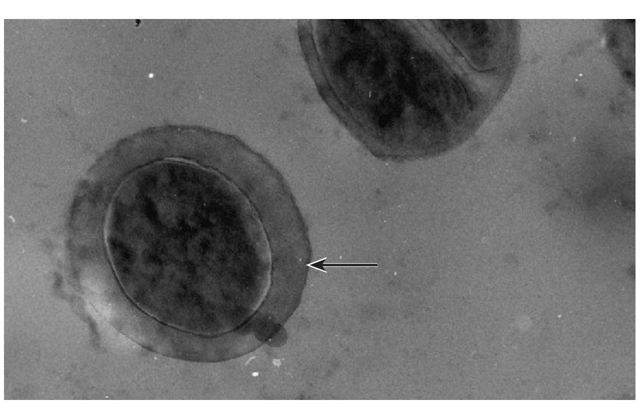
Staphylococci are among the most important bacteria that cause disease in humans. They are normal inhabitants of the upper respiratory tract, skin, intestine, and vagina (*see figure 31.2*). Staphylococci, with pneumococci and streptococci, are members of a group of invasive gram-positive bacteria known as the pyogenic (or pus-producing) cocci. These bacteria cause various suppurative, or pus-forming diseases (e.g., boils, carbuncles, folliculitis, impetigo contagiosa, scalded-skin syndrome) in humans.

Staphylococci can be divided into pathogenic and relatively nonpathogenic strains based on the synthesis of the enzyme coagulase. Coagulase-positive strains, such as *S. aureus* (*see figure 23.12*a), often produce a yellow carotenoid pigment—which has led to their being commonly called golden staph (*see figure 5.9*)—and cause severe chronic infections. Coagulase-negative staphylococci (CoNS) such as *S. epidermidis* do not produce coagulase, are nonpigmented, and are generally less invasive but have increasingly been associated (as opportunistic pathogens) with serious nosocomial infections.

Staphylococci are further classified into **s**lime **p**roducers (SP) and **n**on-**s**lime **p**roducers (NSP). The ability to produce slime has been proposed as a marker for pathogenic strains of staphylococci (**figure 39.17*a***).

Slime is a viscous extracellular glycoconjugate that allows these bacteria to adhere to smooth surfaces such as prosthetic medical devices and catheters. Scanning electron microscopy has clearly demonstrated that biofilms (figure 39.17*b*) consisting of staphylococci encased in a slimy matrix are formed in association with biomaterial-associated infections (**Box 39.3**). Slime also appears to inhibit neutrophil chemotaxis, phagocytosis, and the antimicrobial agents vancomycin and teicoplanin.

Staphylococci, harbored by either an asymptomatic carrier or a person with the disease, can be spread by the hands, expelled from the respiratory tract, or transported in or on animate and inanimate objects. Staphylococci can produce disease in almost



(a)

Figure 39.17 Slime and Biofilms. *S. aureus* and certain coagulase-negative staphylococci produce a viscous extracellular glycoconjugate called slime. (**a**) Cells of *S. aureus,* one of which produces a slime layer (arrowhead; transmission electron microscopy, ×10,000). (**b**) A biofilm on a venous catheter consisting of *S. epidermidis* and slime. The slime encases and adheres the bacterial colonies to the catheter (scanning electron micrograph, ×6,000).

Box 39.3

Biofilms

Biofilms consist of microorganisms immobilized at a substratum surface and typically embedded in an organic polymer matrix of microbial origin (*see section 28.4*). They develop on virtually all surfaces immersed in natural aqueous environments, including both biological (aquatic plants and animals) and abiological (concrete, metal, plastics, stones). Biofilms form particularly rapidly in flowing aqueous systems where a regular nutrient supply is provided to the microorganisms. Extensive microbial growth, accompanied by excretion of copious amounts of extracellular organic polymers, thus leads to the formation of visible slimy layers (biofilms) on solid surfaces.

Most of the human gastrointestinal tract is colonized by specific groups of microorganisms (the normal indigenous microbiota; *see section 31.2*) that give rise to natural biofilms. At times, these natural biofilms provide protection for pathogenic species, allowing them to colonize the host.

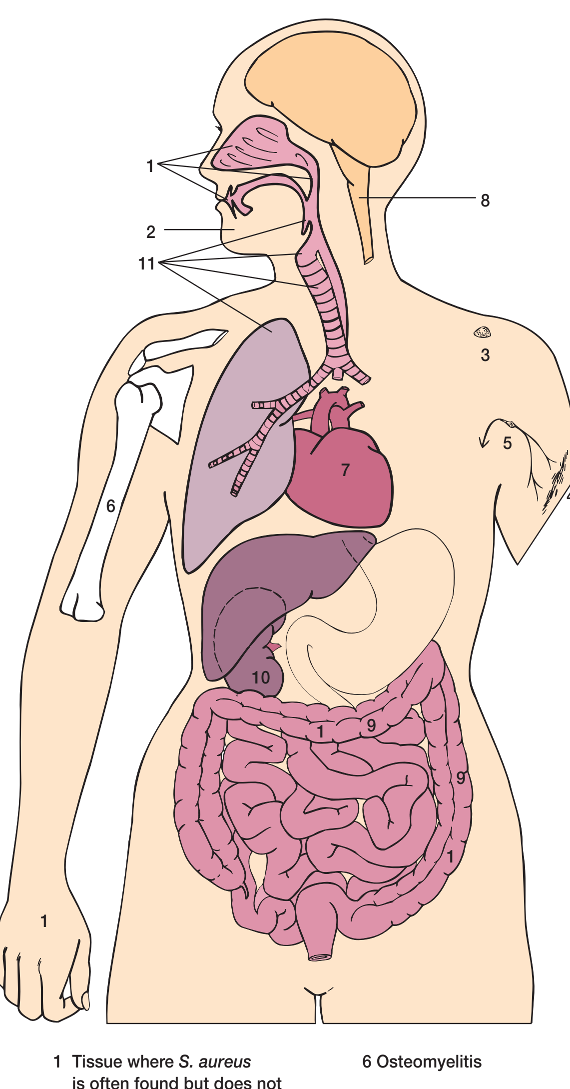
Insertion of a prosthetic device into the human body often leads to the formation of biofilms on the surface of the device. The microorganisms primarily involved are *Staphylococcus epidermidis* (figure 39.17*b*), other coagulase-negative staphylococci, and gram-negative bacteria. These normal skin inhabitants possess the ability to tenaciously adhere to the surfaces of inanimate prosthetic devices. Within the biofilms they are protected from the body's normal defense mechanisms and also from antibiotics; thus the biofilm also provides a source of infection for other parts of the body as bacteria detach during biofilm sloughing.

Some examples of biofilms of medical importance include:

1. The deaths following massive infections of patients receiving the Jarvik 7 artificial hearts
2. Cystic fibrosis patients harboring great numbers of *Pseudomonas aeruginosa* that produce large amounts of alginate polymers, which inhibit the diffusion of antibiotics
3. Teeth, where biofilm forms plaque that leads to tooth decay (figure 39.25)
4. Contact lenses, where bacteria may produce severe eye irritation, inflammation, and infection
5. Air-conditioning and other water retention systems where potentially pathogenic bacteria, such as *Legionella* species, may be protected from the effects of chlorination by biofilms

every organ and tissue of the body (**figure 39.18**). However, it should be emphasized that staphylococcal disease, for the most part, occurs in people whose defensive mechanisms have been compromised, such as those in hospitals.

Staphylococci produce disease through their ability to multiply and spread widely in tissues and through their production of many extracellular substances (**table 39.3**). Some of these substances are exotoxins, and others are enzymes thought to be involved in staphylococcal invasiveness. Many toxin genes are carried on plasmids; in some cases genes responsible for pathogenicity reside on both a plasmid and the host chromosome.



1 Tissue where *S. aureus* is often found but does not normally cause disease

Diseases that may be caused by *S. aureus* are:

2 Pimples and impetigo

3 Boils and carbuncles on any surface area

4 Wound infections and abscesses

5 Spread to lymph nodes and to blood (septicemia), resulting in widespread seeding

6 Osteomyelitis

7 Endocarditis

8 Meningitis

9 Enteritis and enterotoxin poisoning (food poisoning)

10 Nephritis

11 Respiratory infections: Pharyngitis Laryngitis Bronchitis Pneumonia

Figure 39.18 Staphylococcal Diseases. The sites of the major staphylococcal infections of humans are indicated by the above numbers.

Table 39.3 Various Enzymes and Toxins Produced by Staphylococci

Product	Physiological Action
β-lactamase	Breaks down penicillin
Catalase	Converts hydrogen peroxide into water and oxygen and reduces killing by phagocytosis
Coagulase	Reacts with prothrombin to form a complex that can cleave fibrinogen and cause the formation of a fibrin clot; fibrin may also be deposited on the surface of staphylococci, which may protect them from destruction by phagocytic cells; coagulase production is synonymous with invasive pathogenic potential
DNase	Destroys DNA
Enterotoxins	Are divided into heat-stable toxins of six known types (A, B, C1, C2, D, E); responsible for the gastrointestinal upset typical of food poisoning
Exfoliative toxins A and B (superantigens)	Causes loss of the surface layers of the skin in scalded-skin syndrome
Hemolysins	Alpha hemolysin destroys erythrocytes and causes skin destruction
	Beta hemolysin destroys erythrocytes and sphingomyelin around nerves
	Gamma hemolysin destroys erythrocytes
	Delta hemolysin destroys erythrocytes
Hyaluronidase	Also known as spreading factor; breaks down hyaluronic acid located between cells, allowing for penetration and spread of bacteria
Panton-Valentine leukocidin	Inhibits phagocytosis by granulocytes and can destroy these cells by forming pores in their phagosomal membranes
Lipases	Break down lipids
Nuclease	Breaks down nucleic acids
Protein A	Is antiphagocytic by competing with neutrophils for the Fc portion of specific opsonins
Proteases	Break down proteins
Toxic shock syndrome toxin-1 (a superantigen)	Is associated with the fever, shock, and multisystem involvement of toxic shock syndrome

The pathogenic capacity of a particular *S. aureus* strain is due to the combined effect of extracellular factors and toxins, together with the invasive properties of the strain. At one end of the disease spectrum is staphylococcal food poisoning, caused solely by the ingestion of preformed enterotoxin (table 39.3). At the other end of the spectrum are staphylococcal bacteremia and disseminated abscesses in most organs of the body.

The classic example of the staphylococcal lesion is the localized abscess (**figure 39.19*a–d***). When *S. aureus* becomes established in a hair follicle, tissue necrosis results. Coagulase is produced and forms a fibrin wall around the lesion that limits the spread. Within the center of the lesion, liquefaction of necrotic tissue occurs, and the abscess spreads in the direction of least resistance. The abscess may be either a furuncle (boil) or a carbuncle. The central necrotic tissue drains, and healing eventually occurs. However, the bacteria may spread from any focus by the lymphatics and bloodstream to other parts of the body.

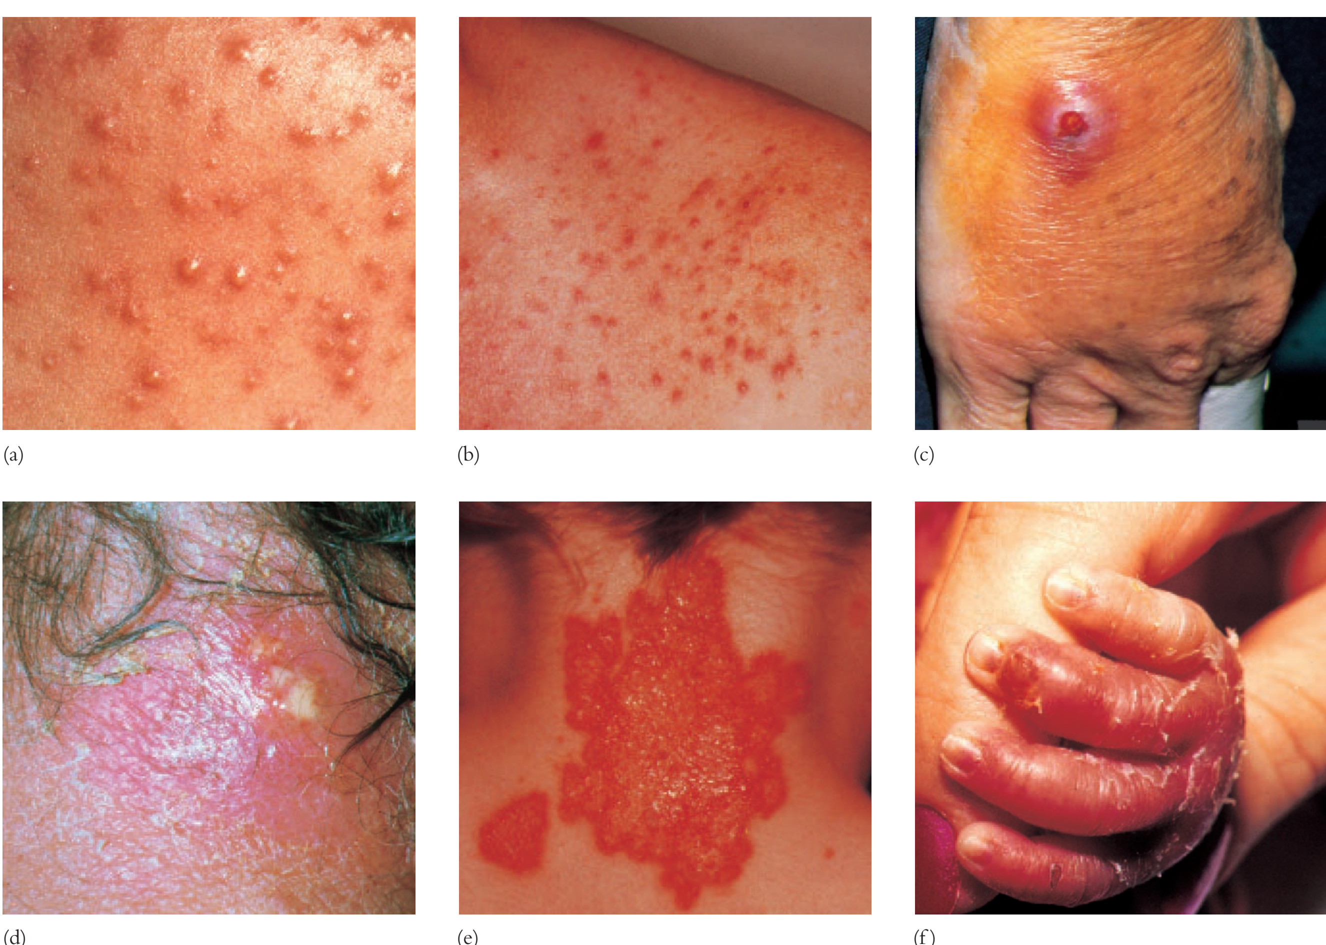


Figure 39.19 Staphylococcal Skin Infections. (**a**) Superficial folliculitis in which raised, domed pustules form around hair follicles. (**b**) In deep folliculitis the microorganism invades the deep portion of the follicle and dermis. (**c**) A furuncle arises when a large abscess forms around a hair follicle. (**d**) A carbuncle consists of a multilocular abscess around several hair follicles. (**e**) Impetigo on the neck of 2-year-old male. (**f**) Scalded skin syndrome in a 1-week-old premature male infant. Reddened areas of skin peel off, leaving "scalded"-looking moist areas.

Newborn infants and children can develop a superficial skin infection characterized by the presence of encrusted pustules (figure 39.19*e*). This disease, called impetigo contagiosa, is caused by *S. aureus* and group A streptococci. It is contagious and can spread rapidly through a nursery or school. It usually occurs in areas where sanitation and personal hygiene are poor.

Toxic shock syndrome (TSS) is a staphylococcal disease with potentially serious consequences. Most cases of this syndrome have occurred in females who use superabsorbent tampons during menstruation. However, the toxin associated with this syndrome is also produced in men and in nonmenstruating women by *S. aureus* present at sites other than the genital area (e.g., in surgical wound infections). Toxic shock syndrome is characterized by low blood pressure, fever, diarrhea, an extensive skin rash, and shedding of the skin. These symptoms are caused by the **t**oxic **s**hock **s**yndrome **t**oxin-**1** (TSST-1 is a superantigen; *see section 32.2*) released by the *S. aureus* (table 39.3), but several other enterotoxins (SEB and SEC_1) also may be involved. Several hundred cases of toxic shock syndrome are reported annually in the United States.

S**taphylococcal *s*****calded *s*****kin *s*****yndrome (SSSS)** is a third example of a common staphylococcal disease (figure 39.19*f*). SSSS is caused by strains of *S. aureus* that carry a plasmid-borne gene for the **exfoliative toxin** or **exfoliatin** (sometimes the toxin gene is on the bacterial chromosome instead). Like TSST-1, exfoliatin is a superantigen. In this disease the epidermis peels off to reveal a red area underneath—thus the name of the disease. SSSS is seen most commonly in infants and children, and neonatal nurseries occasionally suffer large outbreaks of the disease.

The definitive diagnosis of staphylococcal disease can be made only by isolation and identification of the staphylococcus involved. This requires culture, catalase, and coagulase tests; serology; DNA fingerprinting; and phage typing. Commercial rapid test kits also are available. There is no specific prevention for staphylococcal disease. The mainstay of treatment is the administration of specific antibiotics: penicillin, cloxacillin, methicillin, vancomycin, oxacillin, ce-

Box 39.4

Resistant Staphylococci

During the late 1950s and early 1960s, *Staphylococcus aureus* caused considerable morbidity and mortality as a nosocomial, or hospital-acquired, pathogen. Since then, penicillinase-resistant, semisynthetic penicillins have proved to be successful antimicrobial agents in the treatment of staphylococcal infections. Unfortunately **m**ethicillin-**r**esistant ***S. a****ureus* (MRSA) strains have recently emerged as a major nosocomial problem. One way in which staphylococci become resistant is through acquisition of a chromosomal gene (*mecA*) that encodes an alternate target protein which is not inactivated by methicillin. The majority of the strains are resistant to several of the most commonly used antimicrobial agents, including macrolides, aminoglycosides, and the beta-lactam antibiotics, including the latest generation of cephalosporins. Serious infections by methicillin-resistant strains have been most often successfully treated with an older, potentially toxic antibiotic, vancomycin. However, strains of *Enterococcus* and *Staphylococcus* recently have become resistant to vancomycin.

Recently methicillin-resistant *S. epidermidis* strains also have emerged as a nosocomial problem, especially in individuals with prosthetic heart valves or in people who have undergone other forms of cardiac surgery. Resistance to methicillin also may extend to the cephalosporin antibiotics. Difficulties in performing in vitro tests that adequately recognize cephalosporin resistance of these strains continue to exist. Serious infections due to methicillin-resistant *S. epidermidis* have been successfully treated with combination therapy, including vancomycin plus rifampin or an aminoglycoside.

fotaxime, ceftriaxone, a cephalosporin, or rifampin and others. Because of the prevalence of drug-resistant strains (e.g., methicillin-resistant staph), all staphylococcal isolates should be tested for antimicrobial susceptibility (**Box 39.4**). Cleanliness, hygiene, and aseptic management of lesions are the best means of control.

Syphilis

Venereal syphilis [Greek *syn,* together, and *philein,* to love] is a contagious sexually transmitted disease (table 39.4) caused by the spirochete *Treponema pallidum* subsp. *pallidum* (*T. pallidum, see figure 21.15*b). **Congenital syphilis** is the disease acquired in utero from the mother.

T. pallidum enters the body through mucous membranes or minor breaks or abrasions of the skin. It migrates to the regional lymph nodes and rapidly spreads throughout the body. The disease is not highly contagious, and there is only about a 1 in 10 chance of acquiring it from a single exposure to an infected sex partner.

Three recognizable stages of syphilis occur in untreated adults. In the primary stage, after an incubation period of about 10 days to 3 weeks or more, the initial symptom is a small, painless, reddened ulcer, or **chancre** [French *canker,* a destructive sore] with a hard ridge that appears at the infection site (**figure 39.20*a***) and contains spirochetes. Contact with the chancre during sexual intercourse may result in disease transmission. In about 1/3 of the cases, the disease does not progress further and the chancre disappears.

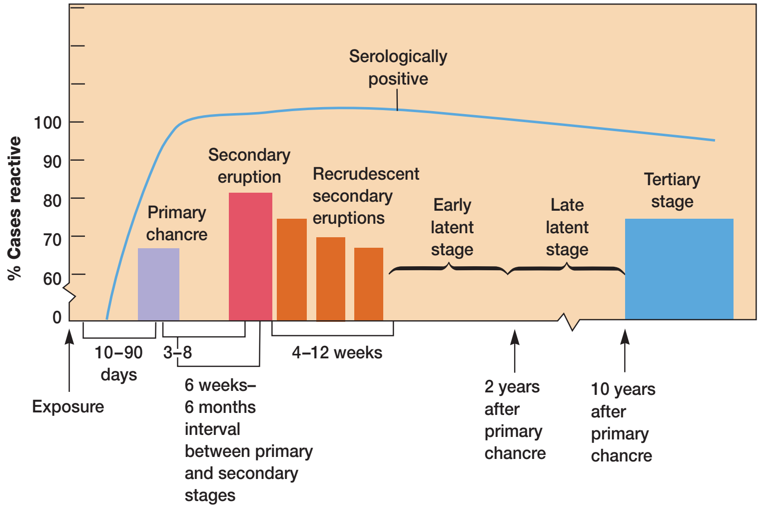

Figure 39.21 The Course of Untreated Syphilis. See text for further details.

Serological tests are positive in about 80% of the individuals during this stage (**figure 39.21**). In the remaining cases the spirochetes enter the bloodstream and are distributed throughout the body.

Within 2 to 10 weeks after the primary lesion, the disease may enter the secondary stage, which is characterized by a skin rash (figure 39.20*b*). By this time 100% of the individuals are serologically positive. Other symptoms during this stage include the loss of patches of hair, malaise, and fever. Both the chancre and the rash lesions are infectious.

After several weeks the disease becomes latent. During the latent period the disease is not normally infectious, except for possible transmission from mother to fetus (congenital syphilis). After many years a tertiary stage develops in about 40% of untreated individuals with secondary syphilis. During this stage degenerative lesions called **gummas** (figure 39.20*c*) form in the skin, bone, and nervous system as the result of hypersensitivity reactions. This stage also is characterized by a great reduction in the number of spirochetes in the body. Involvement of the central nervous system may result in tissue loss that can lead to mental retardation, blindness, a "shuffle" walk (tabes), or insanity. Many of these symptoms have been associated with such well-known people as Al Capone, Francisco Goya, Henry VIII, Adolf Hitler, Scott Joplin, Friedrich Nietzsche, Franz Schubert, Oscar Wilde, and Kaiser Wilhelm (**Box 39.5**).

Diagnosis of syphilis is through a clinical history, a thorough physical examination, and dark-field and immunofluorescence examination of fluids from the lesions (except oral lesions) for typical motile or fluorescent spirochetes. Because humans respond to *T. pallidum* with the formation of antitreponemal antibody and a complement-fixing reagin, serological tests are very informative. Examples include tests for nontreponemal antigens (VDRL, **V**enereal **D**isease **R**esearch **L**aboratories test; RPR, **R**apid **P**lasma **R**eagin test; complement fixation or the Wassermann test) and treponemal antibodies (FTA-ABS, **f**luorescent **t**reponemal **a**ntibody-**abs**orption test; TPI, ***T. p****allidum* **i**mmobilization; *T. pallidum* complement fixation; TPHA, ***T. p****allidum* **h**em**a**gglutination).

Treatment in the early stages of the disease is easily accomplished with long-acting benzathine penicillin G or aqueous procaine penicillin. Later stages of syphilis are more difficult to treat with drugs and require much larger doses over a longer period. For example, in neurosyphilis cases, treponemes occasionally survive such drug treatment. Immunity to syphilis is not complete, and subsequent infections can occur once the first infection has spontaneously disappeared or has been eliminated with antibiotics.

Prevention and control of syphilis depends on (1) public education (2) prompt and adequate treatment of all new cases, (3) follow-up on sources of infection and contact so they can be treated, (4) sexual hygiene, and (5) prophylaxis (condoms) to prevent exposure. At present, the incidence of syphilis, as well as other sexually transmitted diseases, is rising in most parts of the world. In the United States around 50,000 cases of primary and secondary syphilis in the civilian population and about 1,000 cases of congenital syphilis are reported annually. The highest incidence is among those 20 to 39 years of age.

Tetanus

Tetanus [Greek *tetanos,* to stretch] is caused by *Clostridium tetani,* an anaerobic gram-positive spore former (*see figure 23.6*b). The endospores of *C. tetani* are commonly found in hospital environments, in soil and dust, and in the feces of many farm animals and humans.

Transmission to humans is associated with skin wounds. Any break in the skin can allow *C. tetani* endospores to enter, and if the oxygen tension is low enough, the endospores germinate. When the bacteria die and lyse, the neurotoxin tetanospasmin is released. **Tetanospasmin** is an endopeptidase that selectively cleaves the synaptic vesicle membrane protein synaptobrevin. This prevents exocytosis and release of inhibitory neurotransmitters (gamma-aminobutyric acid and glycine) at synapses within the spinal cord motor nerves. The result is uncontrolled stimulation of skeletal muscles.

Early in the course of the disease, tetanospasmin causes tension or cramping and twisting in skeletal muscles surrounding the wound and tightness of the jaw muscles. With more advanced dis-

Box 39.5

A Brief History of Syphilis

Syphilis was first recognized in Europe near the end of the fifteenth century. During this time the disease reached epidemic proportions in the Mediterranean areas. According to one hypothesis, syphilis is of New World origin and Christopher Columbus (1451–1506) and his crew acquired it in the West Indies and introduced it into Spain after returning from their historic voyage. Another hypothesis is that syphilis had been endemic for centuries in Africa and may have been transported to Europe at the same time that vast migrations of the civilian population were occurring (1500).

Syphilis was initially variously called the Italian disease, the French disease, and the great pox as distinguished from smallpox. In 1530 the Italian physician and poet Girolamo Fracastoro wrote *Syphilis sive Morbus Gallicus* (Syphilis or the French Disease). In this poem a Spanish shepherd named Syphilis is punished for being disrespectful to the gods by being cursed with the disease. Several years later Fracastoro published a series of papers in which he described the possible mode of transmission of the "seeds" of syphilis through sexual contact.

Its venereal transmission was not definitely shown until the eighteenth century. The term venereal is derived from the name Venus, the Roman goddess of love. Recognition of the different stages of syphilis was demonstrated in 1838 by Philippe Ricord, who reported his observations on more than 2,500 human inoculations. In 1905 Fritz Schaudinn and Erich Hoffmann discovered the causative bacterium, and in 1906 August von Wassermann introduced the diagnostic test that bears his name. In 1909 Paul Ehrlich introduced an arsenic derivative, arsphenamine or salvarsan, as therapy. During this period, an anonymous limerick aptly described the course of this disease:

There was a young man from Black Bay
Who thought syphilis just went away
He believed that a chancre
Was only a canker
That healed in a week and a day.

But now he has "acne vulgaris"—
(Or whatever they call it in Paris);
On his skin it has spread
From his feet to his head,
And his friends want to know where his hair is.

There's more to his terrible plight:
His pupils won't close in the light
His heart is cavorting,
His wife is aborting,
And he squints through his gun-barrel sight.

Arthralgia cuts into his slumber;
His aorta is in need of a plumber;
But now he has tabes,
And saber-shinned babies,
While of gummas he has quite a number.

He's been treated in every known way,
But his spirochetes grow day by day;
He's developed paresis,
Has long talks with Jesus,
And thinks he's the Queen of the May.

ease, there is trismus ("lockjaw"), an inability to open the mouth because of the spasm of the masseter muscles. Facial muscles may go into spasms producing the characteristic expression known as risus sardonicus. Spasms or contractions of the trunk and extremity muscles may be so severe that there is boardlike rigidity, painful tonic convulsions, and opisthotonos (backward bowing of the back so that the heels and back approach each other [see chapter opening figure]). Death usually results from spasms of the diaphragm and intercostal respiratory muscles. A second toxin **tetanolysin,** is a hemolysin that aids in tissue destruction.

Testing for tetanus is suggested whenever an individual has a history of wound infection and muscle stiffness. Prevention of tetanus involves the use of the tetanus toxoid. The toxoid, which incorporates an adjuvant (aluminum salts) to increase its immunizing potency, is given routinely with diphtheria toxoid and pertussis vaccine. An initial dose is normally administered a few months after birth, a second dose 4 to 6 months later, and finally a reinforcing dose 6 to 12 months after the second injection. A final booster is given between the ages of 4 to 6 years. For many years booster doses of tetanus toxoid were administered every 3 to 5 years. However, that practice has been discontinued since it has been shown that a single booster dose can provide protection for 10 to 20 years. Serious hypersensitivity reactions have occurred when too many doses of toxoid were administered over a period of years. Booster doses today are generally given only when an individual has sustained a wound infection.

Control measures for tetanus are not possible because of the wide dissemination of the bacterium in the soil and the long survival of its endospores. The case fatality rate in generalized tetanus ranges from 30 to 90% because tetanus treatment is not very effective. Therefore prevention is all important and depends on (1) active immunization with toxoid, (2) proper care of wounds contaminated with soil, (3) prophylactic use of antitoxin, and (4) administration of penicillin. Around 100 cases of tetanus are reported annually in the United States—the majority of which are intravenous drug users.

Trachoma

Trachoma [Greek *trachoma,* roughness] is a contagious disease created by *Chlamydia trachomatis* serotypes A–C. It is one of the oldest known infectious diseases of humans and is the greatest single cause of blindness throughout the world. Probably over 500 million people are infected and 20 million blinded each year by this chlamydia. In endemic areas most children are chronically infected within a few years of birth. Active disease in adults over age 20 is three times as frequent in females as in males because

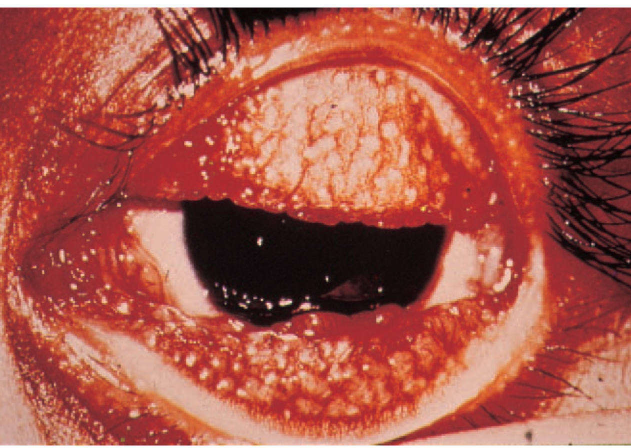

Figure 39.22 **Trachoma.** An active infection showing marked follicular hypertrophy of both eyelids. The inflammatory nodules cover the thickened conjunctiva of the eye.

of mother-child contact. Although uncommon in the United States, except among American Indians in the Southwest, trachoma is widespread in Asia, Africa, and South America.

Trachoma is transmitted by contact with inanimate objects such as soap and towels, by hand-to-hand contact that carries *C. trachomatis* from an infected eye to an uninfected eye, or by flies. The disease begins abruptly with an inflamed conjunctiva. This leads to an inflammatory cell exudate and necrotic eyelash follicles (**figure 39.22**). The disease usually heals spontaneously. However, with reinfection, vascularization of the cornea, or **pannus** formation, occurs, leading to scarring of the conjunctiva. If scar tissue accumulates over the cornea, blindness results.

Diagnosis and treatment of trachoma are the same as for inclusion conjunctivitis (previously discussed). However, prevention and control of trachoma lies more in health education and personal hygiene—such as access to clean water for washing—than in treatment.

Tularemia

The gram-negative bacterium *Francisella tularensis* subsp. *tularensis* (Jellison type A) is widely found in animal reservoirs in the United States and causes the disease **tularemia** (from Tulare, a county in California where the disease was first described). It may be transmitted to humans by biting arthropods (ticks, deer flies, or mosquitoes), direct contact with infected tissue (rabbits), inhalation of aerosolized bacteria, or ingestion of contaminated food or water. After an incubation period of 2 to 10 days, a primary ulcerative lesion appears at the infection site, lymph nodes enlarge, and a high fever develops. Diagnosis is by PCR or culture of the bacterium and fluorescent antibody and agglutination tests; treatment is with streptomycin, tetracycline, or aminoglycoside antibiotics. Prevention and control involves public education, protective clothing, and vector control. An attenuated live vaccine is available from the United States Army for high-risk laboratory workers. Fewer than 300 cases of tularemia are reported annually in the United States.

Sexually Transmitted Diseases

Sexually transmitted diseases (STDs) represent a worldwide public health problem. The various viruses that cause STDs are presented in chapter 38, the responsible bacteria in chapter 39, and the yeasts and protozoa in chapter 40. **Table 39.4** lists the various microorganisms that can be sexually transmitted and the diseases they cause.

The spread of most sexually transmitted diseases is currently out of control. In the United States alone, at least 8 to 10 million persons contract some type of STD each year. Some of the STDs that are prevalent in the United States are gonorrhea, syphilis, genital herpes, chlamydial infections, trichomoniasis, hepatitis B, and the most serious of all because of its high mortality, AIDS.

STDs were formerly called venereal diseases (from Venus, the Roman goddess of love). They occur most frequently in the most sexually active age group—15 to 30 years of age—but anyone who has sexual contact with an infected individual is a potential victim. In general, the more sexual partners a person has, the more likely that the person is to acquire an STD.

As noted in previous chapters, some of the microorganisms that cause STDs can also be transmitted by nonsexual means. Examples include transmission by contaminated hypodermic needles and syringes shared among intravenous drug users, contaminated blood transfusions, and infected mothers to their infants.

Some STDs can be cured quite easily, but others, especially those caused by viruses, are presently difficult or impossible to cure. Because treatments are often inadequate, prevention is essential. Preventive measures are based mainly on better education of the total population and when possible, control of the sources of infection and treatment of infected individuals with chemotherapeutic agents.

1. Describe the three phases of lymphogranuloma venereum.
2. Describe several diseases caused by the staphylococci.
3. How does *C. trachomatis,* serotypes A–C, cause trachoma? Describe how it is transmitted, and the way in which blindness may result.
4. What is nongonococcal urethritis and what agents can cause it? Describe complications that may develop in the absence of treatment.
5. Name and describe the three stages of syphilis.
6. How is the disease tetanus acquired? What are its symptoms and how do they arise?
7. From what animal can tularemia be contracted?
8. Name four ways in which a person may contract an STD.

39.4 Food-Borne and Waterborne Diseases

Many microorganisms contaminating food and water can cause acute gastroenteritis or inflammation of the stomach and intestinal lining. When food is the source of the pathogen, the condition is often called **food poisoning.** Gastroenteritis can arise in two ways. The microorganisms may actually produce a **food-**

Table 39.4 Summary of the Major Sexually Transmitted Diseases (STDs)

Microorganism	Disease	Comments	Treatment
Viruses			
Human immunodeficiency virus (HIV)	Acquired immune deficiency syndrome (AIDS)	Pandemic in many parts of the world	
Herpes simplex virus (HSV-2)	Genital herpes	Painful blisters; enters latent stage, with reactivation due to stress; also oral, pharyngeal, and rectal herpes; no cure; very prevalent in the U.S.	Acyclovir and similar drugs alleviate the symptoms
Human papillomavirus type 6 (HPV-6)	Condyloma acuminata (genital warts)	Predisposes to cervical cancer; no cure; very common in the U.S.	Removal by various mechanical and chemical means; interferon injection
Hepatitis B virus (HBV)	Hepatitis B (serum hepatitis)	Transmitted in semen; cirrhosis, primary hepatocarcinoma	No treatment; recombinant HBV vaccine for prevention
Cytomegalovirus (CMV)	Congenital cytomegalic inclusion disease	Avoid sexual contact with an infected person	Ganciclovir and cidofovir for high-risk patients
Molluscum contagiosum	Genital molluscum contagiosum	Localized wartlike skin lesions	None
Bacteria			
Calymmatobacterium granulomatis	Granuloma inguinale (donovanosis)	Rare in the U.S.; draining ulcers that can persist for years	Tetracycline, erythromycin, newer quinolones
Campylobacter (Heliobacter) cinaedi, C. fennelliae	Diarrhea and rectal inflammation in homosexual men	Common in immunocompromised individuals	Metronidazole, macrolides
Chlamydia trachomatis	Nongonococcal urethritis (NGU); cervicitis, pelvic inflammatory disease (PID), lymphogranuloma venereum	Serovars D-K cause most of the STDs in the U.S.; lymphogranuloma venereum rare in the U.S.	Tetracyclines, erythromycin, doxycycline, ceftriaxone
Gardnerella vaginalis	Bacterial vaginosis	Clue cells present	Metronidazole
Haemophilus ducreyi	Chancroid ("soft chancre")	Open sores on the genitals can lead to scarring without treatment; on the rise in the U.S.	Erythromycin or ceftriaxone
Mycoplasma genitalium	Implicated in some cases of NGU	Only recently described as an STD	Tetracyclines or erythromycin
Mycoplasma hominis	Implicated in some cases of PID	Widespread, often asymptomatic but can cause PID in women	Tetracyclines or erythromycin
Neisseria gonorrhoeae	Gonorrhea, PID	Most commonly reported STD in the U.S.; usually symptomatic in men and asymptomatic in women; new antibiotic-resistant strains	Third-generation cephalosporins
Treponema pallidum subsp. *pallidum*	Syphilis, congenital syphilis	Manifests many clinical syndromes	Benzathine penicillin G
Ureaplasma urealyticum	Urethritis	Widespread, often asymptomatic but can cause PID in women and NGU in men	Tetracyclines or erythromycin
Yeasts			
Candida albicans	Candidiasis (moniliasis)	Produces a thick white vaginal discharge and severe itching	Nystatin, terconazole
Protozoa			
Trichomonas vaginalis	Trichomoniasis	Produces a frothy vaginal discharge; very common in the U.S.	Oral metronidazole

borne infection. That is, they may first colonize the gastrointestinal tract and grow within it, then either invade host tissues or secrete exotoxins. Alternatively the pathogen may secrete an exotoxin that contaminates the food and is then ingested by the host. This is sometimes referred to as a **food intoxication** because the toxin is ingested and the presence of living microorganisms is not required. Because these toxins disrupt the functioning of the intestinal mucosa they are called **enterotoxins.** Common symptoms of enterotoxin poisoning are nausea, vomiting, and diarrhea.

Worldwide, diarrheal diseases are second only to respiratory diseases as a cause of adult death; they are the leading cause of childhood death, and in some parts of the world they are responsible for more years of potential life lost than all other causes combined. For example, each year around 5 million children (more than 13,600 a day) die from diarrheal diseases in Asia, Africa, and South America. In the United States estimates exceed 10,000 deaths per year from diarrhea, and an average of 500 childhood deaths are reported.

This section describes several of the more common bacteria associated with gastrointestinal infections, food intoxications, and waterborne diseases. **Table 39.5** summarizes many of the bacterial pathogens responsible for food poisoning. The protozoa responsible for food- and waterborne diseases are covered in Chapter 40. Diseases transmitted by foods (pp. 973–76); Food spoilage (pp. 966–69); Waterborne pathogens (651–57)

© The McGraw–Hill Companies, 2002

Table 39.5 Bacteria That Cause Acute Bacterial Diarrheas and Food Poisonings

Organism	Incubation Period (Hours)	Vomiting	Diarrhea	Fever	Epidemiology	Pathogenesis
Staphylococcus aureus	1–8 (rarely, up to 18)	+++	+	–	Staphylococci grow in meats, dairy and bakery products and produce enterotoxins.	Enterotoxins act on receptors in gut that transmit impulse to medullary centers; may also act as superantigens.
Bacillus cereus	2–16	+++	++	–	Reheated fried rice causes vomiting or diarrhea.	Enterotoxins formed in food or in gut from growth of *B. cereus.*
Clostridium perfringens	8–16	±	+++	–	Clostridia grow in rewarmed meat dishes. Huge numbers ingested.	Enterotoxin produced during sporulation in gut, causes hypersecretion.
Clostridium botulinum	18–24	±	Rare	–	Clostridia grow in anaerobic foods and produce toxin.	Toxin absorbed from gut and blocks acetylcholine release at neuromuscular junction.
Escherichia coli (enterotoxigenic strain)	24–72	±	++	–	Organisms grow in gut and are a major cause of traveler's diarrhea.	Heat-labile (LT) and heat-stable (ST) enterotoxins cause hypersecretion in small intestine.
Vibrio parahaemolyticus	6–96	+	++	±	Organisms grow in seafood and in gut and produce toxin, or invade.	Toxin causes hypersecretion; vibrios invade epithelium; stools may be bloody.
Vibrio cholerae	24–72	+	+++	–	Organisms grow in gut and produce toxin.	Toxin causes hypersecretion in small intestine. Infective dose $>10^5$ vibrios.
Shigella spp. (mild cases)	24–72	±	++	+	Organisms grow in superficial gut epithelium. *S. dysenteriae* produces toxin.	Organisms invade epithelial cells; blood, mucus, and neutrophils in stools. Infective dose $<10^3$ organisms.
Salmonella spp. (gastroenteritis)	8–48	±	++	+	Organisms grow in gut.	Superficial infection of gut, little invasion. Infective dose $>10^5$ organisms.
Salmonella typhi (typhoid fever)	10–14 days	±	±	++	Bacteria invade the gut epithelium and reach the lymph nodes, liver, spleen, and gallbladder.	Symptoms probably due to endotoxins and tissue inflammation. Infective dose $\geq 10^7$ organisms.
Clostridium difficile	Days to weeks after antibiotic therapy	–	+++	+	Antibiotic-associated colitis.	Toxin causes epithelial necrosis in colon; pseudomembranous colitis.
Campylobacter jejuni	2–10 days	–	+++	++	Infection by oral route from foods, pets. Organism grows in small intestine.	Invasion of mucous membrane. Toxin production uncertain.
Yersinia enterocolitica	4–7 days	±	++	+	Fecal-oral transmission. Food-borne. Animals infected.	Gastroenteritis or mesenteric adenitis. Occasional bacteremia. Toxin produced occasionally.

Adapted from Geo. F. Brooks, et al., *Medical Microbiology,* 21st edition. Copyright 1998 Appleton & Lange, Norwalk, CT. Reprinted by permission.

Clinical Features
Abrupt onset, intense vomiting for up to 24 hours, recovery in 24–48 hours. Occurs in persons eating the same food. No treatment usually necessary except to restore fluids and electrolytes.
With incubation period of 2–8 hours, mainly vomiting. With incubation period of 8–16 hours, mainly diarrhea.
Abrupt onset of profuse diarrhea; vomiting occasionally. Recovery usual without treatment in 1–4 days. Many clostridia in cultures of food and feces of patients.
Diplopia, dysphagia, dysphonia, difficulty breathing. Treatment requires clear airway, ventilation, and intravenous polyvalent antitoxin. Exotoxin present in food and serum. Mortality rate high.
Usually abrupt onset of diarrhea; vomiting rare. A serious infection in newborns. In adults, "traveler's diarrhea" is usually self-limited in 1–3 days.
Abrupt onset of diarrhea in groups consuming the same food, especially crabs and other seafood. Recovery is usually complete in 1–3 days. Food and stool cultures are positive.
Abrupt onset of liquid diarrhea in endemic area. Needs prompt replacement of fluids and electrolytes IV or orally. Tetracyclines shorten excretion of vibrios. Stool cultures positive.
Abrupt onset of diarrhea, often with blood and pus in stools, cramps, tenesmus, and lethargy. Stool cultures are positive. Give trimethoprim sulfamethoxazole or ampicillin or chloramphenicol in severe cases. Do not give opiates. Often mild and self-limited. Restore fluids.
Gradual or abrupt onset of diarrhea and low-grade fever. Nausea, headache, and muscle aches common. No antimicrobials unless systemic dissemination is suspected. Stool cultures are positive. Prolonged carriage is frequent.
Initially fever, headache, malaise, anorexia, and muscle pains. Fever may reach 40°C by the end of the first week of illness and lasts for 2 or more weeks. Diarrhea often occurs, and abdominal pain, cough, and sore throat may be prominent. Antibiotic therapy shortens duration of the illness.
Especially after abdominal surgery, abrupt bloody diarrhea and fever. Toxins in stool. Oral vancomycin useful in therapy.
Fever, diarrhea; PMNs and fresh blood in stool, especially in children. Usually self-limited. Special media needed for culture at 43°C. Erythromycin in severe cases with invasion. Usual recovery in 5–8 days.
Severe abdominal pain, diarrhea, fever; PMNs and blood in stool; polyarthritis, erythema nodosum, especially in children. If severe, treat with gentamicin. Keep stool specimen at 4°C before culture.

Botulism

Food-borne **botulism** [Latin *botulus,* sausage] is a form of food poisoning caused by *Clostridium botulinum,* which is an obligately anaerobic endospore-forming, gram-positive rod that is found in soil and aquatic sediments. The most common source of infection is home-canned food that has not been heated sufficiently to kill contaminating *C. botulinum* endospores. The endospores can germinate, and a toxin is produced during vegetative growth. If the food is then eaten without adequate cooking, the toxin remains active and the disease results.

The botulinum toxin is a neurotoxin that binds to the synapses of motor neurons. It selectively cleaves the synaptic vesicle membrane protein synaptobrevin, thus preventing exocytosis and release of the neurotransmitter acetylcholine. As a consequence, muscles do not contract in response to motor neuron activity, and flaccid paralysis results (**Box 39.6**). Symptoms of botulism occur within 18 to 24 hours of toxin ingestion and include blurred vision, difficulty in swallowing and speaking, muscle weakness, nausea, and vomiting. Without adequate treatment, 1/3 of the patients may die within a few days of either respiratory or cardiac failure.

Laboratory diagnosis is by a hemagglutination test or inoculation of mice with the patient's serum, stools, or vomitus to prove toxigenicity. Treatment relies on supportive care and polyvalent antitoxin. Fewer than 100 cases of botulism occur in the United States annually.

Infant botulism is the most common form of botulism in the United States and is confined to infants under a year of age. Approximately 100 cases are reported each year. It appears that ingested endospores, which may be naturally present in honey or house dust, germinate in the infant's intestine. *C. botulinum* then multiplies and produces the toxin. The infant becomes constipated, listless, generally weak, and eats poorly. Death may result from respiratory failure.

Prevention and control of botulism involves (1) strict adherence to safe food-processing practices by the food industry, (2) educating the public on safe home-preserving (canning) methods for foods, and (3) not feeding honey to infants younger than 1 year of age.

Campylobacter jejuni Gastroenteritis

Campylobacter jejuni is a gram-negative curved rod found in the intestinal tract of animals. Studies with chickens, turkeys, and cattle have shown that as much as 50 to 100% of a flock or herd of these birds or animals secrete *C. jejuni.* These bacteria also can be isolated in high numbers from surface waters. They are transmitted to humans by contaminated food and water, contact with infected animals, or anal-oral sexual activity. *C. jejuni* causes an estimated 2 million cases of *Campylobacter* **gastroenteritis**—inflammation of the intestine—or **campylobacteriosis** and subsequent diarrhea in the United States each year.

The incubation period is 2 to 10 days. *C. jejuni* invades the epithelium of the small intestine, causing inflammation, and also secretes an exotoxin that is antigenically similar to the cholera

Box 39.6

Clostridial Toxins as Therapeutic Agents: Benefits of Nature's Most Toxic Proteins

Some toxins are currently being used for the treatment of human disease. Specifically, botulinum toxin, the most poisonous biological substance known, is being used for the treatment of specific neuromuscular disorders characterized by involuntary muscle contractions. Since approval of type-A botulinum toxin by the FDA in 1989 for three disorders (strabismus [crossing of the eyes], blepharospasm [spasmotic contractions of the eye muscles], and hemifacial spasm [contractions of one side of the face]), the number of neuromuscular problems being treated has increased to include other tremors, cosmetic applications, migraine and tension headaches, and other maladies. The remarkable therapeutic utility of botulinum toxin lies in its ability to specifically and potently inhibit involuntary muscle activity for an extended duration. Overall, the clostridia (currently one of the largest and most diverse genera of bacteria containing about 130 "official" species) produce more protein toxins than any other bacterial genus and are a rich reservoir of toxins for research and medicinal uses. For example, research is underway to use clostridial toxins or toxin domains for drug delivery, prevention of food poisoning, and the treatment of cancer and other diseases. The remarkable success of botulinum toxin as a therapeutic agent has thus created a new field of investigation in microbiology.

toxin. Symptoms include diarrhea, high fever, severe inflammation of the intestine along with ulceration, and bloody stools.

Laboratory diagnosis is by culture in an atmosphere with reduced O_2 and added CO_2. The disease is self-limited, and treatment is supportive; fluids, electrolyte replacement, and erythromycin is used in severe cases. Recovery usually takes from 5 to 8 days. Prevention and control involves good personal hygiene and food handling precautions, including pasteurization of milk and thorough cooking of poultry.

Cholera

Throughout recorded history **cholera** [Greek *chole,* bile] has caused seven pandemics in various areas of the world, especially in Asia, the Middle East, and Africa. The disease has been rare in the United States since the 1800s, but an endemic focus is believed to exist on the gulf coast of Louisiana and Texas.

Cholera is caused by the gram-negative *Vibrio cholerae* bacterium of the family *Vibrionaceae* (**figure 39.23**). Although there are many serogroups, only O1 and O139 have exhibited the ability to cause epidemics. *V. cholerae* O1 is divided into two serotypes, Inaba and Ogawa, and two biotypes, classic and El Tor.

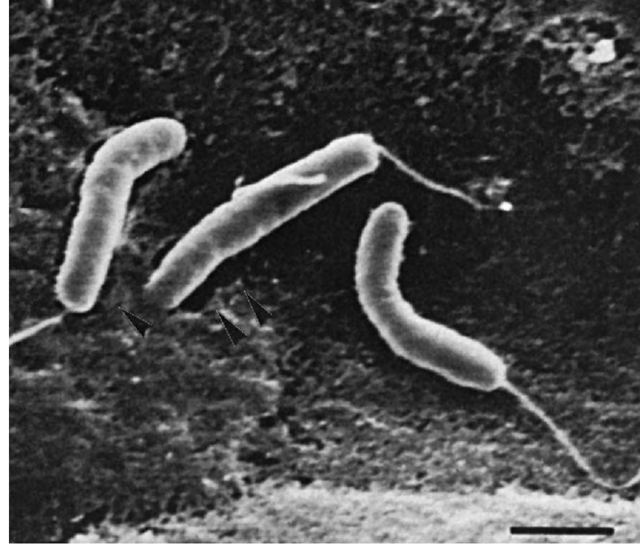

Figure 39.23 Cholera. *Vibrio cholerae* adhering to intestinal epithelium; scanning electron micrograph (× 12,000). Notice that the bacteria is slightly curved with a single polar flagellum.

Cholera is acquired by ingesting food or water contaminated by fecal material from patients or carriers. (Shellfish and copepods are natural reservoirs.) In 1961 the El Tor biotype emerged as an important cause of cholera pandemics, and in 1992 the newly identified strain *V. cholerae* O139 emerged in Asia. This novel toxigenic strain does not agglutinate with O1 antiserum but possesses epidemic and pandemic potential. In Calcutta, India, serogroup O139 of *Vibrio cholerae* has displaced El Tor *V. cholerae* serogroup O1 (causative agent of the seventh pandemic), an event that has never happened in the recorded history of cholera.

Once the bacteria enter the body, the incubation period is from 24 to 72 hours. The bacteria adhere to the intestinal mucosa of the small intestine, where they are not invasive but secrete **choleragen,** a cholera toxin. Choleragen is a protein composed of two functional units, an enzymatic A subunit and an intestinal receptor-binding B subunit. The A subunit enters the intestinal epithelial cells and activates the enzyme adenylate cyclase by the addition of an ADP-ribosyl group in a way similar to that employed by diphtheria toxin (*see figure 34.5*b). As a result choleragen stimulates hypersecretion of water and chloride ions while inhibiting absorption of sodium ions. The patient loses massive quantities of fluid and electrolytes, which is associated with abdominal muscle cramps, vomiting, fever, and watery diarrhea. The diarrhea can be so profuse that a person can lose 10 to 15 liters of fluid during the infection. Death may result from the elevated concentration of blood proteins, caused by reduced fluid levels, which leads to circulatory shock and collapse. There is now evidence that the cholera toxin gene is carried by the CTX filamentous bacteriophage. The phage binds to the pilus used to

© The McGraw–Hill Companies, 2002

colonize the host's gut, enters the bacterium, and incorporates its genes into the bacterial chromosome.

Laboratory diagnosis is by culture of the bacterium from feces and subsequent identification by agglutination reactions with specific antisera. Treatment is by oral rehydration therapy with NaCl plus glucose to stimulate water uptake by the intestine; the antibiotics of choice are a tetracycline, trimethoprim-sulfamethoxazole, or ciprofloxacin. The most reliable control methods are based on proper sanitation, especially of water supplies. The mortality rate without treatment is often over 50%; with treatment and supportive care, it is less than 1%. Fewer than 20 cases of cholera are reported each year in the United States.

Listeriosis

Listeria monocytogenes is a gram-positive rod that can be isolated from soil, vegetation, and many animal reservoirs. Human disease due to *L. monocytogenes* generally occurs in the setting of pregnancy or immunosuppression caused by illness or medication. Recent evidence suggests that a substantial number of cases of human **listeriosis** are attributable to the food-borne transmission of *L. monocytogenes. Listeria* outbreaks have been traced to sources such as contaminated milk, soft cheeses, vegetables, and meat. Unlike many of the food-borne pathogens, which cause primarily gastrointestinal illness, *L. monocytogenes* causes invasive syndromes such as meningitis, sepsis, and stillbirth.

L. monocytogenes is an intracellular pathogen, a characteristic consistent with its predilection for causing illness in persons with deficient cell-mediated immunity. This bacterium can be found as part of the normal gastrointestinal microbiota in healthy individuals. In immunosuppressed individuals, invasion, intracellular multiplication, and cell-to-cell spread of the bacterium appears to be mediated through proteins such as internalin, the hemolysin listeriolysin O, and phospholipase C. *Listeria* also uses host cell actin filaments to move within and between cells (*see figure 4.4*). The increased risk of infection in pregnant women may be due to both systemic and local immunological changes associated with pregnancy. For example, local immunosuppression at the maternal-fetal interface of the placenta may facilitate intrauterine infection following transient maternal bacteremia.

Diagnosis of listeriosis is by culture of the bacterium. Treatment is intravenous administration of either ampicillin or penicillin. Since *L. monocytogenes* is frequently isolated from food, the USDA (the U.S. Department of Agriculture) and manufacturers are pursuing measures to reduce the contamination of food products by this bacterium.

Salmonellosis

Salmonellosis (*Salmonella* gastroenteritis) is caused by over 2,000 *Salmonella* serovars (strains; a subspecies category). The most frequently reported one from humans is *S.* serovar *typhimurium.* This bacterium is a gram-negative, motile, non-spore-forming rod.

The initial source of the bacterium is the intestinal tracts of birds and other animals. Humans acquire the bacteria from contaminated foods such as beef products, poultry, eggs, egg products, or water. Around 45,000 cases a year are reported in the United States, but there actually may be as many as 2 to 3 million cases annually.

Once the bacteria are in the body, the incubation time is only about 8 to 48 hours. The disease results from a true food-borne infection because the bacteria multiply and invade the intestinal mucosa where they produce an enterotoxin and cytotoxin that destroy the epithelial cells. Abdominal pain, cramps, diarrhea, nausea, vomiting, and fever are the most prominent symptoms, which usually persist for 2 to 5 days but can last for several weeks. During the acute phase of the disease, as many as 1 billion salmonella can be found per gram of feces. Most adult patients recover, but the loss of fluids can cause problems for children and elderly people.

Laboratory diagnosis is by isolation of the bacterium from food or patients' stools. Treatment is with fluid and electrolyte replacement. Prevention depends on good food-processing practices, proper refrigeration, and adequate cooking.

Shigellosis

Shigellosis or bacillary dysentery is a diarrheal illness resulting from an acute inflammatory reaction of the intestinal tract caused by the four species of the genus *Shigella* (gram-negative, nonmotile, facultative rods). About 25,000 to 30,000 cases a year are reported in the United States, and around 600,000 deaths a year worldwide are due to bacillary dysentery.

Shigella is restricted to human hosts. *S. sonnei* is the usual pathogen in the United States and Britain, but *S. flexneri* is also fairly common. The organism is transmitted by the fecal-oral route—primarily by food, fingers, feces, and flies (the four "F's")—and is most prevalent among children, especially 1- to 4-year-olds. The infectious dose is only around 10 to 100 bacteria. In the United States shigellosis is a particular problem in day care centers and custodial institutions where there is crowding.

The shigellae are facultative intracellular parasites that multiply within the cells of the colon epithelium. The bacteria induce the mucosal cell to phagocytose them and then disrupt the phagosome membrane. After reproducing in the cytoplasmic matrix, the shigellae invade adjacent mucosal cells. They may produce both endotoxins and exotoxins but do not usually spread beyond the colon epithelium. The watery stools often contain blood, mucus, and pus. In severe cases the colon can become ulcerated.

The incubation period usually ranges from 1 to 3 days and the organisms are shed over a period of 1 to 2 weeks. Identification of isolates is based on biochemical characteristics and serology. The disease normally is self-limiting in adults and lasts an average of 4 to 7 days; in infants and young children it may be fatal. Usually fluid and electrolyte replacement are sufficient, and antibiotics may not be required in mild cases although they can shorten the duration of symptoms. Sometimes, particularly in malnourished infants and children, neurological complications and kidney failure result. When necessary, treatment is with trimethoprim-sulfamethoxazole or fluoroquinolones. Antibiotic-resistant strains are becoming a problem. Prevention is a matter of good personal hygiene and the maintenance of a clean water supply.

Staphylococcal Food Poisoning

Staphylococcal food poisoning is the major type of food intoxication in the United States. It is caused by ingestion of improperly stored or cooked food (particularly foods such as ham, processed meats, chicken salad, pastries, ice cream, and hollandaise sauce) in which *Staphylococcus aureus* has grown.

S. aureus (a gram-positive coccus) is very resistant to heat, drying, and radiation; it is found in the nasal passages and on the skin of humans and other mammals worldwide. From these sources it can readily enter food. If the bacteria are allowed to incubate in certain foods, they produce heat-stable enterotoxins that render the food dangerous even though it appears normal. Once the bacteria have produced the toxin, the food can be extensively and properly cooked, killing the bacteria but without destroying the toxin. Intoxication can therefore result from food that has been thoroughly cooked. Six different enterotoxins have been identified and are designated A, B, C1, C2, D, and E. These toxins appear to act as neurotoxins that stimulate vomiting through the vagus nerve. At least some are superantigens and trigger the release of IL-2 and other lymphokines.

Typical symptoms include severe abdominal pain, cramps, diarrhea, vomiting, and nausea. The onset of symptoms is rapid (usually 1 to 8 hours) and of short duration (usually less than 24 hours). The mortality rate of staphylococcal food poisoning is negligible among healthy individuals.

Diagnosis is based on the symptoms or laboratory diagnosis of the bacteria from foods. Enterotoxins may be detected in foods by animal toxicity tests. Treatment is with fluid and electrolyte replacement. Prevention and control involve avoidance of food contamination, and control of personnel responsible for food preparation and distribution.

Traveler's Diarrhea and *Escherichia coli* Infections

Millions of people travel yearly from country to country (*see section 37.11*). Unfortunately a large percentage of these travelers acquire a rapidly acting, dehydrating condition called **traveler's diarrhea.** This diarrhea results from an encounter with certain viruses, bacteria, or protozoa usually absent from the traveler's environment. One of the major causative agents is *E. coli.* This bacterium circulates in the resident population, typically without causing symptoms due to the immunity afforded by previous exposure. Because many of these bacteria are needed to initiate infection, contaminated food and water are the major means by which the bacteria are spread. This is the basis for the popular warnings to international travelers: "Don't drink the local water" and "Boil it, peel it, cook it, or forget it."

E. coli may cause diarrheal disease by several mechanisms, and six categories or strains of diarrheagenic *E. coli* are now recognized: enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), enteroahemorrhagic *E. coli* (EHEC), enteropathogenic *E. coli* (EPEC), enteroaggregative *E. coli* (EAggEC), and diffusely adhering *E. coli* (DAEC).

The **enterotoxigenic *E. coli* (ETEC)** strains produce one or both of two distinct enterotoxins (*see Box 13.1*), which are responsible for the diarrhea and distinguished by their heat stability: heat-stable enterotoxin (ST) and heat-labile enterotoxin (LT). The genes for ST and LT production and for colonization factors are usually plasmid-borne and acquired by horizontal gene transfer. ST binds to a glycoprotein receptor that is coupled to guanylate cyclase on the surface of intestinal epithelial cells. Activation of guanylate cyclase stimulates the production of cyclic guanosine monophosphate (cGMP), which leads to the secretion of electrolytes and water into the lumen of the small intestine, manifested as the watery diarrhea characteristic of an ETEC infection. LT binds to specific gangliosides on the epithelial cells and activates membrane-bound adenylate cyclase, which leads to increased production of cyclic adenosine monophosphate (cAMP) through the same mechanism employed by cholera toxin. Again, the result is hypersecretion of electrolytes and water into the intestinal lumen.

The **enteroinvasive *E. coli* (EIEC)** strains cause diarrhea by penetrating and multiplying within the intestinal epithelial cells. The ability to invade the epithelial cells is associated with the presence of a large plasmid; EIEC may also produce a cytotoxin and an enterotoxin.

The **enteropathogenic *E. coli* (EPEC)** strains attach to the brush border of intestinal epithelial cells and cause a specific type of cell damage called effacing lesions. **Effacing lesions** or attaching-effacing (AE) lesions represent destruction of brush border microvilli adjacent to adhering bacteria. This cell destruction leads to the subsequent diarrhea. As a result of this pathology, the term AE *E. coli* is used to describe true EPEC strains. It is now known that AE *E. coli* is an important cause of diarrhea in children residing in developing countries.

The **enterohemorrhagic *E. coli* (EHEC)** strains carry the genetic determinants for attaching-effacing lesions and Shiga-like toxin production. The attaching-effacing lesion causes hemorrhagic colitis with severe abdominal pain and cramps followed by bloody diarrhea. The Shiga-like toxins I and II (also called verotoxins 1 and 2) have also been implicated in two extraintestinal diseases; **hemolytic uremic syndrome** and thrombotic thrombocytopenic purpura. It is believed these toxins kill vascular endothelial cells. A major form of EHEC is the *E. coli* O157:H7 that has caused many outbreaks of hemorrhagic colitis in the United States since it was first recognized in 1982. Currently there are a minimum of 20,000 *E. coli* O157:H7 cases and 250 deaths in the United States each year.

The **enteroaggregative *E. coli* (EAggEC)** strains adhere to epithelial cells in localized regions, forming clumps of bacteria with a "stacked brick" appearance. Conventional extracellular toxins have not been detected in EAggEC, but unique lesions are seen in epithelial cells, suggesting the involvement of toxins.

The **diffusely adhering *E. coli* (DAEC)** strains adhere over the entire surface of epithelial cells and usually cause disease in immunologically naive or malnourished children. It has been suggested that DAEC may have an as yet undefined virulence factor.

Diagnosis of traveler's diarrhea caused by *E. coli* is based on past travel history and symptoms. Laboratory diagnosis is by isolation of the specific type of *E. coli* from feces and identification

using DNA probes, the determination of virulence factors, and the polymerase chain reaction. Treatment is with fluid and electrolytes plus doxycycline and trimethroprim-sulfamethoxazole. Recovery is usually without complications. Prevention and control involve avoiding contaminated food and water.

Typhoid Fever

Typhoid [Greek *typhodes,* smoke] **fever** is caused by several virulent serovars of *Salmonella typhi* and is acquired by ingestion of food or water contaminated by feces of infected humans or animals. In earlier centuries the disease occurred in great epidemics.

Once in the small intestine the incubation period is about 10 to 14 days. The bacteria colonize the small intestine, penetrate the epithelium, and spread to the lymphoid tissue, blood, liver, and gallbladder. Symptoms include fever, headache, abdominal pain, anorexia, and malaise, which last several weeks. After approximately 3 months, most individuals stop shedding bacteria in their feces. However, a few individuals continue to shed *S. typhi* for extended periods but show no symptoms. In these carriers, the bacteria continue to grow in the gallbladder and reach the intestine through the bile duct (*see Box 37.2 on "Typhoid Mary," one of the most famous typhoid carriers*).

Laboratory diagnosis of typhoid fever is by demonstration of typhoid bacilli in the blood, urine, or stools and serology (the Widal test). Treatment with ceftriaxone, trimethoprim-sulfamethoxazole, or ampicillin has reduced the mortality rate to less than 1%. Recovery from typhoid confers a permanent immunity. Purification of drinking water, milk pasteurization, prevention of food handling by carriers, and complete isolation of patients are the most successful prophylactic measures. There is a vaccine for high-risk individuals (*see table 33.1*). About 400 to 500 cases of typhoid fever occur annually in the United States.

1. Distinguish between food intoxication, food poisoning, and food borne infection. What is an enterotoxin?
2. Why is cholera the most severe form of gastroenteritis?
3. How does one acquire botulism? Describe how botulinum toxin causes flaccid paralysis.
4. What is the most common form of gastroenteritis in the United States and how are the symptoms caused?
5. What is a common source of *Listeria* infections? How is the intracellular growth of *Listeria* related to the symptoms it produces and the observation that immunocompromised individuals are most at risk?
6. What is the usual source of the bacterium responsible for salmonellosis? Shigellosis? Where and how does Shigella infect people?
7. Describe the most common type of food intoxication in the United States and how it arises.
8. Describe a typhoid carrier. How does one become a carrier?
9. What are some specific causes of traveler's diarrhea? Briefly describe the six major types of pathogenic *E. coli.*

39.5 Sepsis and Septic Shock

Some microbial diseases and their effects cannot be categorized under a specific mode of transmission. Two important examples are sepsis and septic shock. Septic shock is the most common cause of death in intensive care units and the thirteenth most common cause of death in the United States. Unfortunately the incidence of these two disorders continues to rise: 400,000 cases of sepsis and 200,000 episodes of septic shock are estimated to occur annually in the United States, resulting in more than 100,000 deaths.

Sepsis recently has been redefined by physicians as the systemic response to a microbial infection (*see also table 34.2*). This response is manifested by two or more of the following conditions: temperature above 38 or below 36°C; heart rate above 90 beats per minute; respiratory rate above 20 breaths per minute or a pCO_2 below 32 mmHg; leukocyte count above 12,000 cells per ml^3 or below 4,000 cells per ml^3. **Septic shock** is sepsis associated with severe hypotension (low blood pressure due to shock) despite adequate fluid replacement. Gram-positive bacteria, fungi, and endotoxin-containing gram-negative bacteria can initiate the pathogenic cascade of sepsis leading to septic shock. Gram-negative sepsis is most commonly caused by *Escherichia coli,* followed by *Klebsiella* spp., *Enterobacter* spp., and *Pseudomonas aeruginosa.* Endotoxin, or lipopolysaccharide (LPS; *see figure 3.25*), an integral component of the outer membrane of gram-negative bacteria, has been implicated as a primary initiator of the pathogenesis of gram-negative septic shock.

The pathogenesis of sepsis and septic shock begins with the proliferation of the microorganism at the location of infection (**figure 39.24**). The microorganism may invade the bloodstream directly or may proliferate locally and release various products into the bloodstream. These products include both structural components of the microorganisms (endotoxin, teichoic acid antigen) and exotoxins synthesized by the microorganism. All of these products can stimulate the release of the endogenous mediators of sepsis from endothelial cells, plasma cells (monocytes, macrophages, neutrophils), and plasma cell precursors.

The endogenous mediators have profound physiological effects on the heart, vasculature, and other body organs. The consequences are either recovery or septic shock leading to death. Death usually ensues if one or more organ systems fail completely.

39.6 Dental Infections

Some microorganisms found in the oral cavity are discussed in section 31.2 and presented in figure 31.2. Of this large number, only a few bacteria can be considered true dental pathogens or **odontopathogens.** These few odontopathogens are responsible for the most common bacterial diseases in humans: tooth decay and periodontal disease.

Dental Plaque

The human tooth has a natural defense mechanism against bacterial colonization that complements the protective role of saliva. The hard enamel surface selectively absorbs acidic glycoproteins (mucins)

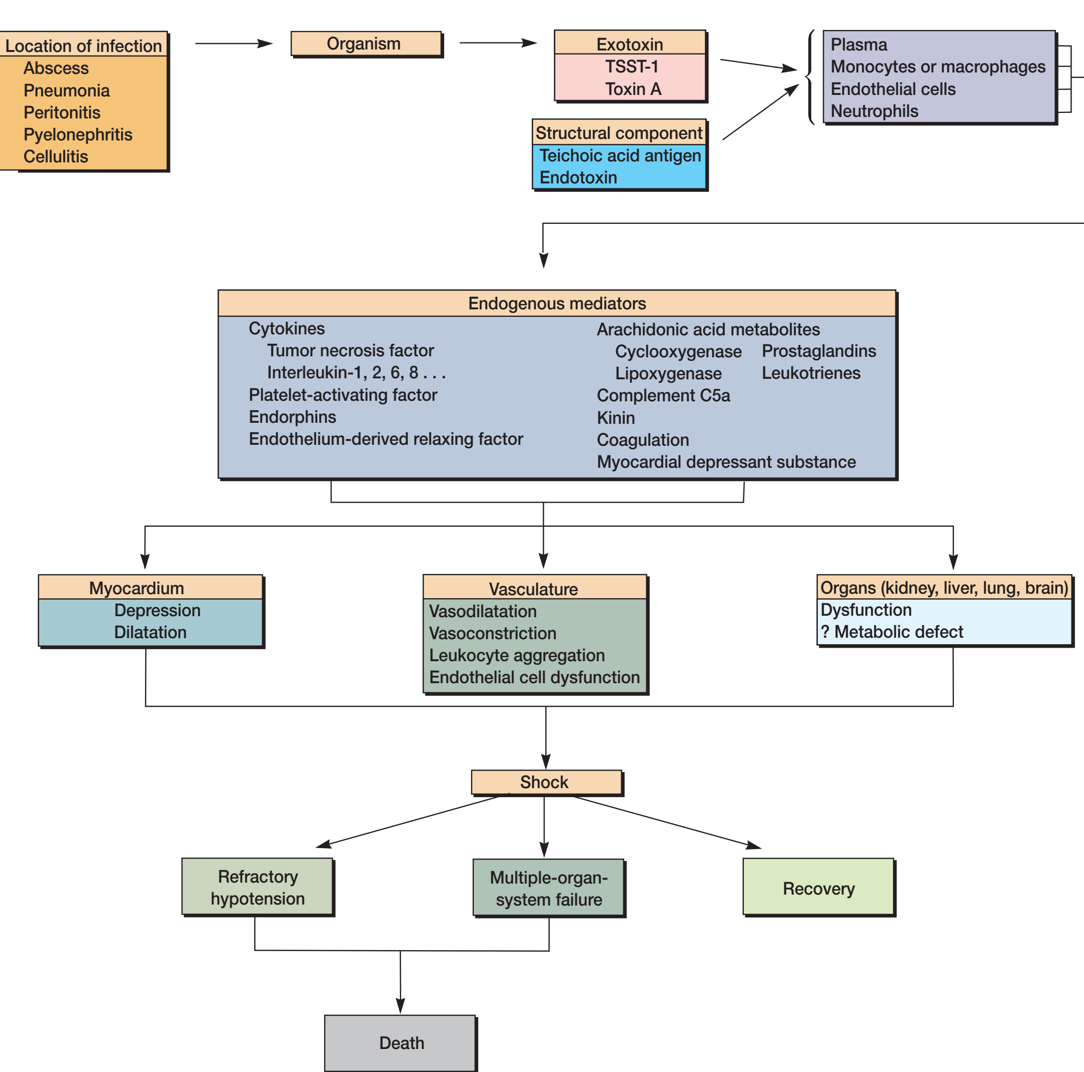

Figure 39.24 **The Septic Shock Cascade.** Microbial exotoxins (toxic shock syndrome toxin-1 [TSST-1], *Pseudomonas aeruginosa* toxin A [toxin A]) and structural components of the microorganism (teichoic acid antigen, endotoxin) trigger the biochemical events that lead to such serious complications as shock, adult respiratory distress syndrome, and disseminated intravascular coagulation.

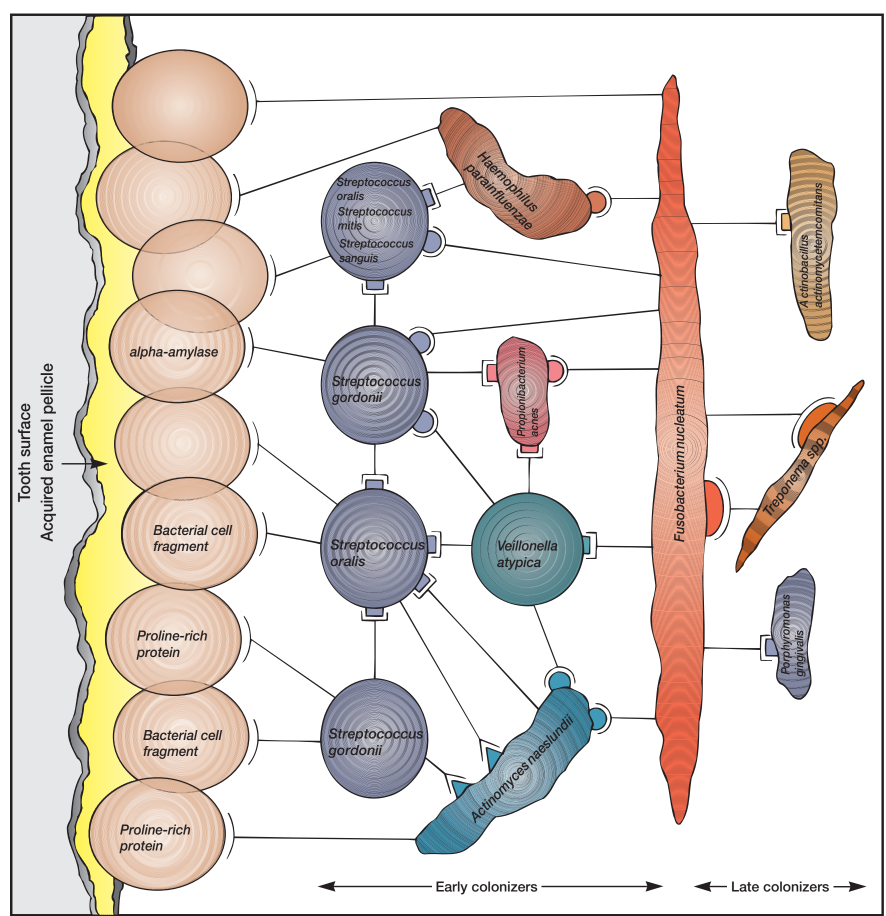
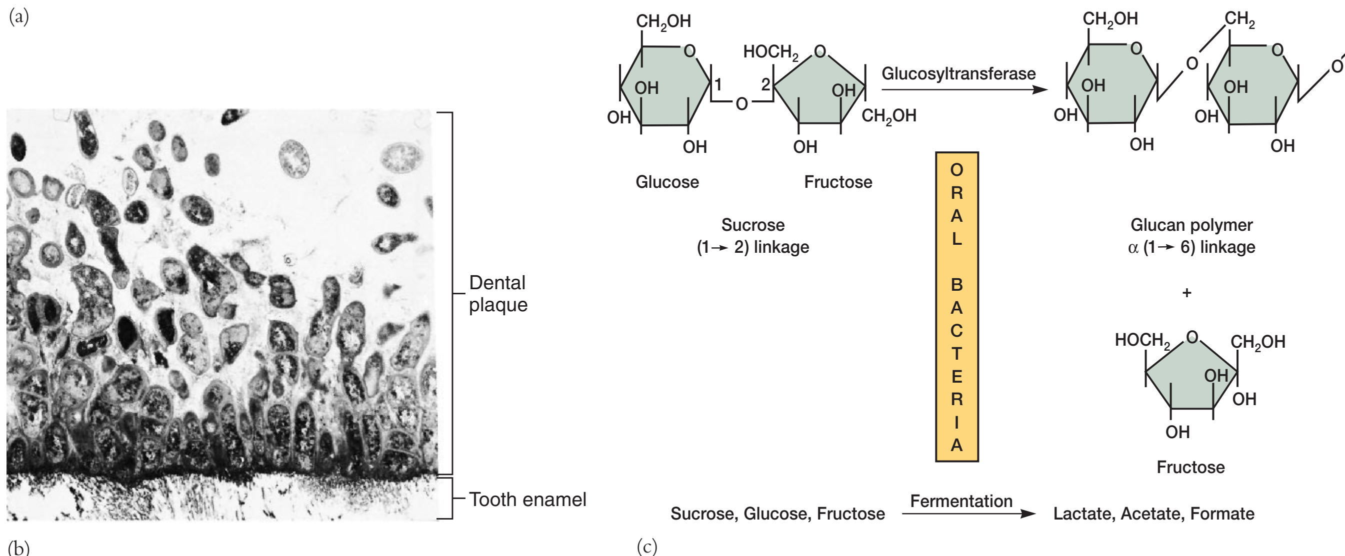
from saliva, forming a membranous layer called the **acquired enamel pellicle.** This pellicle, or organic covering, contains many sulfate (SO_4^{2-}) and carboxylate (—COO^-) groups that confer a net negative charge to the tooth surface. Because most bacteria also have a net negative charge, there is a natural repulsion between the tooth surface and bacteria in the oral cavity. Unfortunately this natural defense mechanism breaks down when dental plaque formation occurs.

Dental plaque formation begins with the initial colonization of the pellicle by *Streptococcus gordonii, S. oralis,* and *S. mitis.* These bacteria selectively adhere to the pellicle by specific ionic, hydrophobic, and lectinlike interactions. Once the tooth surface is colonized, subsequent attachment of other bacteria results from a variety of specific coaggregation reactions (**figure 39.25*a,b***). **Coaggregation** is the result of cell-to-cell recognition between genetically distinct bacteria. Many of these interactions are mediated by a lectin on one bacterium that interacts with a complementary carbohydrate receptor on the other bacterium. The most important species at this stage are *Actinomyces viscosus, A. naeslundii,* and *S. gordonii.* After these species colonize the pellicle, a microenvironment is created that allows *Streptococcus mutans* and *S. sobrinus* to become established on the tooth surface by attaching to these initial colonizers. Biofilms (pp. 620–22)

These streptococci produce extracellular enzymes (glucosyltransferases) that polymerize the glucose moiety of sucrose into a



(a)



(b)

(c)

Figure 39.25 The Formation of Dental Plaque on a Freshly Cleaned Tooth Surface. (**a**) Diagrammatic representation of the proposed temporal relationship of bacterial accumulation and multigeneric coaggregation during the formation of dental plaque on the acquired enamel pellicle. Early colonizers of the tooth surface coaggregate with each other, and late colonizers of the tooth surface coaggregate with each other. With a few exceptions, early colonizers do not recognize late colonizers. After the tooth surface is covered with the earliest colonizers, each newly added bacterium becomes a new surface for recognition by unattached bacteria. (**b**) Dental plaque consisting of bacteria plus polysaccharides such as glucan is shown attached to the enamel surface of a tooth; transmission electron micrograph (×13,600). (**c**) The enzyme glucosyltransferase or dextransucrase (produced by the oral bacteria) cause the assembly of glucose units from sucrose into glucans, and fructose is released. Sucrose, glucose, and fructose molecules also are metabolized by the oral bacteria to produce lactate and other acids. Lactate is responsible for dental caries.

heterogeneous group of extracellular water-soluble and water-insoluble glucan polymers and other polysaccharides. The fructose by-product can be used in fermentation. **Glucans** are branched-chain polysaccharides composed of glucose units; many glucans synthesized by oral streptococci have glucoses held together by $\alpha(1\rightarrow6)$ and $\alpha(1\rightarrow3)$ linkages (figure 39.25*c*). They act like a cement to bind bacterial cells together, forming a plaque ecosystem. (Dental plaque is one of the most dense collections of bacteria in the body—and perhaps the source of the first human microorganisms to be seen under a microscope by Anton van Leeuwenhoek in the seventeenth century.) Once plaque becomes established, a low oxidation reduction potential is created on the surface of the tooth. This leads to the growth of strict anaerobic bacteria (*Bacteroides melaninogenicus, B. oralis,* and *Veillonella alcalescens*), especially between opposing teeth and the dental-gingival crevices.

After the microbial plaque ecosystem develops, bacteria produce lactic and possibly acetic and formic acids from sucrose and other sugars. Because plaque is not permeable to saliva, the acids are not diluted or neutralized, and they demineralize the enamel to produce a lesion on the tooth. It is this chemical lesion that initiates dental decay.

Dental Decay (Caries)

As described previously, a histologically undetectable chemical lesion caused by the diffusion into the tooth's enamel of undissociated fermentation acids initiates the decay process. Once these acids move below the enamel surface, they dissociate and react with the hydroxyapatite of the enamel to form soluble calcium and phosphate ions. As the ions diffuse outward, some reprecipitate as calcium phosphate salts in the tooth's surface layer to create a histologically sound outer layer overlying a porous subsurface area. Between meals and snacks, the pH returns to neutrality and some calcium phosphate reenters the lesion and crystallizes. The result is a demineralization-remineralization cycle.

When fermentable foods high in sucrose are eaten for prolonged periods, acid production overwhelms the repair process and demineralization is greater than remineralization. This leads to dental decay or **caries** [Latin, rottenness]. Once the hard enamel has been breached, bacteria can invade the dentin and pulp of the tooth and cause its death.

No drugs are available to prevent dental caries. The main strategies for prevention include minimal ingestion of sucrose; daily brushing, flossing, and mouthwashes; and professional cleaning at least twice a year to remove plaque. The use of fluorides in toothpaste, drinking water, mouthwashes, or professionally applied to the teeth protects against lactic and acetic acids and reduces tooth decay.

Periodontal Disease

Periodontal disease refers to a diverse group of diseases that affect the periodontium. The **periodontium** is the supporting structure of a tooth and includes the cementum, the periodontal membrane, the bones of the jaw, and the gingivae (gums). The gingiva is dense fibrous tissue and its overlying mucous membrane, that surrounds the necks of the teeth. The gingiva helps hold the teeth in place. Disease is initiated by the formation of **subgingival plaque,** the plaque that forms at the dentogingival margin and extends down into the gingival tissue. Colonization of the subgingival region is aided by the ability of *Porphyromonas gingivalis* to adhere to substrates such as adsorbed salivary molecules, matrix proteins, epithelial cells, and bacteria in biofilms on teeth and epithelial surfaces. Binding to these substrates is mediated by *P. gingivalis* fimbrillin, the structural subunit of the major fimbriae. *P. gingivalis* does not use sugars as an energy source, but requires hemin as a source of iron and peptides for energy and growth. The bacterium produces at least three hemagglutinins and five proteases to satisfy these requirements. It is the proteases that are responsible for the breakdown of the gingival tissue. The result is an initial inflammatory reaction known as **periodontitis,** which is caused by the host's immune response to both the plaque bacteria and the tissue destruction. This leads to swelling of the tissue and the formation of periodontal pockets. Bacteria colonize these pockets and cause more inflammation, which leads to the formation of a periodontal abscess, bone destruction or **periodontosis,** inflammation of the gingiva or **gingivitis,** and general tissue necrosis (**figure 39.26**). If the condition is not treated, the tooth may fall out of its socket.

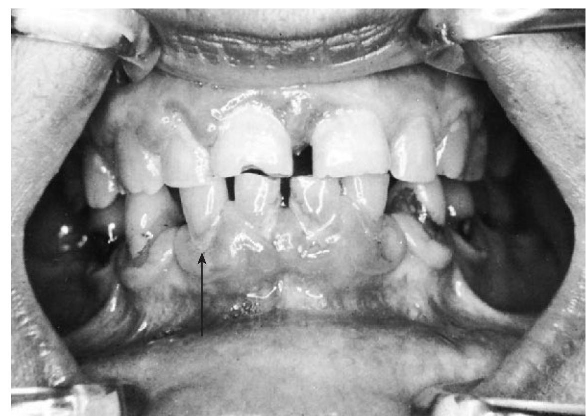


Figure 39.26 Periodontal Disease. Notice the plaque on the teeth (arrow), especially at the gingival (gum) margins, and the inflamed gingiva.

Periodontal disease can be controlled by frequent plaque removal; by brushing, flossing, and mouthwashes; and at times, by oral surgery of the gums and antibiotics.

1. Name some common odontopathogens that are responsible for dental caries, dental plaque, and periodontal disease. Be specific.
2. What is the function of the acquired enamel pellicle?
3. How does plaque formation occur? Dental decay?
4. Describe some pathological manifestations of periodontal disease.
5. How can caries and periodontal diseases be prevented?

Summary

1. Although only a small percentage of all bacteria are responsible for human illness, the suffering and death they cause are significant. Each year, millions of people are infected by pathogenic bacteria using the four major modes of transmission: airborne, arthropod-borne, direct contact, and food-borne and waterborne.
2. As the fields of microbiology, immunology, pathology, pharmacology, and epidemiology have expanded current understanding of the disease process, the incidence of many human illnesses has decreased. Many bacterial infections, once the leading cause of death, have been successfully brought under control in most developed countries. Alternatively, several are increasing in incidence throughout the world.
3. The bacteria emphasized in this chapter and the diseases they cause are as follows:
   a. Airborne diseases
      diphtheria (*Corynebacterium diphtheriae*) (**figure 39.1**)
      Legionnaires' disease and Pontiac fever (*Legionella pneumophila*)
      meningitis (*Haemophilus influenzae* type b, *Neisseria meningitidis,* and *Streptococcus pneumoniae*)
      M. avium–M. intracellulare pneumonia
      Streptococcal diseases (*Streptococcus pyogenes*) (**figure 39.3**)
      tuberculosis (*Mycobacterium tuberculosis*) (**figure 39.7**)
      pertussis (*Bordetella pertussis*)
   b. Arthropod-borne diseases
      ehrlichiosis (*Ehrlichia chaffeensis*)
      epidemic (louse-borne) typhus (*Rickettsia prowazekii*)
      endemic (murine) typhus (*Rickettsia typhi*)
      Lyme disease (*Borrelia burgdorferi*)
      plague (*Yersinia pestis*) (**figure 39.9**)
      Q fever (*Coxiella burnetii*)
      Rocky Mountain spotted fever (*Rickettsia rickettsii*)
   c. Direct contact diseases
      anthrax (*Bacillus anthracis*)
      bacterial vaginosis (*Gardnerella vaginalis*)
      cat-scratch disease (*Bartonella henselae*)
      chancroid (*Haemophilus ducreyi*)
      chlamydial pneumonia (*Chlamydia pneumoniae*)
      gas gangrene or clostridial myonecrosis (*Clostridium perfringens*)
      genitourinary mycoplasmal diseases (*Ureaplasma urealyticum, Mycoplasma hominis*)
      gonorrhea (*Neisseria gonorrhoeae*)
      inclusion conjunctivitis (*Chlamydia trachomatis*)
      leprosy (*Mycobacterium leprae*)
      lymphogranuloma venereum (*Chlamydia trachomatis*)
      mycoplasmal pneumonia (*Mycoplasma pneumoniae*)
      nongonococcal urethritis (various microorganisms)
      peptic ulcer disease (*Helicobacter pylori*)
      psittacosis (ornithosis) (*Chlamydia psittaci*)
      staphylococcal diseases (*Staphylococcus aureus*) (**figure 39.18**)
      syphilis (*Treponema pallidum*)
      tetanus (*Clostridium tetani*)
      trachoma (*Chlamydia trachomatis*)
      tularemia (*Francisella tularensis*)
   d. Food-borne and waterborne diseases
      cholera (*Vibrio cholerae*)
      botulism (*Clostridium botulinum*)
      gastroenteritis (*Campylobacter jejuni* and other bacteria)
      salmonellosis (*Salmonella* serovar *typhimurium*)
      shigellosis (*Shigella* spp.)
      staphylococcal food poisoning (*Staphylococcus aureus*)
      traveler's diarrhea (*Escherichia coli*)
      typhoid fever (*Salmonella typhi*)
4. Gram-positive bacteria, fungi, and endotoxin-containing gram-negative bacteria can initiate the pathogenic cascade of sepsis leading to septic shock (**figure 39.24**). Gram-negative sepsis is most commonly caused by *E. coli,* followed by *Klebsiella* spp., *Enterobacter* spp., and *Pseudomonas aeruginosa.*
5. Dental plaque formation begins on a tooth with the initial colonization of the acquired enamel pellicle by *Streptococcus gordonii, S. oralis,* and *S. mitis.* Other bacteria then become attached and form a plaque ecosystem (**figure 39.25**). The bacteria produce acids that cause a chemical lesion on the tooth and initiate dental decay or caries. Periodontal disease is a group of diverse clinical entities that affect the periodontium. Disease is initiated by the formation of subgingival plaque, which leads to tissue inflammation known as periodontitis and to periodontal pockets. Bacteria that colonize these pockets can cause an abscess, periodontosis, gingivitis, and general tissue necrosis.

vasculitis *909*
venereal syphilis *923*
Weil-Felix reaction *910*

Questions for Thought and Review

1. Briefly describe each of the major or most common bacterial diseases in terms of its causative agent, signs and symptoms, the course of infection, mechanism of pathogenesis, epidemiology, and prevention and/or treatment.
2. Because there are many etiologies of gastroenteritis, how is a definitive diagnosis usually made?
3. Differentiate between the following factors of bacterial intoxication and infection: etiologic agents, onset, duration, symptoms, and treatment.
4. How would you differentiate between salmonellosis and botulism?
5. Why do urinary tract infections frequently occur after catheterization procedures?
6. Why is botulism the most serious form of bacterial food poisoning?
7. Why is tuberculosis still a problem in underdeveloped countries? In the United States?
8. What is the standard treatment for most bacterial diarrheas?
9. Why are most cases of gastroenteritis not treated with antibiotics?
10. How are tetanus, gas gangrene, and botulism related?
11. Give several reasons why treatment of tuberculosis is so difficult.
12. Describe the various bacteria that cause food poisoning and give each one's most probable source.
13. Explain why Lyme disease is receiving increased attention in the United States.
14. Why is septic shock caused by gram-negative sepsis increasing in prevalence in the United States?
15. What is the major difference between trachoma and inclusion conjunctivitis?
16. Why is Rocky Mountain spotted fever the most important rickettsial disease in the United States?
17. As a group of diseases, what are some of the common characteristic symptoms and pathological results of rickettsial disease?
18. Why is it difficult to definitely isolate the microorganism responsible for nongonococcal urethritis?
19. Why are dental diseases relatively new infectious diseases of humans?
20. What makes Q fever a unique rickettsial disease?
21. What specific chlamydial and mycoplasmal diseases are transmitted sexually?

Critical Thinking Questions

1. Why is tetanus a concern only when one has a deep puncture-type wound and not a surface cut or abrasion?
2. Think about our modern, Western lifestyles. Can you name and describe bacterial diseases that result from this life of relative luxury? Refer to *Infections of Leisure,* second edition, edited by David Schlossberg (1999), published by the American Society for Microbiology Press.
3. You have been assigned the task of eradicating gonorrhea in your community. Explain how you would accomplish this.
4. You are a park employee. How would you prevent people from acquiring arthropod-borne diseases?

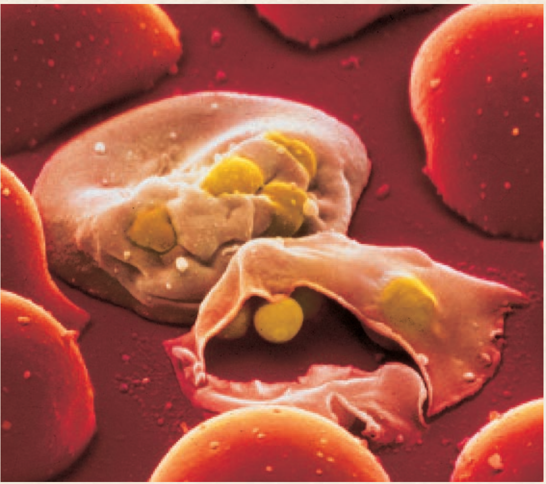
CHAPTER 40

Human Diseases Caused by Fungi and Protozoa



This photograph shows malaria parasites (yellow) bursting out of red blood cells. Malaria is one of the worst scourges of humanity. Indeed, malaria has played an important part in the rise and fall of nations (see the chapter opening quote), and has killed untold millions the world over. Despite the combined efforts of 102 countries to eradicate malaria, it remains the most important disease in the world today in terms of lives lost and economic burden.

Outline

40.1 Fungal Diseases 942
- Superficial Mycoses 942
- Cutaneous Mycoses 943
- Subcutaneous Mycoses 945
- Systemic Mycoses 945
- Opportunistic Mycoses 948

40.2 Protozoan Diseases 950
- Amebiasis 950
- Cryptosporidiosis 952
- Freshwater Amoeba Diseases 953
- Giardiasis 953
- Malaria 954
- Hemoflagellate Diseases 956
- Toxoplasmosis 957
- Trichomoniasis 958

Concepts

1. Fungal diseases (mycoses) are usually divided into five groups according to the level of infected tissue and mode of entry into the host: (1) superficial, (2) cutaneous, (3) subcutaneous, (4) systemic, and (5) opportunistic infections.
2. The superficial mycoses occur mainly in the tropics and include black piedra, white piedra, and tinea versicolor.
3. The cutaneous mycoses—that is, those of the outer layer of the skin—are generally called ringworms, tineas, or dermatomycoses. These diseases occur worldwide and represent the most common fungal diseases in humans.
4. The dermatophytes that cause the subcutaneous—below the skin—mycoses are normal saprophytic inhabitants of the soil. They must be introduced into the body beneath the cutaneous layer. Examples of these diseases include chromomycosis, maduromycosis, and sporotrichosis.
5. The systemic mycoses are the most serious of the fungal infections in the normal host because the responsible fungi can disseminate throughout the body. Examples include blastomycosis, coccidioidomycosis, cryptococcosis, and histoplasmosis.
6. The opportunistic mycoses can create life-threatening situations in the compromised host. Examples of these diseases include aspergillosis, candidiasis, and *Pneumocystis carinii* pneumonia.

Concepts *(Continued)*

7. About 20 different protozoa cause human diseases that afflict hundreds of millions of people throughout the world. Examples include amebiasis, cryptosporidiosis, giardiasis, malaria, the hemoflagellate diseases, toxoplasmosis, and trichomoniasis.
8. Certain fungal and protozoan diseases are increasing in incidence because of organ transplants, immunosuppressive drugs, and AIDS.

Historians believe that malaria has probably had a greater impact on world history than any other infectious disease, influencing the outcome of wars, various population movements, and the development and decline of various civilizations.

—*Lynne S. Garcia*

The purpose of this chapter is to describe some of the fungal and protozoan microorganisms that are pathogenic to humans and to discuss the clinical manifestations, diagnosis, epidemiology, pathogenesis, and treatment of the diseases caused by them.

Besides the viruses and bacteria, two other major groups of microorganisms cause infectious diseases in humans: fungi and protozoa. The biology of these organisms is covered in chapters 25 and 27, respectively. This chapter emphasizes the diseases they cause.

40.1 Fungal Diseases

Although hundreds of thousands of fungal species are found in the environment, only about 50 can produce disease in humans. **Medical mycology** is the discipline that deals with the fungi that causes human disease. These fungal diseases, known as **mycoses** [s., mycosis; Greek *mykes,* fungus], are divided into five groups according to the type of infected tissue in the host: superficial, cutaneous, subcutaneous, systemic, and opportunistic mycoses (**tables 40.1** and **40.2**). It should be noted that the importance of opportunistic fungal pathogens is increasing because of the expansion of the immunocompromised patient population.

Superficial Mycoses

The superficial mycoses are extremely rare in the United States, and most occur in the tropics. The fungi responsible are limited to the outer surface of hair and skin and hence are called superficial. Infections of the hair shaft are collectively

Table 40.1 Examples of Some Medically Important Fungi

Group	Pathogen	Location	Disease
Superficial mycoses	*Piedraia hortae*	Scalp	Black piedra
	Trichosporon beigelii	Beard, mustache	White piedra
	Malassezia furfur	Trunk, neck, face, arms	Tinea versicolor
Cutaneous mycoses	*Trichophyton mentagrophytes, T. verrucosum, T. rubrum*	Beard hair	Tinea barbae
	Trichophyton, Microsporum canis	Scalp hair	Tinea capitis
	Trichophyton rubrum, T. mentagrophytes, Microsporum canis	Smooth or bare parts of the skin	Tinea corporis
	Epidermophyton floccosum, T. mentagrophytes, T. rubrum	Groin, buttocks	Tinea cruris (jock itch)
	T. rubrum, T. mentagrophytes, E. floccosum	Feet	Tinea pedis (athlete's foot)
	T. rubrum, T. mentagrophytes, E. floccosum	Nails	Tinea unguium (onychomycosis)
Subcutaneous mycoses	*Phialophora verrucosa, Fonsecaea pedrosoi*	Legs, feet	Chromoblastomycosis
	Madurella mycetomatis	Feet, other areas of body	Maduromycosis
	Sporothrix schenckii	Puncture wounds	Sporotrichosis
Systemic mycoses	*Blastomyces dermatitidis*	Lungs, skin	Blastomycosis
	Coccidioides immitis	Lungs, other parts of body	Coccidioidomycosis
	Cryptococcus neoformans	Lungs, skin, bones, viscera, central nervous system	Cryptococcosis
	Histoplasma capsulatum	Within phagocytes	Histoplasmosis
Opportunistic mycoses	*Aspergillus fumigatus, A. flavus*	Respiratory system	Aspergillosis
	Candida albicans	Skin or mucous membranes	Candidiasis
	Pneumocystis carinii	Lungs, sometimes brain	Pneumocystis pneumonia

Table 40.2 Examples of Some Human Fungal Diseases Recognized Since 1973

Year	Fungus	Disease
	Molds	
1974	*Phialophora parasitica*	Phaeohyphomycosis
1992	*Penicillium marneffei*	Disseminated infection
	Yeasts	
1989	*Candida lusitaniae*	Fungemia
1989	*Malassezia furfur*	Fungemia
1990	*Rhodotorula rubra*	Fungemia
1991	*Candida ciferrii*	Fungemia
1993	*Hansenula anomala*	Fungemia
1993	*Trichosporon beigelii*	Fungemia

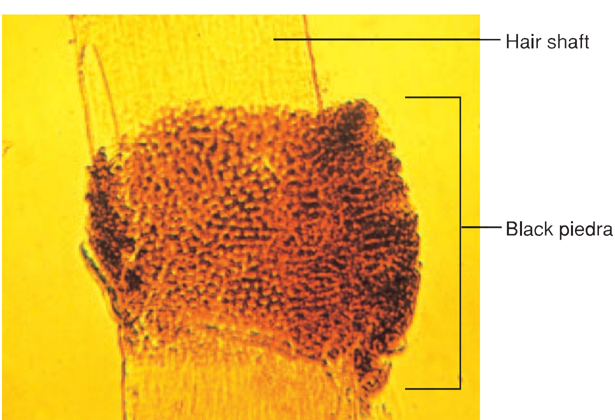


Figure 40.1 Superficial Mycosis: Black Piedra. Hair shaft infected with *Piedraia hortae;* light micrograph (×200).

called **piedras** (Spanish for stone because they are associated with the hard nodules formed by mycelia [*see figure 25.4*] on the hair shaft). For example, **black piedra** is caused by *Piedraia hortae* and forms hard black nodules on the hairs of the scalp (**figure 40.1**). **White piedra** is caused by the yeast *Trichosporon beigelii* and forms light-colored nodules on the beard and mustache. Some superficial mycoses are called **tineas** [Latin for grub, larva, worm], the specific type being designated by a modifying term. Tineas are superficial fungal infections involving the outer layers of the skin, nails, and hair. **Tinea versicolor** is caused by the yeast *Malassezia furfur* and forms brownish-red scales on the skin of the trunk, neck, face, and arms. Treatment involves removal of the skin scales with a cleansing agent and removal of the infected hairs. Good personal hygiene prevents these infections.

Cutaneous Mycoses

Cutaneous mycoses—also called **dermatomycoses, ringworms,** or tineas—occur worldwide and represent the most common fungal diseases in humans. Three genera of cutaneous fungi, or **dermatophytes,** are involved in these mycoses: *Epidermophyton, Microsporum,* and *Trichophyton*. Diagnosis is by microscopic examination of biopsied areas of the skin cleared with 10% potassium hydroxide and by culture on Sabouraud dextrose agar. Treatment is with topical ointments such as miconazole (Monistat-Derm), tolnaftate (Tinactin), or clotrimazole (Lotrimin) for 2 to 4 weeks. Griseofulvin (Grifulvin V) and itraconazole (Sporanox) are the only oral fungal agents currently approved by the FDA for treating dermatophytoses. The mode of action of ketoconazole, miconazole, tolnaftate, and griseofulvin (p. 820)

Tinea barbae [Latin *barba,* the beard] is an infection of the beard hair (**figure 40.2**) caused by *Trichophyton mentagrophytes* or *T. verrucosum.* It is predominantly a disease of men who live in rural areas and acquire the fungus from infected animals.

Tinea capitis [Latin *capita,* the head] is an infection of the scalp hair (**figure 40.3*a***). It is characterized by loss of hair, inflammation, and scaling. Tinea capitis is primarily a childhood disease caused by *Trichophyton* or *Microsporum* species. Person-to-person transmission of the fungus occurs frequently when poor hygiene and overcrowded conditions exist. The fungus also occurs in domestic animals, from whom it can be transmitted to humans. A Wood's light (a UV light) can help with the diagnosis of tinea capitis because fungus-infected hair fluoresces when illuminated by UV radiation (figure 40.3*b*).

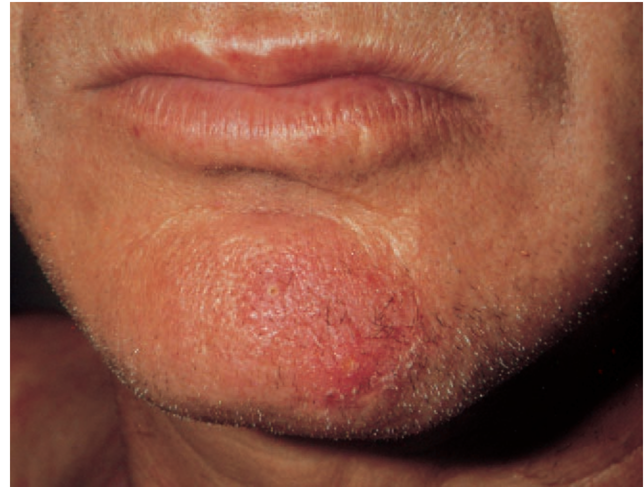

Figure 40.2 Cutaneous Mycosis: Tinea Barbae. Ringworm of the beard caused by *Trichophyton mentagrophytes.*

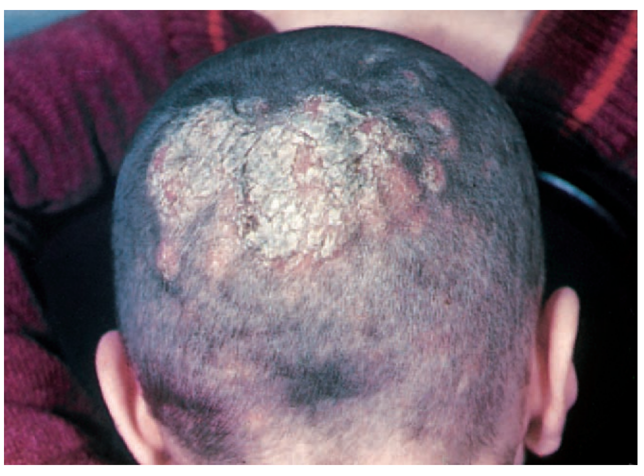
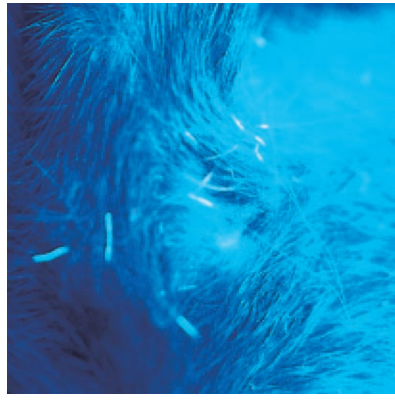
Tinea corporis [Latin *corpus,* the body] is a dermatophytic infection of the smooth or bare parts of the skin (**figure 40.4**). The disease is characterized by circular, red, well-demarcated, scaly, vesiculopustular lesions accompanied by itching. Tinea corporis is caused by *Trichophyton rubrum, T. mentagrophytes,* or *Microsporum canis.*



(a)



(b)

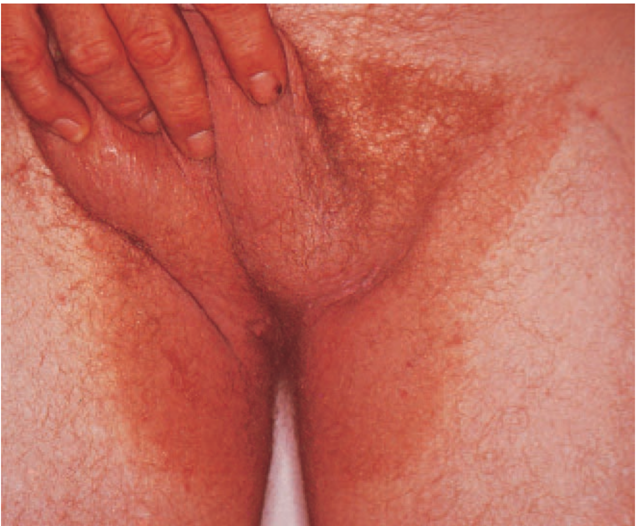

Figure 40.5 Cutaneous Mycosis: Tinea Cruris. Ringworm of the groin caused by *Epidermophyton floccosum.*

Transmission of the disease is by direct contact with infected animals (*see figure 25.1*b) or humans or by indirect contact through fomites.

Tinea cruris [Latin *crura,* the leg] is a dermatophytic infection of the groin (**figure 40.5**). The pathogenesis and clinical manifestations are similar to those of tinea corporis. The responsible fungi are *Epidermophyton floccosum, T. mentagrophytes,* or *T. rubrum.* Factors predisposing one to recurrent disease are moisture, occlusion, and skin trauma. Wet bathing suits, athletic supporters (**jock itch**), tight-fitting slacks, panty hose, and obesity are frequently contributing factors.

Tinea pedis [Latin *pes,* the foot], also known as **athlete's foot,** and **tinea manuum** [Latin *mannus,* the hand] are dermatophytic infections of the feet (**figure 40.6**) and hands, respectively. Clinical symptoms vary from a fine scale to a vesiculopustular eruption. Itching is frequently present. Warmth, humidity, trauma, and occlusion increase susceptibility to infection. Most infections are caused by *T. rubrum, T. mentagrophytes,* or *E. floccosum.* Tinea pedis and tinea manuum occur throughout the world, are most commonly found in adults, and increase in frequency with age.

Tinea unguium [Latin *unguis,* nail] is a dermatophytic infection of the nail bed (**figure 40.7**). In this disease the nail becomes discolored and then thickens. The nail plate rises and separates from the nail bed. *Trichophyton rubrum* or *T. mentagrophytes* are the causative fungi.

Subcutaneous Mycoses

The dermatophytes that cause subcutaneous mycoses are normal saprophytic inhabitants of soil and decaying vegetation. Because they are unable to penetrate the skin, they must be introduced into the subcutaneous tissue by a puncture wound that has been contaminated with soil containing the fungi. Most infections involve barefooted agricultural workers. Once in the subcutaneous tissue, the disease develops slowly—often over a period of years. During this time the fungi produce a nodule that eventually ulcerates and the organisms spread along lymphatic channels producing more subcutaneous nodules. At times such nodules drain to the skin surface. The administration of oral 5-fluorocytosine, iodides, amphotericin B, and surgical excision are the usual treatments. Diagnosis is accomplished by culture of the infected tissue. The mode of action of amphotericin B (p. 820)

One type of subcutaneous mycosis is **chromoblastomycosis.** The nodules are pigmented a dark brown. This disease is caused by the black molds *Phialophora verrucosa* or *Fonsecaea pedrosoi.* These fungi exist worldwide, especially in tropical and subtropical regions. Most infections involve the legs and feet (**figure 40.8**).

Another subcutaneous mycosis is **maduromycosis,** caused by *Madurella mycetomatis,* which is distributed worldwide and is especially prevalent in the tropics. Because the fungus destroys subcutaneous tissue and produces serious deformities, the resulting infection is often called a **eumycotic mycetoma** or fungal tumor (**figure 40.9**). One form of mycetoma, known as Madura foot, occurs through skin abrasions acquired while walking barefoot on contaminated soil.

Sporotrichosis is the subcutaneous mycosis caused by the dimorphic (*see table 25.2*) fungus *Sporothrix schenckii.* The disease occurs throughout the world and is the most common subcutaneous mycotic disease in the United States. The fungus can be found in the soil, on living plants, such as barberry shrubs and roses, or in plant debris, such as sphagnum moss and pine-bark mulch. Infection occurs by a puncture wound from a thorn or splinter contaminated with the fungus. The disease is an occupational hazard to florists, gardeners, and forestry workers. After an incubation period of 1 to 12 weeks, a small red papule arises and begins to ulcerate (**figure 40.10**). New lesions appear along lymph channels and can remain localized or spread throughout the body, producing **extracutaneous sporotrichosis.**

Systemic Mycoses

Except for *Cryptococcus neoformans,* which has only a yeast form, the fungi that cause the systemic or deep mycoses are dimorphic—that is, they exhibit a parasitic yeastlike phase (Y) and a saprophytic

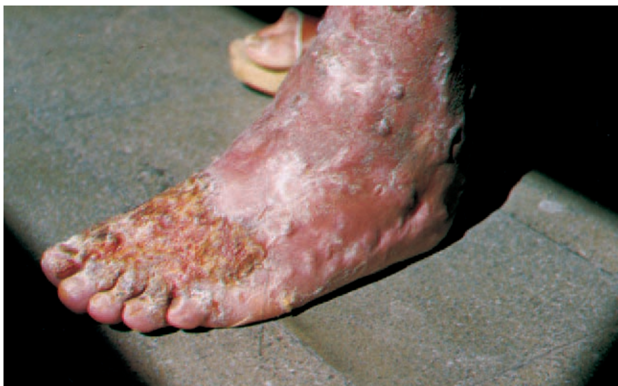

Figure 40.9 **Subcutaneous Mycosis.** Eumycotic mycetoma of the foot caused by *Madurella mycetomatis.*

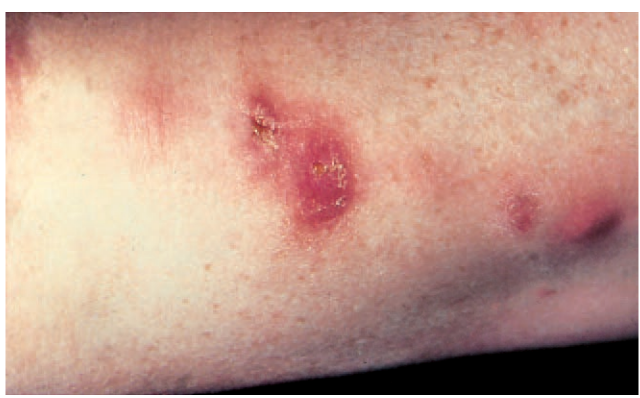

Figure 40.10 **Subcutaneous Mycosis.** Sporotrichosis of the arm caused by *Sporothrix schenckii.*

mold or mycelial phase (M). (*See the YM shift, section 25.3.*) Most systemic mycoses are acquired by the inhalation of spores from soil in which the mold-phase of the fungus resides. If a susceptible person inhales enough spores, an infection begins as a lung lesion, becomes chronic, and spreads through the bloodstream to other organs (the target organ varies with the species).

Blastomycosis is the systemic mycosis caused by *Blastomyces dermatitidis,* a fungus that grows as a budding yeast in humans but as a mold on culture media and in the environment. It is found predominately in the soil of the Mississippi and Ohio River basins. The disease occurs in three clinical forms: cutaneous, pulmonary, and disseminated. The initial infection begins when blastospores (*see figure 25.7*f) are inhaled into the lungs. The fungus can then spread rapidly, especially to the skin, where cutaneous ulcers and abscess formation occur (**figure 40.11**). *B. dermatitidis* can be isolated from pus and biopsy sections. Diagnosis requires the demonstration of thick-walled, yeastlike cells 8 to 15 μm in diameter. Complement-fixation, immunodiffusion, and skin (blastomycin) tests are also useful. Amphotericin B (Fungizone), itraconazole (Sporanox), or ketoconazole (Nizoral) are the drugs of choice for treatment. Surgery may be necessary for the drainage of large abscesses. Approximately 30 to 60 deaths are reported each year in the United States. There are no preventive or control measures.

Coccidioidomycosis, also known as valley fever, San Joaquin fever, or desert rheumatism because of the geographical distribution of the fungus, is caused by *Coccidioides immitis. C. immitis* exists in the dry, highly alkaline soils of North, Central, and South America. It has been estimated that in the United States about 100,000 people are infected annually with 50 to 100 deaths. Endemic areas have been defined by massive skin testing with the antigen coccidioidin. In the soil and on culture media, this fungus grows as a mold that forms arthroconidia (*see figure 25.7*b) at the tips of hyphae. Arthroconidia are so abundant in these endemic areas that by simply moving through such an area, one can acquire the disease by inhaling them. Wind turbulence and even construction of outdoor structures have been associated with increased exposure and infection. In humans the fungus grows as a yeast-forming, thick-walled spherule filled with endospores (**figure 40.12**). Most cases of coccidioidomycosis are asymptomatic or indistinguishable from ordinary upper respiratory infections. Almost all cases resolve themselves in a few weeks, and a lasting immunity results. A few infections result in a progressive chronic pulmonary disease. The fungus also can spread throughout the body, involving almost any organ or site. Diagnosis is accomplished by aspiration and identification of the large spherules (approximately 80 μm in diameter) in pus, sputum, and aspirates. Culturing clinical samples in the presence of penicillin and streptomycin on Sabouraud agar also is diagnostic. Newer methods of rapid confirmation include the testing of supernatants of liquid media cultures for antigens, serology, and skin testing. Miconazole (Lotrimin), itraconazole, ketoconazole, and amphotericin B

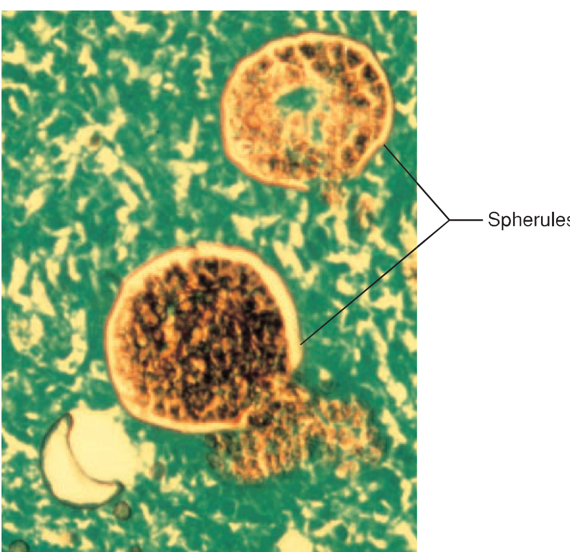

Figure 40.12 Systemic Mycosis: Coccidioidomycosis. *Coccidioides immitis* mature spherules filled with endospores within a tissue section; light micrograph (×400).

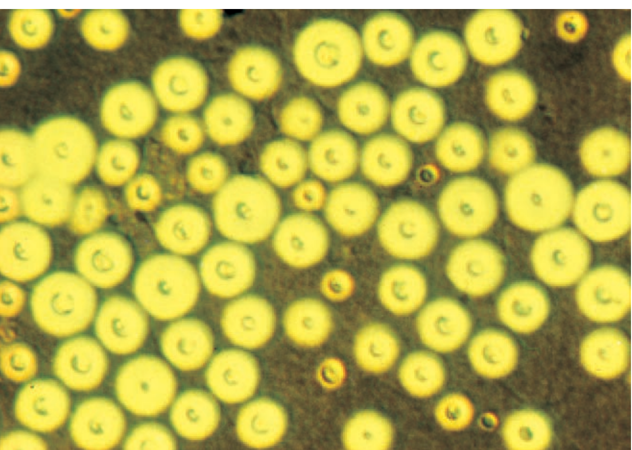

Figure 40.13 Systemic Mycosis: Cryptococcosis. are the drugs of choice for treatment. Prevention involves reducing exposure to dust (soil) in endemic areas.

Cryptococcosis is a systemic mycosis caused by *Cryptococcus neoformans.* This fungus always grows as a large budding yeast. In the environment *C. neoformans* is a saprophyte with a worldwide distribution. Aged, dried pigeon droppings are an apparent source of infection. Cryptococcosis is found in approximately 15% of AIDS patients. The fungus enters the body by the respiratory tract, causing a minor pulmonary infection that is usually transitory. Some pulmonary infections spread to the skin, bones, viscera, and central nervous system. Once the nervous system is involved, cryptococcal meningitis usually results. Diagnosis is accomplished by detection of the thick-walled spherical yeast cells (**figure 40.13**) in pus, sputum, or exudate smears using India ink to define the organism. The fungus can be easily cultured on Sabouraud dextrose agar. Identification of the fungus in body fluids is made by immunologic procedures. Treatment includes amphotericin B or itraconazole. There are no preventive or control measures.

Histoplasmosis is caused by *Histoplasma capsulatum* var. *capsulatum,* a facultative parasitic fungus that grows intracellularly. It appears as a small budding yeast in humans and on culture media at 37°C. At 25°C it grows as a mold, producing small microconidia (1 to 5 μm in diameter) that are borne singly at the tips of short conidiophores. Large macroconidia or chlamydospores (8 to 16 μm in diameter) are also formed on conidiophores (**figure 40.14*a***). In humans the yeastlike form grows within phagocytic cells (figure 40.14*b*). *H. capsulatum* var. *capsulatum* is found as the mycelial form in soils throughout the world and is localized in areas that have been contaminated with bird or bat excrement. The chlamydospores, particularly the microconidia, are easily spread by air currents. Within the United States, histoplasmosis is endemic within the Mississippi, Kentucky, Tennessee, Ohio, and Rio Grande River basins. More than 75% of the people who reside in parts of these areas have antibodies against the fungus. It has been estimated that in endemic areas of the United States, about 500,000 individuals are infected annually: 50,000 to 200,000 become ill; 3,000 require hospitalization; and about 50 die. The total number of infected individuals may be over 40 million in the United States alone. Histoplasmosis is an occupational disease among spelunkers (people who explore caves) and bat guano miners.

Humans acquire histoplasmosis from airborne microconidia that are produced under favorable environmental conditions. Microconidia are most prevalent where bird droppings, or guanos—especially from starlings, crows, blackbirds, cowbirds, sea gulls, turkeys, and chickens—have accumulated. It is noteworthy that the birds themselves are not infected because of their high body temperature; their droppings simply provide the nutrients for this fungus. Only bats and humans demonstrate the disease and harbor the fungus.

Histoplasmosis is a disease of the monocyte-macrophage system; thus many organs of the body can be infected (*see figure 31.4*). More than 95% of "histo" cases have either no symptoms or mild symptoms such as coughing, fever, and joint pain. Lesions may appear in the lungs and show calcification; most infections resolve on their own. Only rarely does the disease disseminate.

Laboratory diagnosis is accomplished by complement-fixation tests and isolation of the fungus from tissue specimens. Most individuals with this disease exhibit a hypersensitive state that can be demonstrated by the histoplasmin skin test. Currently

the most effective treatment is with amphotericin B, ketoconazole, or itraconazole. Prevention and control involve wearing protective clothing and masks before entering or working in infested habitats. Soil decontamination with 3 to 5% formalin is effective where economically and physically feasible.

Opportunistic Mycoses

An **opportunistic microorganism** is generally harmless in its normal environment but becomes pathogenic in a compromised host. A **compromised host** is seriously debilitated and has a lowered resistance to infection. There are many causes of this condition, among them the following: malnutrition; alcoholism; cancer, diabetes, leukemia, or another infectious disease; trauma from surgery or injury; an altered microbiota from the prolonged use of antibiotics (e.g., in vaginal candidiasis); and immunosuppression by drugs, viruses (HIV), hormones, genetic deficiencies, chemotherapy of patients, and old age. The most important opportunistic mycoses include systemic aspergillosis, candidiasis, and *Pneumocystis carinii* pneumonia.

Of all the fungi that cause disease in compromised hosts, none are as widely distributed as the *Aspergillus* species. *Aspergillus* is omnipresent in nature, being found wherever organic debris occurs. *Aspergillus fumigatus* is the usual cause of **aspergillosis.** *A. flavus* is the second most important species, particularly in invasive disease of immunosuppressed patients.

The major portal of entry for *Aspergillus* is the respiratory tract. Inhalation of conidiospores (*see figure 25.7*e) can lead to several types of pulmonary aspergillosis. One type is allergic aspergillosis. Infected individuals may develop an immediate allergic response and suffer typical asthmatic attacks when exposed to fungal antigens on the conidiospores. In bronchopulmonary aspergillosis the major clinical manifestation of the allergic response is a bronchitis resulting from both type I and type III hypersensitivities (*see figures 33.2* and *33.6*). Although tissue invasion seldom occurs in bronchopulmonary aspergillosis, *Aspergillus* often can be cultured from the sputum. A most common manifestation of pulmonary involvement is the occurrence of colonizing aspergillosis, in which *Aspergillus* forms colonies within the lungs that develop into "fungus balls" called aspergillomas. These consist of a tangled mass of mycelia growing in a circumscribed area. From the pulmonary focus, the fungus may spread, producing disseminated aspergillosis in a variety of tissues and organs (**figure 40.15**). In patients whose resistance has been severely compromised, invasive aspergillosis may occur and fill the lung with fungal mycelia.

Figure 40.16 Opportunistic Mycoses Caused by *Candida albicans.* (**a**) Scanning electron micrograph of the yeast form (×10,000). Notice that some of the cells are reproducing by budding. (**b**) Thrush, or oral candidiasis, is characterized by the formation of white patches on the mucous membranes of the tongue and elsewhere in the oropharyngeal area. These patches form a pseudomembrane composed of spherical yeast cells, leukocytes, and cellular debris. (**c**) Paronychia and onychomycosis of the hands.

Box 40.1

The Emergence of Candidiasis

Written descriptions of oral lesions that were probably thrush date back to the early 1800s. In 1839 Bernard Langenbeck in Germany described the organism he found in oral lesions of a patient as "Typhus-Leichen" (typhus bodies). By 1841 Emil Berg established the fungal etiology of thrush by infecting healthy babies with what he called "aphthous membrane material." In 1843 Charles Robin gave the organism its first name: *Oidium albicans.* Since then, more than 100 synonyms have been used for this fungus; of them all, *Candida albicans,* the name Roth Berkhout proposed in 1923, has persisted.

In 1861 Albert Zenker described the first well-documented case of systemic candidiasis. Historically, the most interesting period for candidiasis research coincided with the introduction of antibiotics. Since then there have been documented cases of this fungus involving all tissues and organs of the body, as well as an increase in the overall incidence of candidiasis. Some *Candida*-associated infections and diseases include arthritis, endophthalmitis, meningitis, myocarditis, myositis, and peritonitis. Besides the widespread use of antibiotics, other therapeutic and surgical procedures such as organ transplants and prostheses have been important in the expanding worldwide incidence of candidiasis.

Laboratory diagnosis of aspergillosis depends on identification, either by direct examination of pathological specimens or by isolation and characterization of the fungus. Successful therapy depends on treatment of the underlying disease so that host resistance increases. Treatment is with itraconazole.

Candidiasis is the mycosis caused by the dimorphic fungus *Candida albicans* (**figure 40.16*a***). In contrast to the other pathogenic fungi, C. *albicans* is a member of the normal microbiota within the gastrointestinal tract, respiratory tract, vaginal area, and mouth (*see figure 31.2*). In healthy individuals *C. albicans* does not produce disease. Growth is suppressed by other microbiota. However, if anything upsets the normal microbiota, *Candida* may multiply rapidly and produce candidiasis. Recently *Candida* species have become important nosocomial pathogens. In some hospitals they may represent almost 10% of nosocomial bloodstream infections. Because *Candida* can be transmitted sexually, it is also listed by the CDC as a sexually transmitted disease (*see table 39.4*).

No other mycotic pathogen produces as diverse a spectrum of disease in humans as does *C. albicans* (**Box 40.1**). Most infections involve the skin or mucous membranes. This occurs because *C. albicans* is a strict aerobe and finds such surfaces very suitable for growth. Cutaneous involvement usually occurs when the skin becomes overtly moist or damaged.

Oral candidiasis, or **thrush** (figure 40.16*b*), is a fairly common disease in newborns. It is seen as many small white flecks that cover the tongue and mouth. At birth, newborns do not have a normal microbiota in the oropharyngeal area. If the mother's vaginal area is heavily infected with *C. albicans,* the upper respiratory tract of the newborn becomes colonized during passage through the birth canal. Thrush occurs because growth of *C. albicans* cannot be inhibited by the other microbiota. Once the newborn has developed

its own normal oropharyngeal microbiota, thrush becomes uncommon. **Paronychia** and **onychomycosis** are associated with *Candida* infections of the subcutaneous tissues of the digits and nails, respectively (figure 40.16*c*). These infections usually result from continued immersion of the appendages in water.

Intertriginous candidiasis involves those areas of the body, usually opposed skin surfaces, that are warm and moist: axillae, groin, skin folds. **Napkin (diaper) candidiasis** is typically found in infants whose diapers are not changed frequently and therefore are not kept dry. **Candidal vaginitis** can result from diabetes, antibiotic therapy, oral contraceptives, pregnancy, or any other factor that compromises the female host. Normally the omnipresent lactobacilli (Döderlein's bacilli) can control *Candida* in this area by the low pH they create. However, if their numbers are decreased by any of the aforementioned factors, *Candida* may proliferate, causing a curdlike, yellow-white discharge from the vaginal area. *Candida* can be transmitted to males during intercourse and lead to **balanitis;** thus it also can be considered a sexually transmitted disease. Balanitis is a *Candida* infection of the male glans penis and occurs primarily in uncircumcised males. The disease begins as vesicles on the penis that develop into patches and are accompanied by severe itching and burning.

Diagnosis of candidiasis is difficult because (1) this fungus is a frequent secondary invader in diseased hosts, (2) a mixed microbiota is most often found in the diseased tissue, and (3) no completely specific immunologic procedures for the identification of *Candida* currently exist. There is no satisfactory treatment for candidiasis. Cutaneous lesions can be treated with topical agents such as sodium caprylate, sodium propionate, gentian violet, nystatin, miconazole, and trichomycin. Ketoconazole, amphotericin B, fluconazole, itraconazole, and flucytosine also can be used for systemic candidiasis.

Pneumocystis carinii are eucaryotic protists found in the lungs of a wide variety of mammals. The natural history of *P. carinii* is poorly understood, in large part because of a lack of a continuous in vitro culture system for its propagation. Although it was once considered a protozoan parasite, recent comparisons of rRNA and DNA sequences from several genes have shown that *P. carinii* is more closely related to fungi than protozoa.

The disease that this protist causes, **pneumocystis pneumonia** or ***Pneumocystis carinii* pneumonia (PCP),** occurs almost exclusively in immunocompromised hosts. Extensive use of immunosuppressive drugs and irradiation for the treatment of cancers and following organ transplants accounts for the formidable prevalence rates noted recently. This pneumonia also occurs in more than 80% of AIDS patients. Both the organism and the disease remain localized in the lungs—even in fatal cases. Within the lungs *Pneumocystis* causes the alveoli to fill with a frothy exudate.

Laboratory diagnosis of pneumocystis pneumonia can be made definitively only by microscopically demonstrating the presence of the microorganisms in infected lung material or by a PCR analysis. Treatment is by means of oxygen therapy and either a combination of trimethoprim (Bactrim) and sulfamethoxazole (Septra), atovaquone (Mepron), or trimetrexate (Neutrexin). Prevention and control is through prophylaxis with drugs in susceptible persons.

1. How are human fungal diseases categorized?

3. Briefly describe the major tineas that occur in humans.
4. Describe the three types of subcutaneous mycoses that affect humans.
5. Why is *Histoplasma capsulatum* found in bird feces but not within the birds themselves?
6. Why are some mycotic diseases of humans called opportunistic mycoses?
7. What parts of the human body can be affected by *Candida* infections?
8. When is *Pneumocystis carinii* pneumonia likely to occur in humans?

40.2 Protozoan Diseases

Protozoa have become adapted to practically every type of habitat on the face of the earth, including the human body. Though fewer than 20 genera of protozoa cause disease in humans (**tables 40.3** and **40.4**), their impact is formidable. For example, there are over 150 million cases of malaria in the world each year. In tropical Africa alone, malaria is responsible each year for the deaths of more than a million children under the age of 14. It is estimated that there are at least 8 million cases of trypanosomiasis, 12 million cases of leishmaniasis, and over 500 million cases of amebiasis yearly. There is an increasing problem with *Cryptosporidium* and *Cyclospora* contamination of food and water supplies. More of our population is elderly, and a growing number of persons are immunosuppressed due to the human immunodeficiency virus, organ transplantation, or cancer chemotherapy. These populations are at increased risk for protozoan infections. The remainder of this chapter discusses some of these important protozoan diseases of humans.

Amebiasis

It is now accepted that two species of *Entamoeba* infect humans: the nonpathogenic *E. dispar* and the pathogenic *E. histolytica. E. histolytica* is responsible for **amebiasis (amebic dysentery).** This very common parasite is endemic in warm climates where adequate sanitation and effective personal hygiene is lacking. Within the United States about 3,000 to 5,000 cases are reported annually. However, it is a major cause of parasitic death worldwide; about 500 million people are infected and as many as 100,000 die of amebiasis each year.

Infection occurs by ingestion of mature cysts. After excystation in the lower region of the small intestine, the metacyst di-

1998	*Brachiola vesicularum*	Myositis

vides rapidly to produce eight small trophozoites (**figure 40.17**). These trophozoites move to the large intestine where they can invade the host tissue, live as commensals in the lumen of the intestine, or undergo encystation.

If the infective trophozoites invade the intestinal tissues, they multiply rapidly and spread laterally, while feeding on erythrocytes, bacteria, and yeasts. The invading trophozoites destroy the epithelial lining of the large intestine by producing cysteine proteinases. Cysteine proteinases possibly are a virulence factor of *E. histolytica* and may play a role in intestinal invasion by degrading extracellular matrix and circumventing the host immune response through cleavage of secretory immunoglobulin A (sIgA), IgG, and complement factors. Cysteine proteinases are encoded by at least seven genes, several of which are found in *E. histolytica* but not *E. dispar*. Lesions (ulcers) are characterized by minute points of entry into the mucosa and extensive enlargement of the lesion after penetration into the submucosa. *E. histolytica* also may invade and produce lesions in extraintestinal foci, especially the liver, to cause hepatic amebiasis. However, all extraintestinal amebic lesions are secondary to the ones established in the large intestine.

The symptoms of amebiasis are highly variable, ranging from an asymptomatic infection to fulminating dysentery, exhaustive diarrhea accompanied by blood and mucus, appendicitis, and abscesses in the liver, lungs, or brain.

Laboratory diagnosis of amebiasis is based on finding trophozoites in fresh warm stools and cysts in ordinary stools. Serological testing also should be done. The therapy for amebiasis is complex and depends on the location of the infection within the host and the host's condition. Asymptomatic carriers that are passing cysts should always be treated with iodoquinol or paromomycin because they represent the most important reservoir of the parasite in the population. In symptomatic intestinal amebiasis, metronidazole (Flagyl) or iodoquinol (Yodoxin) are the drugs of choice. Prevention and control of amebiasis is achieved by avoiding water or food that might be contaminated with human feces in endemic areas. Viable cysts in water can be destroyed by hyperchlorination or iodination.

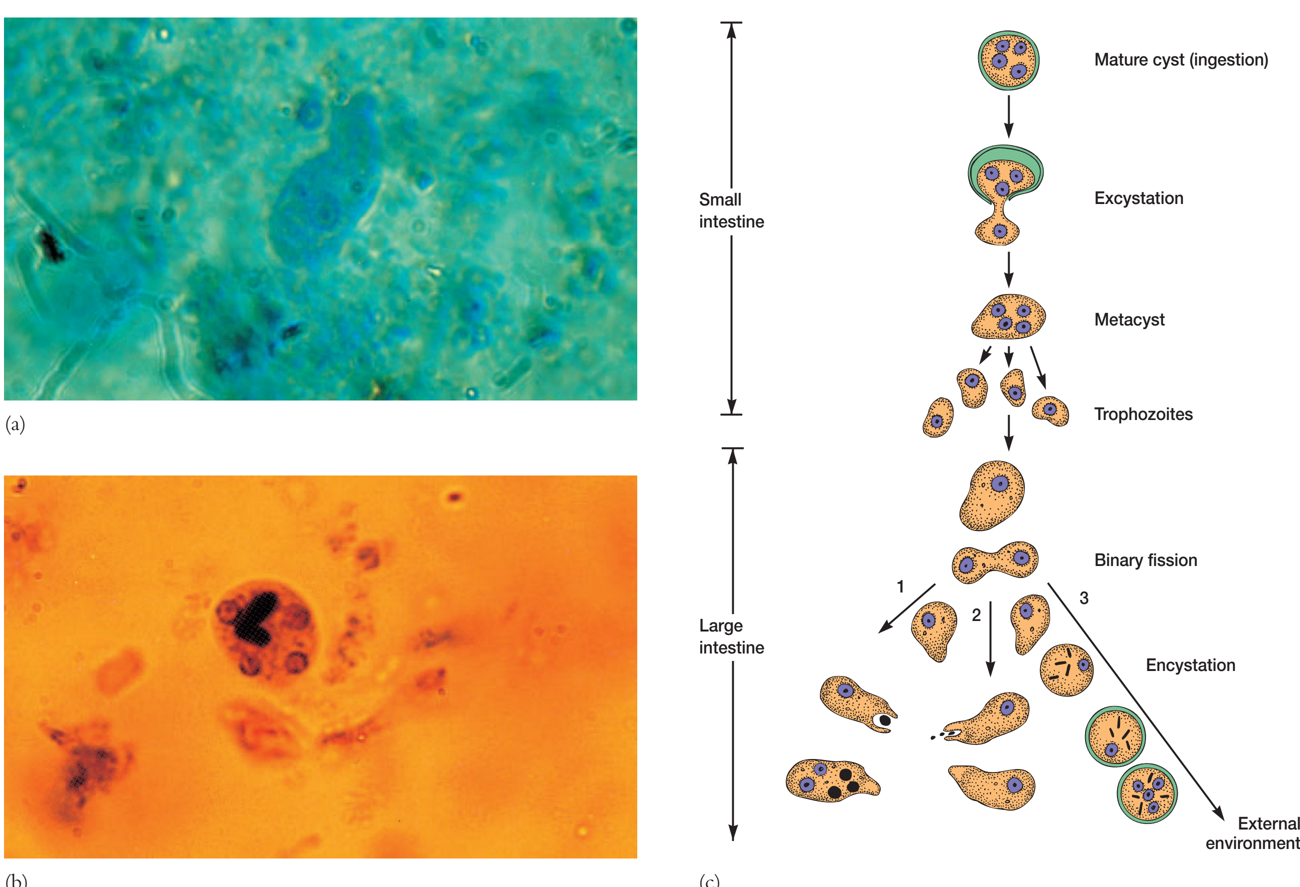

Figure 40.17 Amebiasis Caused by *Entamoeba histolytica*. (**a**) Light micrographs of a trophozoite (×1,000) and (**b**) a cyst (×1,000). (**c**) Life cycle. Infection occurs by the ingestion of a mature cyst of the parasite. Excystation occurs in the lower region of the small intestine and the metacyst rapidly divides to give rise to eight small trophozoites (only four are shown). These enter the large intestine, undergo binary fission, and may (1) invade the host tissues, (2) live in the lumen of the large intestine without invasion, or (3) undergo encystation and pass out of the host in the feces.

Cryptosporidiosis

The first case of human **cryptosporidiosis** was reported in 1976 (table 40.4). The protozoan responsible was identified as *Cryptosporidium parvum.* In 1993 *C. parvum* contaminated the Milwaukee, Wisconsin, water supply and caused severe diarrheal disease in about 400,000 individuals, the largest recognized outbreak of waterborne illness in U.S. history. *Cryptosporidium* ("hidden spore cysts") is found in about 90% of sewage samples, in 75% of river waters, and in 28% of drinking waters.

C. parvum is a common coccidial apicomplexan parasite found in the intestine of many birds and mammals. When these animals defecate, oocysts are shed into the environment. If a human ingests food or water that is contaminated with the oocysts, excystation occurs within the small intestine and sporozoites enter epithelial cells and develop into merozoites. Some of the merozoites subsequently undergo sexual reproduction to produce zygotes, and the zygotes differentiate into thick-walled oocysts. Oocyst release into the environment begins the life cycle again. A major problem for public health arises from the fact that the oocysts are only 4 to 6 μm in diameter, much too small to be easily removed by the sand filters used to produce drinking water. *Cryptosporidium* also is extremely resistant to disinfectants such as chlorine. The problem is made worse by the low infectious dose, around 10 to 100 oocysts, and the fact that the oocysts may remain viable for 2 to 6 months in a moist environment. Water purification (pp. 651–53).

The incubation period for cryptosporidiosis ranges from 5 to 28 days. Diarrhea, which characteristically may be choleralike, is the most common symptom. Other symptoms include abdominal pain, nausea, fever, and fatigue. The pathogen is routinely diagnosed by fecal concentration and acid-fast stained smears; rapid EIA and DFA techniques also have been developed. No chemotherapy is available and patients are simply rehydrated. Although the

disease usually is self-limiting in healthy individuals, patients that have late-stage AIDS or are immunocompromised in other ways may develop prolonged, severe, and life-threatening diarrhea.

Freshwater Amoeba Diseases

Free-living amoebae of the genera *Naegleria* and *Acanthamoeba* are facultative parasites responsible for causing **primary amebic meningoencephalitis** (*see table 39.2*) in humans. They are among the most common protozoa found in freshwater and moist soil. In addition, several *Acanthamoeba* spp. are known to infect the eye, causing a chronically progressive ulcerative *Acanthamoeba* **keratitis,** inflammation of the cornea, which may result in blindness. Wearers of soft contact lenses may be predisposed to this infection and should take care to prevent contamination of their lens cleaning and soaking solutions. Diagnosis of these infections is by demonstration of the amoebae in clinical specimens. Most freshwater amoebae are resistant to commonly used antibiotic agents. These amoebae are reported in fewer than 100 human disease cases annually in the United States although the incidence (especially of *Acanthamoeba* keratitis) is likely higher.

Giardiasis

Giardia lamblia [syn., *G. duodenalis, G. intestinalis*] is a flagellated protozoan (**figure 40.18*a***) that causes the very common intestinal disease **giardiasis.** (It was discovered by van Leeuwenhoek in 1681 when he examined his own stools.) *G. lamblia* is worldwide in distribution, and it affects children more seriously than it does adults. In the United States this protozoan is the most common cause of epidemic waterborne diarrheal disease (about 30,000 cases yearly). Approximately 7% of the population are healthy carriers and shed cysts in their feces. *G. lamblia* is endemic in child day-care centers in the United States, with estimates of 5 to 15% of diapered children being infected.

Transmission is most frequent by cyst-contaminated water supplies. Epidemic outbreaks have been recorded in wilderness areas, suggesting that humans may be infected from "clean water" with *Giardia* harbored by rodents, deer, cattle, or household pets. This implies that human infections also can be a zoonosis (*see table 37.1*). As many as 200 million humans may be infected worldwide.

Following ingestion, the cysts undergo excystation in the duodenum, forming trophozoites. The trophozoites inhabit the upper portions of the small intestine, where they attach to the intestinal mucosa by means of their sucking disks (figure 40.18*a*). The ability of the trophozoites to adhere to the intestinal epithelium accounts for the fact that they are rarely found in stools. It is thought that the trophozoites feed on mucous secretions and reproduce to form such a large population that they interfere with nutrient absorption by the intestinal epithelium.

Giardiasis varies in severity, and asymptomatic carriers are common. The disease can be acute or chronic. Acute giardiasis is characterized by severe diarrhea, epigastric pain, cramps, voluminous flatulence ("passing gas"), and anorexia. Chronic giardiasis

Box 40.2

A Brief History of Malaria

No other single infectious disease has had the impact on humans that malaria has. The first references to its periodic fever and chills can be found in early Chaldean, Chinese, and Hindu writings. In the late fifth century B.C., Hippocrates described certain aspects of malaria. In the fourth century B.C., the Greeks noted an association between individuals exposed to swamp environments and the subsequent development of periodic fever and enlargement of the spleen (splenomegaly). In the seventeenth century the Italians named the disease *mal' aria* (bad air) because of its association with the ill-smelling vapors from the swamps near Rome. At about the same time, the bark of the quina-quina (cinchona) tree of South America was used to treat the intermittent fevers, although it was not until the mid-nineteenth century that quinine was identified as the active alkaloid. The major epidemiological breakthrough came in 1880, when French army surgeon Charles Louis Alphonse Laveran observed exflagellated gametocytes in fresh blood. Five years later the Italian histologist Camillo Golgi observed the multiplication of the asexual blood forms. In the late 1890s Patrick Manson postulated that malaria was transmitted by mosquitoes. Sir Ronald Ross, a British army surgeon in the Indian Medical Service, subsequently observed developing plasmodia in the intestine of mosquitoes, supporting Manson's theory. Using birds as experimental models, Ross definitively established the major features of the life cycle of *Plasmodium* and received the Nobel Prize in 1902.

Human malaria is known to have contributed to the fall of the ancient Greek and Roman empires. Troops in both the United States Civil War and the Spanish-American War were severely incapacitated by the disease. More than 25% of all hospital admissions during these wars were malaria patients. During World War II malaria epidemics severely threatened both the Japanese and Allied forces in the Pacific. The same can be said for the military conflicts in Korea and Vietnam.

In the twentieth century efforts have been directed toward understanding the biochemistry and physiology of malaria, controlling the mosquito vector, and developing antimalarial drugs. In the 1960s it was demonstrated that resistance to *P. falciparum* among West Africans was associated with the presence of hemoglobin-S (Hb-S) in their erythrocytes. Hb-S differs from normal hemoglobin-A by a single amino acid, valine, in each half of the Hb molecule. Consequently these erythrocytes—responsible for sickle cell disease—have a low binding capacity for oxygen. Because the malarial parasite has a very active aerobic metabolism, it cannot grow and reproduce within these erythrocytes.

In 1955 the World Health Organization began a worldwide malarial eradication program that finally collapsed by 1976. Among the major reasons for failure were the development of resistance to DDT by the mosquito vectors and the development of resistance to chloroquine by strains of *Plasmodium.* Currently scientists are exploring new approaches, such as the development of vaccines and more potent drugs. For example, in 1984 the gene encoding the sporozoite antigen was cloned, permitting the antigen to be mass-produced by genetic engineering techniques. Overall, no greater achievement for molecular biology could be imagined than the control of malaria—a disease that has caused untold misery throughout the world since antiquity and remains one of the world's most serious infectious diseases.

is characterized by intermittent diarrhea, with periodic appearance and remission of symptoms.

Laboratory diagnosis is based on the identification of trophozoites—only in the severest of diarrhea—or cysts in stools. A commercial ELISA test is also available for the detection of *G. lamblia* antigen in stool specimens. Quinacrine hydrochloride (Atabrine) and metronidazole (Flagyl) are the drugs of choice for adults, and furazolidone is used for children because it is available in a pleasant-tasting liquid suspension. Prevention and control involves proper treatment of community water supplies, especially the use of slow sand filtration (*see section 29.5*) because the cysts are highly resistant to chlorine treatment.

Malaria

The most important human parasite among the sporozoa is *Plasmodium,* the causative agent of **malaria** (**Box 40.2**). It has been estimated that more than 150 million people are infected, and about one million die annually of malaria in Africa alone. About 1,000 cases are reported each year in the United States, divided between returning U.S. travelers and non-U.S. citizens.

Human malaria is caused by four species of *Plasmodium: P. falciparum, P. malariae, P. vivax,* and *P. ovale.* The life cycle of *P. vivax* is shown in **figure 40.19.** The parasite first enters the bloodstream through the bite of an infected female *Anopheles* mosquito. As she feeds, the mosquito injects a small amount of saliva containing an anticoagulant along with small haploid sporozoites (*see figure 27.3*c). The sporozoites in the bloodstream immediately enter hepatic cells of the liver. In the liver they undergo multiple asexual fission (schizogony) and produce merozoites. After being released from the liver cells, the merozoites attach to erythrocytes and penetrate these cells.

Once inside the erythrocyte, the *Plasmodium* begins to enlarge as a uninucleate cell termed a trophozoite. The trophozoite's nucleus then divides asexually to produce a schizont that has 6 to 24 nuclei. The schizont divides and produces mononucleated merozoites. Eventually the erythrocyte lyses, releasing the merozoites into the bloodstream to infect other erythrocytes. This erythrocytic stage is cyclic and repeats itself approximately every 48 to 72 hours or longer, depending on the species of *Plasmodium* involved. This sudden release of merozoites, toxins, and erythrocyte debris triggers an attack of the chills and fever, so characteristic of malaria. Occasionally, merozoites differentiate into macrogametocytes and microgametocytes, which do not rupture the erythrocyte. When these are ingested by a mosquito, they develop into female and male gametes, respectively. In the mosquito's gut the

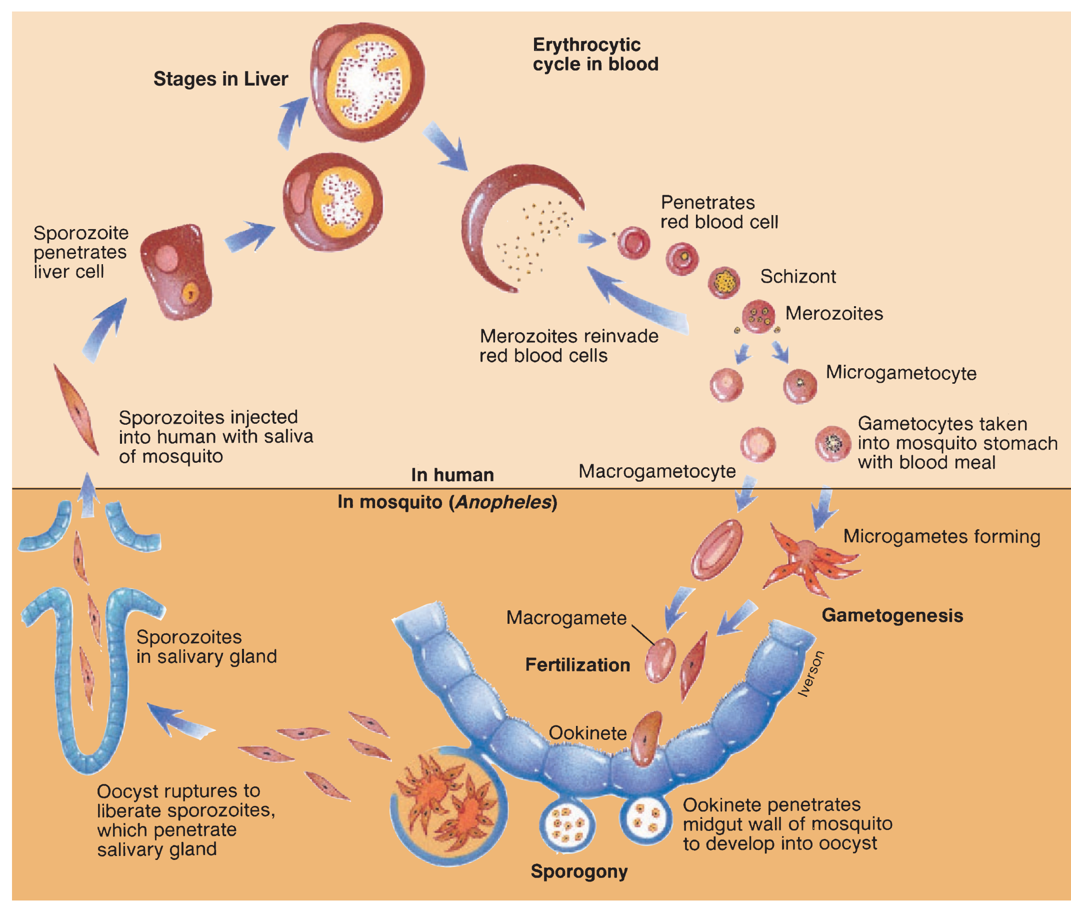

Figure 40.19 **Malaria.** Life cycle of *Plasmodium vivax.* See text for details.

infected erythrocytes lyse and the gametes fuse to form a diploid zygote called the ookinete. The ookinete migrates to the mosquito's gut wall, penetrates, and forms an oocyst on its outer surface. In a process called sporogony, the oocyst undergoes meiosis and forms sporozoites that migrate to the salivary glands of the mosquito. The cycle is now complete, but when the mosquito bites another human host, the cycle begins anew.

The pathological changes caused by malaria involve not only the erythrocytes but also the spleen and other visceral organs. Classic symptoms first develop with the synchronized release of merozoites and erythrocyte debris into the bloodstream, resulting in the malarial paroxysms—shaking chills, then burning fever followed by sweating. It may be that the fever and chills are caused partly by a malarial toxin that induces macrophages to release TNF-α and interleukin-1. Several of these paroxysms constitute an attack. After one attack there is a remission that lasts from a few weeks to several months. Then there is a relapse. Between paroxysms, the patient feels normal. Anemia can result from the loss of erythrocytes, and the spleen and liver often hypertrophy. Children and nonimmune individuals can die of cerebral malaria.

Diagnosis of malaria is made by demonstrating the presence of parasites within Wright- or Giemsa-stained erythrocytes (**figure 40.20**). When blood smears are negative, serological testing can establish a diagnosis of malaria in individuals. Specific recommendations for treatment are region dependent. Treatment includes administration of chloroquine, amodiaquine, or mefloquine. These suppressant drugs are effective in eradicating erythrocytic asexual stages. Primaquine has proved satisfactory in eradicating the exoerythrocytic stages. However, because resistance to these drugs is occurring rapidly, more expensive drug combinations are being used. One example is Fansidar, a combination of pyrimethamine and sulfadoxine. It is worth noting that individuals who are traveling to areas where malaria is endemic (**figure 40.21**) should receive chemoprophylactic treatment with chloroquine. Efforts to develop a vaccine are under way.

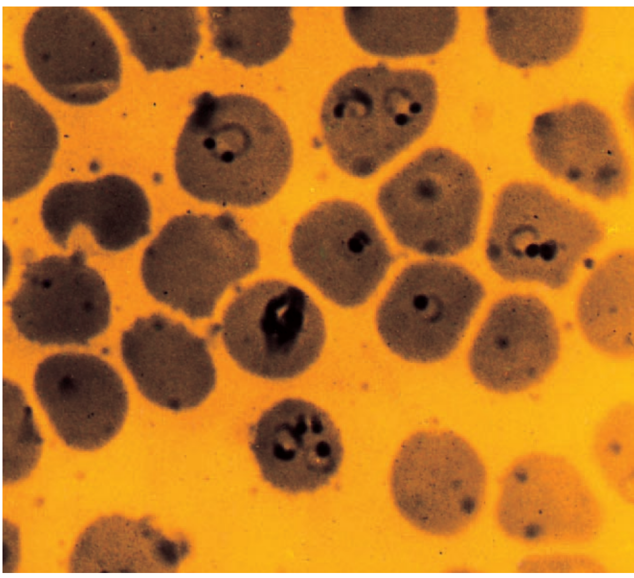

Figure 40.20 Malaria: Erythrocytic Cycle. Trophozoites of *P. falciparum* in circulating erythrocytes; light micrograph (×1,100). The young trophozoites resemble small rings resting in the erythrocyte cytoplasm.

Hemoflagellate Diseases

The flagellated protozoa that are transmitted by the bites of infected arthropods and infect the blood and tissues of humans are called **hemoflagellates.** There are two major groups of pathogens: the leishmanias and the trypanosomes.

Leishmaniasis

Leishmanias are flagellated protozoa that cause a group of human diseases collectively called **leishmaniasis.** The primary reservoirs of these parasites are canines and rodents. All species of *Leishmania* use sand flies such as those of the genera *Lutzomyia* and *Phlebotomus* as intermediate hosts. The leishmanias are transmitted from animals to humans or between humans by these sand flies. When an infected sand fly takes a human blood meal, it introduces flagellated promastigotes into the skin of the definitive host. Within the skin the promastigotes are engulfed by macrophages, multiply by binary fission and form small nonmotile cells called amastigotes. These destroy the host cell, and are engulfed by other macrophages in which they continue to develop and multiply.

Leishmania braziliensis, which has an extensive distribution in forest regions of tropical America, causes mucocutaneous leishmaniasis (espundia) (**figure 40.22*a***). The disease produces

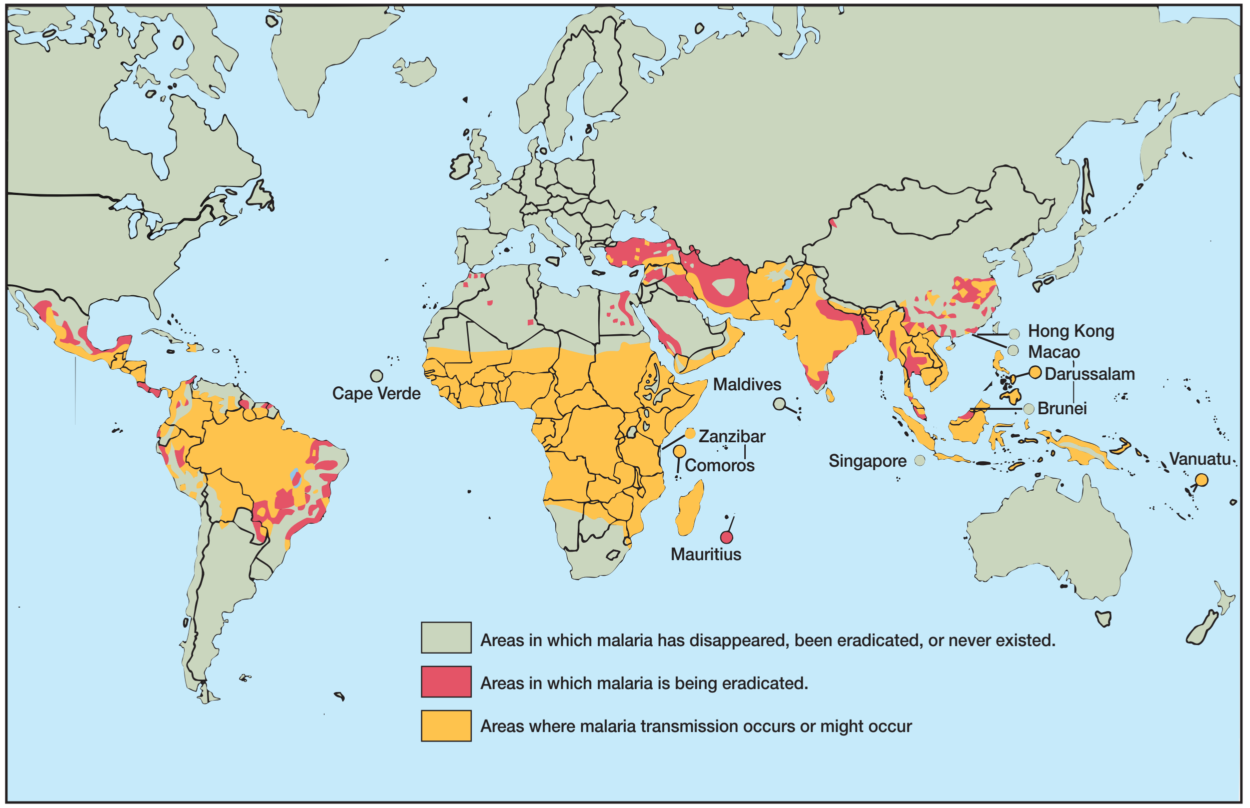

Figure 40.21 Geographic Distribution of Malaria. Notice that malaria is endemic around the equator. *Source: Data from the* World Health Statistics Quarterly, *41:69, 1988, World Health Organization, Switzerland.*

lesions involving the mouth, nose, throat, and skin and results in extensive scarring and disfigurement.

Leishmania donovani is endemic in large areas within northern China, eastern India, the Mediterranean countries, the Sudan, and Latin America. It produces visceral leishmaniasis (kala-azar). The disease involves the reticuloendothelial system and often results in intermittent fever and enlargement of the spleen and liver. Individuals who recover develop a permanent immunity.

Leishmania tropica and *L. mexicana* occur in the more arid regions of the Eastern Hemisphere and cause cutaneous leishmaniasis. *L. mexicana* is also found in the Yucatan Peninsula (Mexico) and has been reported as far north as Texas. In this disease a relatively small red papule forms at the site of each insect bite—the inoculation site. These papules are frequently found on the face and ears. They eventually develop into crustated ulcers (figure 40.22*b*). Healing occurs with scarring and a permanent immunity.

Laboratory diagnosis of leishmaniasis is based on finding the parasite within infected macrophages in stained smears from lesions or infected organs. Treatment includes the pentavalent antimonial compounds (Pentostam, Glucantime). Vector and reservoir control and aggressive epidemiological surveillance are the best options for prevention and containment of this disease.

Trypanosomiasis

Another group of flagellated protozoa called **trypanosomes** (*see figure 27.3*a) cause the aggregate of diseases termed **trypanosomiasis.** *Trypanosoma brucei gambiense,* found in the rain forests of west and central Africa, and *T. brucei rhodesiense,* found in the upland savannas of east Africa, cause African trypanosomiasis. Reservoirs for these trypanosomes are domestic cattle and wild animals, within which the parasites cause severe malnutrition. Both species use tsetse flies as intermediate hosts. The parasites are transmitted through the bite of the fly to humans. Once the protozoa enter the bloodstream, they begin to multiply. They cause interstitial inflammation and necrosis within the lymph nodes and small blood vessels of the brain and heart. In *T. brucei rhodesiense* infection the disease develops so rapidly that infected individuals often die within a year. In *T. brucei gambiense* infection the parasites invade the central nervous system, where necrotic damage causes a variety of nervous disorders, including the characteristic sleeping sickness. The name sleeping sickness is derived from the lethargy of the host—characteristically lying prostrate, drooling from the mouth, and insensitive to pain. Usually the victim dies in 2 to 3 years. Trypanosomiasis is such a problem in parts of Africa that millions of square miles are not fit for human habitation.

T. cruzi causes **American trypanosomiasis (Chagas' disease),** which occurs in the tropics and subtropics of continental America. The parasite uses the triatomid (kissing) bug as a vector. As the triatomid bug takes a blood meal, the parasites are discharged in the insect's feces. Some trypanosomes enter the bloodstream through the wound and invade the liver, spleen, lymph nodes, and central nervous system, where they multiply and destroy the parasitized cells. In some parts of Latin America, a high percentage of heart disease is due to parasitized cardiac cells.

Trypanosomiasis is diagnosed by finding motile parasites in fresh blood and by serological testing. Treatment for African trypanosomiasis uses suramin and pentamidine for non-nervous-system involvement and melarsoprol when the nervous system is involved. Currently there is no drug suitable for Chagas' disease, although nifurtimox (Lampit) and benznidazole have shown some value. Vaccines are not useful because the parasite is able to change its protein coat and evade the immunologic response.

Toxoplasmosis

Toxoplasmosis is a disease caused by the protozoan *Toxoplasma gondii.* This apicomplexan protozoan has been found in nearly all animals and most birds; cats are the definitive host and required

for completion of the sexual cycle. Animals shed oocysts in the feces; the oocysts enter another host by way of the nose or mouth; and the parasites colonize the intestine. Toxoplasmosis also can be transmitted by the ingestion of raw or undercooked meat, congenital transfer, blood transfusion, or a tissue transplant. Originally toxoplasmosis gained public notice when it was discovered that in pregnant women the protozoan might also infect the fetus, causing serious congenital defects or death.

Most cases of toxoplasmosis are asymptomatic. Adults usually complain of an "infectious mononucleosis-like" syndrome. In immunoincompetent or immunosuppressed individuals, it frequently results in fatal disseminated disease with a heavy cerebral involvement.

Acute toxoplasmosis is usually accompanied by lymph node swelling (lymphadenopathy) with reticular cell enlargement or hyperplasia. Pulmonary necrosis, myocarditis, and hepatitis caused by tissue necrosis are common. Retinitis (inflammation of the retina of the eye) is associated with the necrosis due to the proliferation of the parasite within retinal cells. Currently toxoplasmosis has become a major cause of death in AIDS patients from a unique encephalitis with necrotizing lesions accompanied by inflammatory infiltrates. It continues to cause more than 3,000 congenital infections per year in the United States.

Laboratory diagnosis of toxoplasmosis is by serological tests. Epidemiologically, toxoplasmosis is ubiquitous in all higher animals. Treatment of toxoplasmosis is with a combination of pyrimethamine (Daraprim) and sulfadiazine. Prevention and control requires minimizing exposure by the following: avoiding eating raw meat and eggs, washing hands after working in the soil, cleaning cat litterboxes daily, keeping personal cats indoors if possible, and feeding them commercial food.

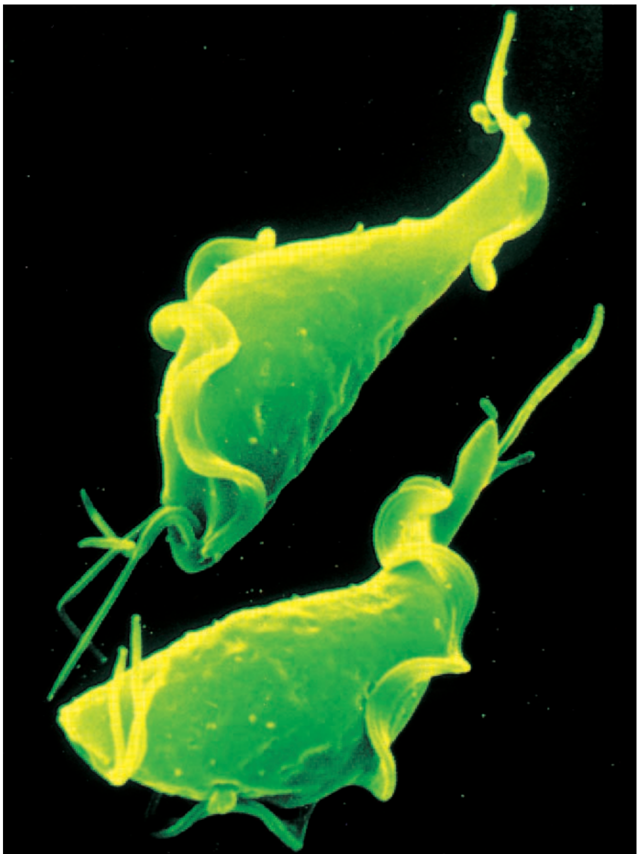

Figure 40.23 **Trichomoniasis.** *Trichomonas vaginalis,* showing the characteristic undulating membranes and flagella; scanning electron micrograph (×12,000).

Trichomoniasis

Trichomoniasis is a sexually transmitted disease (*see table 39.4*) caused by the protozoan flagellate *Trichomonas vaginalis* (**figure 40.23**). It is one of the most common sexually transmitted diseases, with an estimated 7 million cases annually in the United States and 180 million cases annually worldwide. In response to the parasite, the body accumulates leukocytes at the site of the infection. In females this usually results in a profuse purulent vaginal discharge that is yellowish to light cream in color and characterized by a disagreeable odor. The discharge is accompanied by itching. Males are generally asymptomatic because of the trichomonacidal action of prostatic secretions; however, at times a burning sensation occurs during urination. Diagnosis is made in females by microscopic examination of the discharge and identification of the parasite. Infected males will demonstrate the parasite in semen or urine. Treatment is by administration of metronidazole (Flagyl).

1. How do infections caused by *Entamoeba histolytica* occur?
2. What is the most common cause of epidemic waterborne diarrheal disease?
3. Describe in detail the life cycle of the malarial parasite.
4. What protozoa are represented within the hemoflagellates? What diseases do they cause?
5. In what two ways does *Toxoplasma* affect human health?
6. How would you diagnose trichomoniasis in a female? In a male?

Summary

1. Human fungal diseases, or mycoses, can be divided into five groups according to the level and mode of entry into the host. These are the superficial, cutaneous, subcutaneous, systemic, and opportunistic mycoses (**table 40.1**).
2. Superficial mycoses of the hair shaft are collectively called piedras. Two major types are black piedra (**figure 40.1**) and white piedra. Tinea versicolor is a third common superficial mycosis.
3. The cutaneous fungi that parasitize the hair, nails, and outer layer of the skin are called dermatophytes, and their infections are termed dermatophytoses, ringworms, or tineas. At least seven types can occur in humans:

   tinea barbae (ringworm of the beard; **figure 40.2**), tinea capitis (ringworm of the scalp; **figure 40.3**), tinea corporis (ringworm of the body; **figure 40.4**), tinea cruris (ringworm of the groin; **figure 40.5**), tinea pedis (ringworm of the feet; **figure 40.6**), tinea manuum (ringworm of the hands), and tinea unguium (ringworm of the nails; **figure 40.7**).
4. The dermatophytes that cause the subcutaneous mycoses are normal saprophytic inhabitants of soil and decaying vegetation. Three types of subcutaneous mycoses can occur in humans: chromoblastomycosis (**figure 40.8**), maduromycosis (**figure 40.9**), and sporotrichosis (**figure 40.10**).
5. Most systemic mycoses that occur in humans are acquired by inhaling the spores from the soil where the free-living fungi are found. Four types can occur in humans: blastomycosis (**figure 40.11**), coccidioidomycosis, cryptococcosis, and histoplasmosis.
6. An opportunistic organism is one that is generally harmless in its normal environment but that can become pathogenic in a compromised host. The most important opportunistic mycoses affecting humans include systemic aspergillosis (**figure 40.15**), candidiasis (**figure 40.16*b***), and *Pneumocystis carinii* pneumonia.
7. Protozoa are responsible for some of the most serious human diseases that affect hundreds of millions of people worldwide (**table 40.3**).
8. *Entamoeba histolytica* is the amoeboid protozoan responsible for amebiasis. This is a very common disease in warm climates throughout the world. It is acquired when one ingests the cysts with contaminated food or water (**figure 40.17**).
9. *Cryptosporidium parvum* is a common coccidial apicomplexan parasite that causes severe diarrheal disease. It is acquired from contaminated food or water.
10. *Giardia lamblia* is a flagellated protozoan that causes the common intestinal disease giardiasis (**figure 40.18**). This disease is distributed throughout the world, and in the United States it is the most common cause of waterborne diarrheal disease.
11. The most important human parasite among the sporozoa is *Plasmodium,* the causative agent of malaria (**figure 40.19**). Human malaria is caused by four species of *Plasmodium: P. falciparum, P. vivax, P. malariae,* and *P. ovale.*
12. The flagellated protozoa that are transmitted by arthropods and infect the blood and tissues of humans are called hemoflagellates. Two major groups occur: the leishmanias, which cause the diseases collectively termed leishmaniasis (**figure 40.22**), and the trypanosomes, which cause trypanosomiasis.
13. Toxoplasmosis is a disease caused by the protozoan *Toxoplasma gondii.* It is one of the major causes of death in AIDS patients.
14. Trichomoniasis is a sexually transmitted disease caused by the protozoan flagellate *Trichomonas vaginalis* (**figure 40.23**).

Questions for Thought and Review

1. Briefly describe each of the major or most common fungal and protozoan diseases in terms of its causative agent, signs and symptoms, the course of infection, mechanism of pathogenesis, epidemiology, and prevention and/or treatment.
2. There are no antibiotics—nothing equivalent to penicillin or streptomycin—to control fungi in the human body. Recalling the mechanisms by which antibiotics affect bacteria, why do you think there has been no similar success in the control of fungal pathogens?
3. Give several reasonable explanations why most fungal diseases in humans are not contagious.
4. What factors determine one's susceptibility to fungal diseases?
5. What is the relationship between AIDS and mycotic and protozoan diseases?
6. Why do most protozoan diseases occur in the tropics?
7. Give several reasons why malaria is still one of the most serious of all infectious diseases that affect humans.
8. What morphological property is the most important in the identification of fungi?
9. Compared to fungal parasites, how are protozoan parasites transmitted?
10. What are dermatomycoses?

Critical Thinking Questions

1. Compare and contrast treatment of diseases caused by fungi with those caused by viruses or bacteria.
2. What is one distinct feature of fungi that could be exploited for antibiotic therapy?
3. Trypanosomes are notorious for their ability to change their surface antigens frequently. Given the kinetics of a primary immune response (primary antibody production), how often would the surface antigen need to be changed in order to stay "ahead" of the antibody specificity? Why shouldn't it change the expression every time transcription occurs?

- Cheese Production 979
- Meat and Fish 982
- Production of Alcoholic Beverages 982
- Production of Breads 984
- Other Fermented Foods 985

41.7 Microorganisms as Foods and Food Amendments 986

Concepts

1. Foods often provide an ideal environment for microbial survival and growth.
2. Microbial growth in foods involves successional changes, with intrinsic, or food-related, and extrinsic, or environmental, factors interacting with the microbial community over time.
3. Food spoilage is a major problem in all societies. This can occur at any point in the course of food production, transport, storage, or preparation. Food-borne toxins are of increasing concern, especially with increases in international shipments and extended storage of food products before use. Growth of fungi can result in the synthesis of toxins such as aflatoxins, fumonisins, and ergot alkaloids. Algal-derived toxins can be transmitted to humans through freshwater and marine-derived food products.
4. Foods can be preserved by physical, chemical, and biological processes. Refrigeration does not significantly reduce microbial populations but only retards spoilage. Pasteurization results in a pathogen-free product with a longer shelf life.
5. Chemicals can be added to foods to control microbial growth. Such chemicals include sugar, salt (decreasing water availability), and many organic chemicals that affect specific groups of microorganisms. Microbial products, such as bacteriocins, can be added to foods to control spoilage organisms.
6. Foods can transmit a wide range of diseases to humans. In food infection the food serves as a vehicle for the transfer of the pathogen to the consumer, in whom the pathogen grows and causes disease. With food intoxication the microorganisms grow in the food and produce toxins that can then affect the consumer.

Concepts *(Continued)*

7. New pathogens continue to be discovered. This may be due to an increased ability to detect these pathogens as well as to better reporting and monitoring of disease occurrence.
8. Foods that are consumed raw, such as sprouts, shellfish/finfish, and fruits, are increasingly popular. There is a risk of disease transmission if care is not taken in production, storage, and transport of these perishable foods. Without adequate care, major disease outbreaks can occur because foods travel around the globe in extremely short times.
9. Detection of food-borne pathogens is carried out using classic culture techniques, as well as immunological and molecular procedures. Modern techniques make it possible to quickly link food-borne disease occurrences to common pathogen sources. With kit-type rapid diagnostic systems, pathogens often can be detected in 1 to 2 days.
10. Dairy products, grains, meats, fruits, and vegetables can be fermented. It has been suggested that some fermented dairy products have antimicrobial and anticancer characteristics, especially when particular lactic acid bacteria are used.
11. Wines are produced by the direct fermentation of fruit juices or musts. For fermentation of cereals and grains, starches and proteins contained in these substrates must first be hydrolyzed to provide substrates for the alcoholic fermentation.
12. The making of bread, sauerkraut, sufu, pickles, and many other foods also involves the use of complex fermentation processes. When chopped plant materials are fermented, silages are created, which can be stored and used by animals.
13. Microbial cells can be used as food sources and food amendments. These include mushrooms, cyanobacteria such as *Spirulina,* and yeasts. There is an increasing interest in probiotics, or the use of microorganisms to change the microbial community in the intestine. Microbial colonization of surfaces in the intestine plays a critical role in these processes.

Tell me what you eat, and I will tell you what you are.

—Brillat-Savarin

Foods, microorganisms, and humans have had a long and interesting association that developed long before the beginning of recorded history. Foods are not only of nutritional value to those who consume them but often are ideal culture media for microbial growth. Fermentation by some microorganisms can lead to food preservation instead of food spoilage.

Microorganisms can be used to transform raw foods into gastronomic delights, including cheeses, pickles, sausages, and soy sauce. Wines, beers, and other alcoholic products also are produced through microbial activity. On the other hand, foods also can serve as vehicles for disease transmission, and the detection and control of pathogens and food spoilage microorganisms are important parts of food microbiology. During the entire sequence of food handling, from the producer to the final consumer, microorganisms can affect food quality and human health.

Wholesome, nutrient-rich foods are important for all people. Microbial growth in foods can result in either preservation or spoilage, depending on the microorganisms involved and the food storage conditions. Contamination by disease-causing microorganisms can occur at any point in the food-handling sequence.

41.1 Microorganism Growth in Foods

Foods, because they provide nutrients for us, also are excellent environments for the growth of microorganisms. Microbial growth is controlled by factors related to the food itself, or **intrinsic factors,** and also to the environment where the food is being stored, or what are described as **extrinsic factors,** as shown in **figure 41.1.**

The intrinsic or food-related factors include pH, moisture content, water activity or availability, oxidation-reduction potential, physical structure of the food, available nutrients, and the possible presence of natural antimicrobial agents. Extrinsic or environmental factors include temperature, relative humidity, gases (CO_2, O_2) present, and the types and numbers of microorganisms present in the food.

Intrinsic Factors

Food composition is a critical intrinsic factor that influences microbial growth. If a food consists primarily of carbohydrates, spoilage does not result in major odors. Thus foods such as breads, jams, and some fruits first show spoilage by fungal growth. In contrast, when foods contain large amounts of proteins and/or fats (for example, meat and butter), spoilage can produce a variety of foul odors. One only need think of rotting eggs. This proteolysis and anaerobic breakdown of proteins that yields foul-

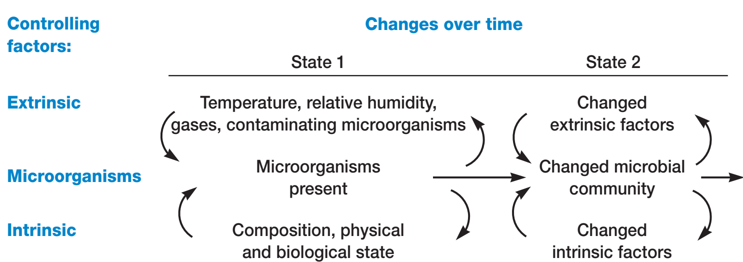

Figure 41.1 Intrinsic and Extrinsic Factors. A variety of intrinsic and extrinsic factors can influence microbial growth in foods. Time-related successional changes occur in the microbial community and the food.

Table 41.1 Differences in Spoilage Processes in Relation to Food Characteristics

Substrate	Food Example	Chemical Reactions or Processes[a]	Typical Products and Effects
Pectin	Fruits	Pectinolysis	Methanol, uronic acids (loss of fruit structure, soft rots)
Proteins	Meat	Proteolysis, deamination	Amino acids, peptides, amines, H_2S, ammonia, indole (bitterness, souring, bad odor, sliminess)
Carbohydrates	Starchy foods	Hydrolysis, fermentations	Organic acids, CO_2, mixed alcohols (souring, acidification)
Lipids	Butter	Hydrolysis, fatty acid degradation	Glycerol and mixed fatty acids (rancidity, bitterness)

[a]Other reactions also occur during the spoilage of these substrates.

smelling amine compounds is called **putrefaction.** One major source of odor is the organic amine cadaverine (imagine the origin of that name). Degradation of fats ruins food as well. For example, the production of short-chained fatty acids from fats renders butter rancid and unpleasant.

The pH of a food also is critical because a low pH favors the growth of yeasts and molds (*see section 6.4*). In neutral or alkaline pH foods, such as meats, bacteria are more dominant in spoilage and putrefaction. Depending on the major substrate present in a food, different types of spoilage may occur (**table 41.1**).

The presence and availability of water also affect the ability of microorganisms to colonize foods. Simply by drying a food, one can control or eliminate spoilage processes. Water, even if present, can be made less available by adding solutes such as sugar and salt. Water availability is measured in terms of water activity (a_w). This represents the ratio of relative humidity of the air over a test solution compared with that of distilled water. When large quantities of salt or sugar are added to food, most microorganisms are dehydrated by the hypertonic conditions and cannot grow (**table 41.2;** *see also table 6.4*). Even under these adverse conditions, osmophilic and xerophilic microorganisms may spoil food. **Osmophilic** [Greek *osmus,* impulse, and *philein,* to love] **microorganisms** grow best in or on media with a high osmotic concentration, whereas **xerophilic** [Greek *xerosis,* dry, and *philein,* to love] **microorganisms** prefer a low a_w environment and may not grow under high a_w conditions. Water activity and microbial growth (pp. 121–23)

The oxidation-reduction potential of a food also influences spoilage. When meat products, especially broths, are cooked, they often have lower oxidation-reduction potentials. These products with their readily available amino acids, peptides, and growth factors are ideal media for the growth of anaerobes, including *Clostridium* (*see table 39.5*).

The physical structure of a food also can affect the course and extent of spoilage. The grinding and mixing of foods such as sausage and hamburger not only increase the food surface area and alter cellular structure, but also distribute contaminating microorganisms throughout the food. This can result in rapid spoilage if such foods are stored improperly. Vegetables and fruits have outer skins (peels and rinds) that protect them from spoilage. Often spoilage microorganisms have specialized enzymes that help them weaken and penetrate protective peels and rinds, especially after the fruits and vegetables have been bruised.

Many foods contain natural antimicrobial substances, including complex chemical inhibitors and enzymes. Coumarins found in fruits and vegetables exhibit antimicrobial activity. Cow's milk and eggs also contain antimicrobial substances. Eggs are rich in the enzyme lysozyme that can lyse the cell walls of contaminating gram-positive bacteria (*see figure 31.9*). Other interesting foods with antimicrobial activities include the hot sauces used on raw oysters and other seafoods. Tabasco and other hot red pepper sauces apparently have particularly desirable antimicrobial characteristics.

Herbs and spices often possess significant antimicrobial substances; generally fungi are more sensitive than most bacteria. Sage and rosemary are two of the most antimicrobial spices. Aldehydic and phenolic compounds are found in cinnamon, mustard, and oregano. These compounds inhibit microbial growth. Other important inhibitors are garlic, which contains allicin, and cloves, which have eugenol. However, spices also can contain pathogenic and spoilage organisms. Coliforms, *B. cereus, C. perfringens,* and *Salmonella* species have been detected in most spices. Microorganisms can be eliminated or reduced by ethylene oxide sterilization. This treatment can result in *Salmonella*-free spices and herbs and a 90% reduction in the levels of general spoilage organisms.

Unfermented green and black teas also have well-documented antimicrobial properties because of their polyphenol contents, which apparently are diminished when the teas are fermented. Such teas are active against bacteria, viruses, and fungi and may have anticancer properties.

Extrinsic Factors

Temperature and relative humidity are important extrinsic factors in determining whether a food will spoil. At higher relative humidities microbial growth is initiated more rapidly, even at lower temperatures (especially when refrigerators are not maintained in a defrosted state). When drier foods are placed in moist environments, moisture absorption can occur on the food surface, eventually allowing microbial growth.

The atmosphere in which the food is stored also is important. This is especially true with shrink-packed foods because many plastic films allow oxygen diffusion, which results in increased growth of surface-associated microorganisms. Excess CO_2 can decrease the solution pH, inhibiting microbial growth. Storing

Table 41.2 Approximate Minimum Water Activity Relationships of Microbial Groups and Specific Organisms of Important in Food Spoilage

Organisms	a_w	Organisms	a_w
Groups		**Groups**	
Moist spoilage bacteria	0.9	Halophilic bacteria	0.75
Most spoilage yeasts	0.88	Xerophilic molds	0.61
Most spoilage molds	0.80	Oxmophilic yeasts	0.61
Specific Microorganisms		**Specific Microorganisms**	
Clostridium botulinum, type E	0.97	*Candida scottii*	0.92
Pseudomonas spp.	0.97	*Trichosporon pullulans*	0.91
Acinetobacter spp.	0.96	*Candida zeylanoides*	0.90
Escherichia coli	0.96	*Geotrichum candidum*	~ 0.90
Enterobacter aerogenes	0.95	*Trichothecium* spp.	~ 0.90
Bacillus subtilis	0.95	*Byssochlamys nivea*	~ 0.87
Clostridium botulinum, types A and B	0.94	*Staphylococcus aureus*	0.86
Candida utilis	0.94	*Alternaria citri*	0.84
Vibrio parahaemolyticus	0.94	*Pencillium patulum*	0.81
Botrytis cinerea	0.93	*Eurotium repens*	0.72
Rhizopus stolonifer	0.93	*Aspergillus conicus*	0.70
Mucor spinosus	0.93	*Aspergillus echinulatus*	0.64
		Zygosaccharomyces rouxii	0.62
		Xeromyces bisporus	0.51

meat in a high CO_2 atmosphere inhibits gram-negative bacteria, resulting in a population dominated by the lactobacilli.

The observation that food storage atmosphere is important has led to the development **modified atmosphere packaging (MAP).** By the use of modern shrink-wrap materials and vacuum technology, it is possible to package foods with controlled atmospheres. With a carbon dioxide content of 60% or greater in the atmosphere surrounding a food, spoilage fungi will not grow, even if low levels of oxygen are present. Some oxygen is kept because if all the oxygen is removed, the psychrophile *Clostridium gasigenes* can grow. This organism can produce gases in 14 days at 2°C, which leads to swollen food packages. Such MAP procedures, while assisting in controlling spoilage, also cause a shift in the general structure of the microbial community, from gram-negative to gram-positive organisms.

1. What are the effects of food composition on spoilage processes?
2. What are some intrinsic factors that influence food spoilage and how do they exert their effects?
3. Why might sausage and other ground meat products provide a better environment for the growth of food spoilage organisms than raw cuts of meats?
4. List some antimicrobial substances found in foods. What is the mechanism of action of lysozyme?
5. What primary extrinsic factors can determine whether food spoilage will occur?
6. What are the major gases involved in MAP? How are their concentrations varied to inhibit microbial growth?

41.2 Microbial Growth and Food Spoilage

Because foods are such excellent sources of nutrients, if the intrinsic and extrinsic conditions are appropriate, microorganisms grow rapidly and make what once was an attractive and appealing food into a sour, foul-smelling or fungus-covered mass suitable only for the garbage can. Microbial growth in foods can lead to visible changes, including a variety of colors caused by spoilage organisms, which often have been associated with "miracles" and "witchcraft." One of the most famous is the report of "blood" on communion wafers and other bread, called the "Miracle of Bolsena," which occurred in 1263. The riddle was eventually solved by Bartolomeo Bizio in 1879, when he described the bacterium responsible for this phenomenon. He also named the bacterium *Serratia marcescens.*

Meat and dairy products, with their high nutritional value and the presence of easily usable carbohydrates, fats, and proteins, provide ideal environments for microbial spoilage. Proteolysis and putrefaction are typical results of microbial spoilage of such high-protein materials. Unpasteurized milk undergoes a predictable four-step succession during spoilage; acid production by *Lactococcus lactis* subsp. *lactis* is followed by additional acid production associated with the growth of more acid tolerant organisms such as *Lactobacillus.* At this point yeasts and molds become dominant and degrade the accumulated lactic acid, and the acidity gradually decreases. Eventually protein-digesting bacteria become active, resulting in a putrid odor and bitter flavor. The milk, originally opaque, can eventually become clear (**figure 41.2**).

Figure 41.2 Spoilage of a Dairy Product. Fresh (left) and curdled (right) milk are shown. The curdled milk has undergone a natural four-step sequence of spoilage organism activity, resulting in separated curds and whey.

(a)

(b)

Figure 41.3 Food Spoilage. When foods are not stored properly, microorganisms can cause spoilage. Typical examples are fungal spoilage of (**a**) bread and (**b**) corn. Such spoilage of corn is called ear rot. This can result in major economic losses.

In comparison with meat and dairy products, most fruits and vegetables have a much lower protein and fat content and undergo a different kind of spoilage. Readily degradable carbohydrates favor vegetable spoilage by bacteria, especially bacteria that cause soft rots, such as *Erwinia carotovora,* which produces hydrolytic enzymes. The high oxidation-reduction potential and lack of reduced conditions permits aerobes and facultative anaerobes to contribute to the decomposition processes. Bacteria do not seem important in the initial spoilage of whole fruits; instead such spoilage often is initiated by molds. These organisms have enzymes that contribute to the weakening and penetration of the protective outer skin.

Food spoilage problems occur with minimally processed, concentrated frozen citrus products. These are prepared with little or no heat treatment, and major spoilage can be caused by *Lactobacillus* and *Leuconostoc* spp., which produce diacetyl-butter flavors. *Saccharomyces* and *Candida* can also spoil juices. Concentrated juice has a decreased water activity ($a_w = 0.8$ to 0.83), and when kept frozen at about −9°C, the juices can be stored for long periods. However, when concentrated juices are diluted with water that contains spoilage organisms, or if the juice is stored in improperly washed containers, problems can occur. Also, microorganisms in the frozen concentrated juices can begin the spoilage process after addition of water. Ready-to-serve (RTS) juices present other problems as the a_w values are sufficiently high to allow microbial growth. This is especially true with extended storage at refrigeration temperatures. Although pasteurization can be used, most consumers are sensitive to the loss of flavor that this process entails.

Molds are a special problem for tomatoes. Even the slightest bruising of the tomato skin, exposing the interior, will result in rapid fungal growth. Frequently observed genera include *Alternaria, Cladosporium, Fusarium,* and *Stemphylium.* This growth affects the quality of tomato products, including tomato juices and ketchups.

Molds can rapidly grow on grains and corn when these products are held under moist conditions (**figure 41.3**). Infection of grains by the ascomycete *Claviceps purpura* causes **ergotism,** a toxic condition. Hallucinogenic alkaloids produced by this fungus can lead to altered behavior, abortion, and death if infected grains are eaten. Ergotism is further discussed in chapter 25 (*see p. 561*).

Fungus-derived carcinogens include the aflatoxins and fumonisins. **Aflatoxins** are produced most commonly in moist grains and nut products. Aflatoxins were discovered in 1960, when 100,000 turkey poults died from eating fungus-infested peanut meal. *Aspergillus flavus* was found in the infected peanut meal, together with alcohol-extractable toxins termed aflatoxins. These flat-ringed planar compounds intercalate with the cells' nucleic acids and act as frameshift mutagens and carcinogens. This occurs primarily in the liver, where they are converted to unstable derivatives.

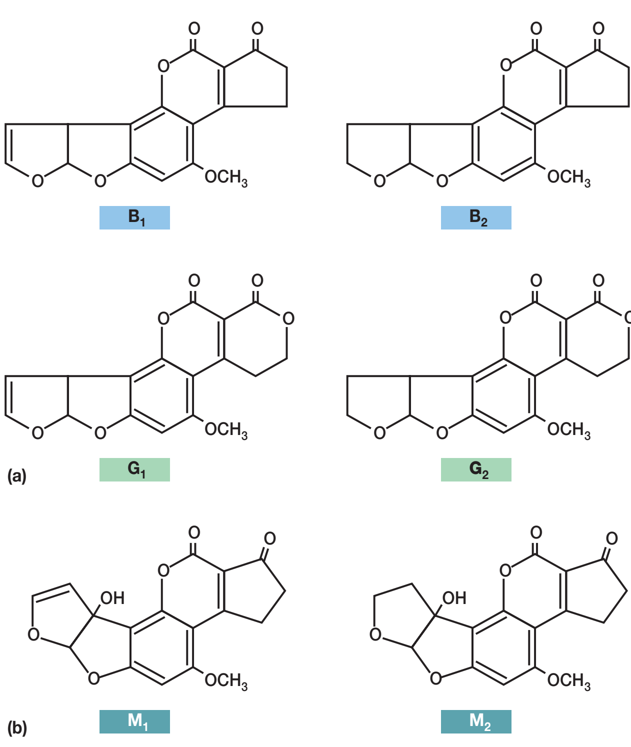

Figure 41.4 Aflatoxins. When *Aspergillus flavus* and related fungi grow on foods, carcinogenic aflatoxins can be formed. These have four basic structures. (**a**) The letter designations refer to the color of the compounds under ultraviolet light after extraction from the grain and separation by chromatography. The B_1 and B_2 compounds fluoresce with a blue color, and the G_1 and G_2 appear green. (**b**) The two type M aflatoxins are found in the milk of lactating animals that have ingested type B aflatoxins.

Figure 41.5 Fumonisin Structure. The basic structure of fumonisins FB1 and FB2 produced by *Fusarium moniliforme,* a fungal contaminant that can grow in improperly stored corn. A total of at least ten different fumonisins have been isolated. These are strongly polar compounds that cause diseases in domestic animals and also in humans. FB1, R=—OH; FB2, R=H.

Aflatoxins B_1 and B_2, after ingestion by lactating animals, will be modified in the animal body to yield the aflatoxins M_1 and M_2, noted in **figure 41.4.** If cattle consume aflatoxin-contaminated feeds, these also can appear in milk and dairy products. With the ability to screen grains and corns rapidly for these compounds, it is possible to limit shipments of potentially contaminated grains and feedstuffs. The aflatoxins are potent hepatocarcinogens, which have been linked to effects on immunocompetence, growth, and disease resistance in livestock and laboratory animals. The major aflatoxin types and their derivatives can be separated by chromatographic procedures and can be recognized under UV light by their characteristic fluorescence. Besides their importance in grains, they have also been observed in beer, cocoa, raisins, and soybean meal.

Ultimately, the critical concern is the amounts of aflatoxins that are ingested. Diet preferences appear to be related to aflatoxin exposure: the average aflatoxin intake in the typical European-style diet is 19 ng/day, whereas for Far Eastern diets it is estimated to be 103 ng/day. Aflatoxin sensitivity also can be influenced by prior disease exposure. It has been found that individuals who have had hepatitis B have a 30-fold higher risk of liver cancer upon exposure to aflatoxins than individuals who have not had this disease. Based on this linkage, it has been observed that prevention of hepatitis B infections by vaccination and reduction of carrier populations will help to significantly control the potential effects of aflatoxins in foodstuffs.

More recently discovered fungal contaminants of corn are the **fumonisins,** first isolated in 1988. These are produced by *Fusarium moniliforme* and cause leukoencephalomalacia in horses, pulmonary edema in pigs, and esophageal cancer in humans. The fumonisins function by disrupting the synthesis and metabolism of sphingolipids, important biochemically active compounds, which influence a wide variety of cell functions.

There are at least ten different fumonisins; the basic structures of fumonisins FB1 and FB2 are shown in **figure 41.5.** Corn and corn-based feeds and foods, including cornmeal and corn grits, often are contaminated. The fumonisins inhibit ceramide synthase, a key enzyme for the proper use of fatty subtances in the cell. Thus it is extremely important to store corn and corn products under dry conditions where these fungi cannot develop.

Eucaryotic microorganisms can synthesize potent toxins other than aflatoxins and fumonisins. **Algal toxins** contaminate fish and thus affect the health of marine animals higher in the food chain; they also can contaminate shellfish and fin fish, which are later consumed by humans. Most toxins are produced by dinoflagellates, but some diatoms also are toxic. Major human diseases that result from algal toxins in marine products include amnesic, diarrhetic, and neurotoxic shellfish poisoning (**table 41.3**). These complex algal toxins (**figure 41.6**), most of which are temperature stable, are known to cause peripheral neurological system effects, often in less than one hour after ingestion. Toxic algal blooms (Box 26.2)

Table 41.3 Toxic Syndromes Associated with Marine Algal Toxins

Syndrome	Causative Organism(s)	Primary Vector	Toxin Type
Parasitic shellfish poisoning	*Alexandrium* spp. *Gymnodinium* spp. *Pyrodinium* spp.	Shellfish	Saxitoxins
Neurotoxic shellfish poisoning	*Gymnodinium breve*	Shellfish	Brevitoxins
Ciguatera fish poisoning	*Gambierdiscus toxicus*	Reef fish	Ciguatoxins
Amnesic shellfish poisoning	*Pseudo-nitzchia* spp.	Shellfish	Domoic acid
Diarrhetic shellfish poisoning	*Dinophysis* spp. *Prorocentrum* spp.	Shellfish	Dinophysistoxins Okadaic acid
Estuary syndrome	*Pfiesteria piscicida*	Water	Unknown

1. What fungal genus produces ergot alkaloids? What conditions are required for the synthesis of these substances?
2. Aflatoxins are produced by which fungal genus? How do they damage animals that eat the contaminated food?
3. What microbial genus produces fumonisins and why are these compounds of concern? If improperly stored, what are the major foods and feeds in which these chemicals might be found?
4. Describe in general how food spoilage occurs. What factors influence the nature of the spoilage organisms responsible?
5. Why do concentrated citrus juices present such interesting spoilage problems?
6. What is the usual route by which humans consume algal toxins? What are the major groups of algae that produce these complex substances?

41.3 Controlling Food Spoilage

With the beginning of agriculture and a decreasing dependence on hunting and gathering, the need to preserve surplus foods became essential to survival. The use of salt as a meat preservative and the production of cheeses and curdled milks was introduced in Near Eastern civilization as early as 3000 B.C. The production of wines and the preservation of fish and meat by smoking also were common by this time. Despite a long tradition of efforts to preserve food from spoilage, it was not until the nineteenth century that the microbial spoilage of food was studied rigorously. Louis Pasteur established the modern era of food microbiology in 1857, when he showed that microorganisms cause milk spoilage. Pasteur's work in the 1860s proved that heat could be used to control spoilage organisms in wines and beers (*see section 1.4*). Control of microorganism growth (chapter 7)

Foods can be preserved by a variety of methods (**table 41.4**). It is vital to eliminate or reduce the populations of spoilage and disease-causing microorganisms and to maintain the microbiological quality of a food with proper storage and packaging. Contamination often occurs after a package or can is opened and just before the food is served. This can provide an ideal opportunity for growth and transmission of pathogens, if care is not taken.

Table 41.4 Basic Approaches to Food Preservation

Approach	Examples of Process
Removal of microorganisms	Avoidance of microbial contamination; physical filtration, centrifugation
Low temperature	Refrigeration, freezing
High temperature	Partial or complete heat inactivation of microorganisms (pasteurization and canning)
Reduced water availability	Water removal, as with lyophilization or freeze drying; use of spray dryers or heating drums; decreasing water availability by addition of solutes such as salt or sugar
Chemical-based preservation	Addition of specific inhibitory compounds (e.g., organic acids, nitrates, sulfur dioxide)
Radiation	Use of ionizing (gamma rays) and nonionizing (UV) radiation
Microbial product–based inhibition	The addition of substances such as bacteriocins to foods to control food-borne pathogens

Removal of Microorganisms

Microorganisms can be removed from water, wine, beer, juices, soft drinks, and other liquids by filtration. This can keep bacterial populations low or eliminate them entirely. Prefilters and centrifugation often are used to maximize filter life and effectiveness. Several major brands of beer are filtered rather than pasteurized to better preserve the flavor and aroma of the original product.

Low Temperature

Refrigeration at 5°C retards microbial growth, although with extended storage, psychrophiles and psychrotrophs will eventually grow and produce spoilage. Slow microbial growth at temperatures below −10°C has been described, particularly with fruit juice concentrates, ice cream, and some fruits. Some microorganisms are very sensitive to cold and their numbers will be reduced, but cold does not lead to significant decreases in overall microbial populations. Temperature effects on microbial growth (pp. 125–27)

High Temperature

Controlling microbial populations in foods by means of high temperatures can significantly limit disease transmission and spoilage.

Heating processes, first used by Nicholas Appert in 1809 (**Box 41.1**), provide a safe means of preserving foods, particularly when carried out in commercial **canning** operations (**figure 41.7**). Canned food is heated in special containers called retorts at about 115°C for intervals ranging from 25 to over 100 minutes. The precise time and temperature depend on the nature of the food. Sometimes canning does not kill all the microorganisms, but only those that will spoil the food (remaining bacteria are unable to grow due to acidity of the food, as an example). After heat treatment the cans are cooled as rapidly as possible, usually with cold water. Quality control and processing effectiveness are sometimes compromised, however, in home processing of foods, especially with less acidic (pH values greater than 4.6) products such as green beans or meats. Destruction of microorganisms by heat (pp. 139–42)

Pasteurization involves heating food to a temperature that kills disease-causing microorganisms and substantially reduces the levels of spoilage organisms. In the processing of milk, beers, and fruit juices by conventional low-temperature holding (LTH) pasteurization, the liquid is maintained at 62.8°C for 30 minutes. Products can also be held at 71°C for 15 seconds, a high-temperature, short-time (HTST) process; milk can be treated at 141°C for 2 seconds for ultra-high-temperature (UHT) processing. Shorter-term processing results in improved flavor and extended product shelf life.

Such heat treatment is based on a statistical probability that the number of remaining viable microorganisms will be below a

An Army Travels on Its Stomach

The movement and maintenance of large numbers of military personnel have always been limited by food supplies. The need to maintain large numbers of troops under hostile and inclement conditions led the French government in 1795 to offer a prize of 12,000 francs to the individual who could preserve foods for use under field conditions. Eventually the prize was awarded to Nicholas Appert, a candy maker, for his development of a heating process in which meats and other products could be preserved under sealed conditions.

Appert's work was based on the assumptions that heating and boiling control "ferments" and that sealing the food in bottles before heating it avoids the effects of air on spoilage. Despite Leeuwenhoek's earlier work, Appert did not have the concept of microorganisms to assist him in explaining the effectiveness of his process. His containers were large glass bottles, sealed with laminated corks and fish glue. With extreme care and attention to detail, he was able to heat these bottles in boiling water to provide food that could be stored for several years. Appert's work was an important foundation for the later studies of Louis Pasteur.

Figure 41.7 A Canning Operation. Microbial control is important in the processing and preservation of many foods. Worker pouring peas into a large, clean vat during the preparation of vegetable soup. After preparation the soup is transferred to cans. Each can is heated for a short period, sealed, processed at temperatures around 110–121°C in a canning retort to destroy spoilage microorganisms, and finally cooled.

Figure 41.8 Food Preservation by Canning. This technique is widely used and very effective. Improper canning can occasionally occur, as shown by this bent and leaking can.

certain level after a particular heating time at a specific temperature. This process is discussed in detail on pp. 138–40.

Despite efforts to eliminate spoilage microorganisms during canning, sometimes canned foods are spoiled (**figure 41.8**). This may be due to spoilage before canning, underprocessing during canning, and leakage of contaminated water through can seams during cooling. Spoiled food can be altered in such characteristics as color, texture, odor, and taste. Organic acids, sulfides, and gases (particularly CO_2 and H_2S) may be produced. In flat sour spoilage no gas is generated and the can does not swell, but its contents are rendered sour by the presence of fermentation acids. If spoilage microorganisms produce gas, both ends of the can will bulge outward to give a swell. Sometimes the swollen ends can be moved by thumb pressure (soft swells); in other cases the gas pressure is so great that the ends cannot be dented by hand (hard swells). It should be noted that swelling is not always due to microbial spoilage. Acid in high-acid foods may react with the iron of the can to release hydrogen and generate a hydrogen swell. Hydrogen sulfide production by *Desulfotomaculum* can cause "sulfur stinkers."

Water Availability

Dehydration, such as lyophilization to produce freeze-dried foods, is now a common means of eliminating microbial growth. The modern process is simply an update of older procedures in which grains, meats, fish, and fruits were dried. The combination of free-water loss with an increase in solute concentration in the remaining water makes this type of preservation possible.

Chemical-Based Preservation

Various chemical agents can be used to preserve foods, and these substances are closely regulated by the U.S. Food and Drug Administration and are listed as being "generally recognized as safe" or

Table 41.5 Major Groups of Chemicals Used in Food Preservation

Preservatives	Approximate Maximum Use Range	Organisms Affected	Foods
Propionic acid/propionates	0.32%	Molds	Bread, cakes, some cheeses, inhibitor of ropy bread dough
Sorbic acid/sorbates	0.2%	Molds	Hard cheeses, figs, syrups, salad dressings, jellies, cakes
Benzoic acid/benzoates	0.1%	Yeasts and molds	Margarine, pickle relishes, apple cider, soft drinks, tomato ketchup, salad dressings
Parabens[a]	0.1%	Yeasts and molds	Bakery products, soft drinks, pickles, salad dressings
SO_2/sulfites	200–300 ppm	Insects and microorganisms	Molasses, dried fruits, wine, lemon juice (not to be used in meats or other foods recognized as sources of thiamine)
Ethylene/propylene oxides	700 ppm	Yeasts, molds, vermin	Fumigant for spices, nuts
Sodium diacetate	0.32%	Molds	Bread
Dehydroacetic acid	65 ppm	Insects	Pesticide on strawberries, squash
Sodium nitrite	120 ppm	Clostridia	Meat-curing preparations
Caprylic acid	—	Molds	Cheese wraps
Ethyl formate	15–200 ppm	Yeasts and molds	Dried fruits, nuts

[a]Methyl-, propyl-, and heptyl-esters of *p*-hydroxybenzoic acid.

GRAS (**table 41.5**). They include simple organic acids, sulfite, ethylene oxide as a gas sterilant, sodium nitrite, and ethyl formate. These chemical agents affect microorganisms by disrupting a critical cell factor. For example, they may damage the plasma membrane or denature various cell proteins. Still other compounds interfere with the functioning of nucleic acids, thus inhibiting cell reproduction.

The effectiveness of many of these chemical preservatives depends on the food pH. As an example, sodium propionate is most effective at lower pH values, where it is primarily undissociated and able to be taken up by lipids of microorganisms. Breads, with their low pH values, often contain sodium propionate as a preservative. Chemical preservatives are used with grain, dairy, vegetable, and fruit products. Sodium nitrite is an important chemical used to help preserve ham, sausage, bacon, and other cured meats by inhibiting the growth of *Clostridium botulinum* and the germination of its spores. This protects against botulism and reduces the rate of spoilage. Besides increasing meat safety, nitrite decomposes to nitric acid, which reacts with heme pigments to keep the meat red in color. Current concern about nitrite arises from the observation that it can react with amines to form carcinogenic nitrosamines. Nitrite is added in very small amounts, and eventually it may be possible to eliminate its use entirely.

Radiation

Radiation, both ionizing and nonionizing, has an interesting history in relation to food preservation. Ultraviolet radiation is used to control populations of microorganisms on the surfaces of laboratory and food-handling equipment, but it does not penetrate food. The major method used for radiation sterilization of food is gamma irradiation from a cobalt-60 source (*see p. 144*). Such electromagnetic radiation has excellent penetrating power and must be used with moist foods because the radiation produces peroxides from water in the microbial cells, resulting in oxidation of sensitive cellular constituents. This process of **radappertization,** named after Nicholas Appert, can extend the shelf life of seafoods, fruits, and vegetables. To sterilize meat products, commonly 4.5 to 5.6 megarads are used.

Among the more interesting radiation-resistant bacteria that have been studied is *Deinococcus radiodurans* (*see section 21.2*). This bacterium has a complex cell wall structure and tetrad-forming growth patterns (*see figure 21.2*). It also has an extraordinary capacity to withstand high doses of radiation, although the mechanism for its resistance is not understood.

Microbial Product–Based Inhibition

There is increasing interest in the use of **bacteriocins** (*see p. 712*) for the preservation of foods. Bacteriocins are bactericidal proteins active against closely related bacteria, which bind to specific sites on the cell, and affect cell membrane integrity and function. The only currently approved product is nisin. Nisin, produced by some strains of *Streptococcus lactis,* is a small hydrophobic protein. It is nontoxic to humans and affects mainly gram-positive bacteria, especially *Enterococcus faecalis.* Nisin can be used particularly in low-acid foods to improve inactivation of *Clostridium botulinum* during the canning process or to inhibit germination of any surviving spores.

Bacteriocins function by dissipating the proton motive force (PMF) of a susceptible bacterium. These compounds have a wide

Table 41.6 Major Food-Borne Infectious Diseases

Disease	Organism	Incubation Period and Characteristics	Major Foods Involved
Salmonellosis	*S. typhimurium, S. enteritidis*	8–48 hr Enterotoxin and cytotoxins	Meats, poultry, fish, eggs, dairy products
Arcobacter diarrhea	*Arcobacter butzleri*	Severe diarrhea, recurrent cramps	Meat products, especially poultry
Campylobacteriosis	*Campylobacter jejuni*	Usually 2–10 days Most toxins are heat-labile	Milk, pork, poultry products, water
Listeriosis	*L. monocytogenes*	Varying periods Related to meningitis and abortion; newborns and the elderly especially susceptible	Meat products, especially pork and milk
Escherichia coli diarrhea and colitis	*E. coli,* including serotype O157:H7	24–72 hr Enterotoxigenic positive and negative strains; hemorrhagic colitis	Undercooked ground beef, raw milk
Shigellosis	*Shigella sonnei, S. flexneri*	24–72 hr	Egg products, puddings
Yersiniosis	*Yersinia enterocolitica*	16–48 hr Some heat-stable toxins	Milk, meat products, tofu
Plesiomonas diarrhea	*Plesiomonas shigelloides*	1–2 hr	Uncooked mollusks and foreign travel
Vibrio parahaemolyticus gastroenteritis	*V. parahaemolyticus*	16–48 hr	Seafood, shellfish

variety of names, depending on the organisms that produce them. Bacteriocins function by the formation of hydrophilic pores in a susceptible bacterium and the release of low-molecular-weight molecules; this may occur as a result of peptidoglycan synthesis inhibition and detergent-like effects on the cytoplasmic membrane. Bacteriocin addition to foods such as cheddar cheese can lead to a two- to threefold reduction in *Listeria monocytogenes* in 180-day-old cheeses. Similar compounds also occur in the eucaryotes.

1. Describe the major approaches used in food preservation.
2. What types of chemicals can be used to preserve foods?
3. Nitrite is often used to improve the storage characteristics of prepared meats. What toxicological problems may result from the use of this chemical?
4. Under what conditions can ultraviolet light and gamma radiation be used to control microbial populations in foods and in food preparation? What is radappertization?
5. In principle, how do bacteriocins such as nisin function? What bacterial genus produces this important polypeptide?

41.4 Food-Borne Diseases

Food-borne illnesses impact the entire world. In the United States, based on recent information from the Centers for Disease Control and Prevention, annual incidences of food-related diseases involve 76 million cases, of which only 14 million can be attributed to known pathogens. Food-borne diseases result in 325,000 hospitalizations and at least 5,000 deaths per year. Since 1942, the number of recognized food-borne pathogens has increased over fivefold! Are these new microorganisms? In most cases, these pathogens are simply agents that we now can describe, based on an improved understanding of microbial diversity. Recent estimates indicate that Norwalk-like viruses, *Campylobacter jejuni* and *Salmonella* are the major causes of food-borne diseases. In addition, *Escherichia coli* O157:H7 and *Listeria* are important food-related pathogens.

Many diseases transmitted by foods, or food poisonings, are discussed in chapters 38 and 39, and only a few of the more important food-borne bacterial pathogens are mentioned here. There are two primary types of food-related diseases: food-borne infections and food intoxications. Food-borne and waterborne diseases (pp. 891–93, 926–33)

All these food-borne diseases are associated with poor hygienic practices. Whether by water or food transmission, the fecal-oral route is maintained, with the food providing the vital link between hosts. Fomites, such as sink faucets, drinking cups, and cutting boards, also play a role in the maintenance of the fecal-oral route of contamination.

Food-Borne Infection

A **food-borne infection** involves the ingestion of the pathogen, followed by growth in the host, including tissue invasion and/or the release of toxins. The major diseases of this type are summarized in **table 41.6** (*see also table 39.5*).

Salmonellosis results from ingestion of a variety of *Salmonella* serovars, particularly *typhimurium* and *enteritidis* (*see also section 39.4*). Gastroenteritis is the disease of most concern in relation to foods such as meats, poultry, and eggs, and the onset of symptoms occurs after an incubation time as short as 8 hours. *Salmonella* infection can arise from contamination by workers in food-processing plants and restaurants, as well in canning processes (**Box 41.2**).

Campylobacter jejuni is considered a leading cause of acute bacterial gastroenteritis in humans and can affect persons of all ages. This important pathogen is often transmitted by uncooked or poorly cooked poultry products. For example, transmission

Box 41.2

Typhoid Fever and Canned Meat

Minor errors in canning have led to major typhoid outbreaks. In 1964 canned corned beef produced in South America was cooled, after sterilization, with nonchlorinated water; the vacuum created when the cans were cooled drew *S. typhi* into some of the cans, which were not completely sealed. This contaminated product was later sliced in an Aberdeen, Scotland, food store, and the meat slicer became a continuing contamination source; the result was a major epidemic that involved 400 people. The *S. typhi* was a South American strain, and eventually the contamination was traced to the contaminated water used to cool the cans.

This case emphasizes the importance of careful food processing and handling to control the spread of disease during food production and preparation.

often occurs when kitchen utensils and containers are used for chicken preparation and then for salads. Contamination with as few as 10 viable *Campylobacter jejuni* cells can lead to the onset of diarrhea. *Campylobacter jejuni* also is transmitted by raw milk, and the organism has been found on various red meats. Thorough cooking of food prevents this disease transmission problem.

Listeriosis, caused by *Listeria monocytogenes* (*see section 39.4*), is of continuing interest, as shown by the outbreak that occurred in Southern California in 1985. This outbreak was caused by improper pasteurization of milk used in the commercial production of Mexican-style cheeses. At least 86 cases of infection occurred, including 58 cases involving mother-infant pairs. Forty-seven people died. The outbreak was traced to pinhole leaks in the heat exchangers of a pasteurizing unit. The leaks allowed incoming raw milk to contaminate the pasteurized milk before production of the cheese. *Listeria* is difficult to work with because an extended incubation of samples is required for growth and detection.

Escherichia coli is now recognized as an important food-borne disease organism. Enteropathogenic, enteroinvasive, and enterotoxigenic types can cause diarrhea. *E. coli* O157:H7 (*see p. 932*) with its specific somatic (O) and flagellar (H) antigens (*see Box 33.3*), is thought to have acquired enterohemorrhagic genes from *Shigella,* including the genes for shigalike verocytotoxins. This produced a new pathogenic strain, first discovered in 1982 and now known around the world. The pathogen is spread by the fecal-oral route, and an infectious dose appears to be only 500 bacteria. Enterohemorrhagic *E. coli* has been found in meat products such as hamburger and salami, in unpasteurized fruit drinks, on fruits and vegetables, and in untreated well water. In August 1997, 25 million pounds of hamburger were recalled by a meat processing plant because of *E. coli* O157:H7 contamination. A few years ago a child died in Denver, Colorado, after drinking a popular unpasteurized fruit drink that contained the organism. Those most susceptible to this pathogen are the young.

Prevention of food contamination by *E. coli* O157:H7 is essential from the time of production until consumption. Hygiene must be monitored carefully in larger-volume slaughterhouses where contact of meat with fecal material can occur. Even fruits and vegetables should be handled with care because disease outbreaks have been caused by imported produce. Caution also is essential at the point of use. For example, avoidance of food contamination by hands and utensils is critical. Utensils used with raw foods should not contact cooked food; proper cleaning of cutting boards and utensils minimizes contamination. It may be possible to reduce this threat by destroying the pathogen with gamma irradiation, a food preservation method under consideration for wider use.

An infectious agent of increasing worldwide concern with respect to food safety is a prion that causes the poorly understood new variant Creutzfeldt-Jakob Disease (vCJD). This is one of a group of progressively degenerative neuronal diseases termed transmissible spongiform encephalopathies (TSEs), and is associated with beef cattle. It is often called the "mad cow disease." With recent occurrences of new variant CJD in humans, bans on beef importation have been put in place in many areas. Major problems in controlling new variant CJD include the long incubation period, which can last many years before onset of the invariably fatal disease, and the lack of reliable detection methods. The major means of vCJD transmission between animals is the use of mammalian tissue in ruminant animal feeds; at the present time, there are major problems in detecting such prohibited animal products in ruminant feeds. Creutzfeldt-Jakob Disease (CJD), *section 38.5*; Prions, *see section 18.9*

Foods that are transported and consumed in an uncooked state are an increasingly important source of food-borne infection. This is especially of concern when there is a possibility of contact with contaminated water at any point between production and consumption. The problem becomes more critical with increasingly rapid movement of people and products around the world. International trade in uncooked foods, aided by rapid air transport, provides many opportunities for disease transmission. Fresh foods such as sprouts, seafood, and raspberries pose significant hazards, which will be discussed here.

Sprouts are an increasingly popular part of the new "healthy" life-style. They are fresh, delicate and form an exciting garnish to complement a variety of foods. Unfortunately, if these are not germinated in pathogen-free waters and grown under sanitary conditions, major growth of pathogens can occur. Care must be taken especially when the seeds are germinated, because a newly germinating seed releases organic matter and creates a **spermosphere** that stimulates microbial growth in a way similar to that which occurs in the rhizosphere. Sprouts produced in areas of the world where there is poor control of water quality and sanitation should be used with caution. Contaminated alfalfa, beans, watercress, mungbean, mustard, and soybean sprouts can be major sources of typhoid and cholera.

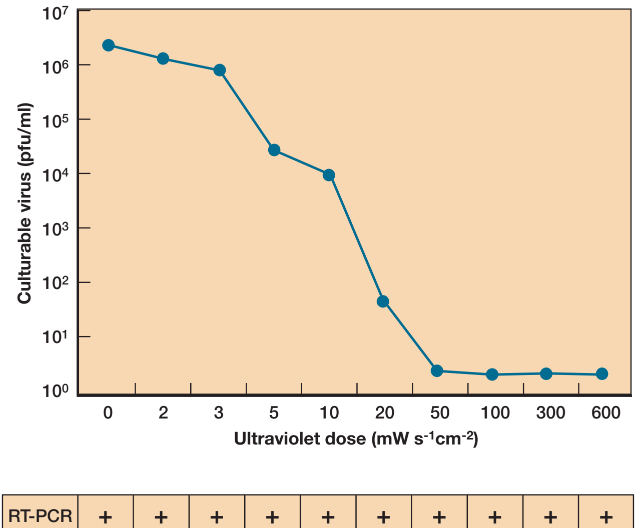

Figure 41.9 Cultural versus Molecular-Based Virus Detection. Comparison of plaque-forming ability and recovery of RNA from poliovirus type 2 by RT-PCR with varying UV doses. Even when plaque-forming ability is lost, nucleic acids are still detectable.

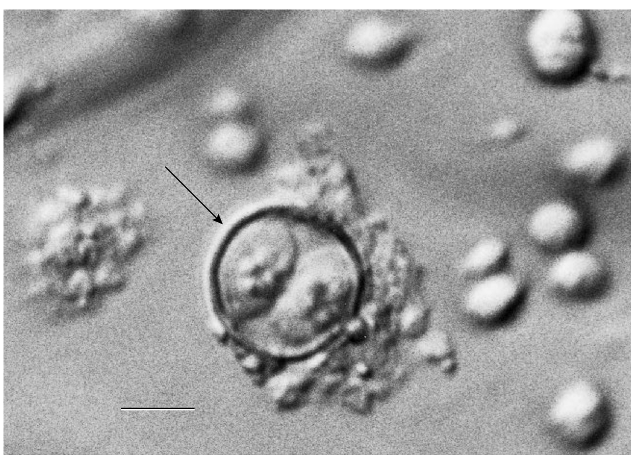

Figure 41.10 *Cyclospora cayetanensis,* an Important Contaminant of Raw Foods. ***Cyclospora cayetanensis*** can be recognized in waste waters and after recovery from contaminated foods due to the occurrence of an oocyst with two sporocysts. Bar = 5 µm.

Shellfish and finfish also present major concerns. Raw sewage can contaminate shellfish-growing areas; in addition, waterborne pathogens such as *Vibrio* are more prevalent in the water column during the warm months (e.g., in Chesapeake Bay on the mid-Atlantic coast of the United States). Viruses also can be a problem. Oysters are filter feeders that process several liters of water per day, leading to the potential concentration of at least 100 types of enteric viruses. Reverse transcriptase PCR (RT-PCR) can be used to detect RNA viruses in oysters based on the presence of their nucleic acids. However, the inability of molecular techniques to differentiate between infectious and noninfectious particles is a major problem. For example, UV treatment can inactivate many RNA viruses without eliminating the RT-PCR signal, although the virions no longer replicate in a suitable tissue culture environment (**figure 41.9**). Heavy rainfall in shellfish areas can cause runoff of pathogens from adjacent summer cottage septic systems and contaminate coastal waters. Often it is necessary to ban shellfish harvesting until the animals void pathogens from their digestive systems. Alternatively, shellfish from contaminated areas can be moved to clean waters to allow them to clean their digestive systems. The polymerase chain reaction (pp. 326–27)

Raspberries provide an important example of another major problem: the rapid air transport of raw agricultural products around the world. A major recent outbreak of *Cyclospora cayetanensis* poisoning was traced to raspberries imported from Central America into the United States and Canada. In the growth and harvesting process, the raspberries apparently became contaminated, resulting in serious diarrhea in affected individuals. This organism has a complex life cycle, which is not fully understood at the present time. In comparison with *Giardia* and *Cryptosporidium,* which are infective immediately after being shed in feces, *Cyclospora* is not immediately infectious; sporulation or maturing requires 12 hours after release from the body. The mature infective cyst has two sporocysts (**figure 41.10**), an important criterion for confirming the presence of this parasite on foods or in the environment. *Cyclospora* (p. 653)

1. What are the major food-borne diseases in the United States?
2. Discuss the major characteristic of a food-borne infection in terms of the time required between ingestion of the pathogen and the onset of the disease. Why does this occur?
3. What common food is often related to *Campylobacter*-caused gastroenteritis? What means can be used to control the occurrence of this disease from this source?
4. Give some of the sources of *E. coli* O157:H7 that have been of concern in terms of disease transmission.
5. Why is new variant Creutzfeldt-Jakob disease (vCJD) of such concern?
6. What are some uncooked foods that have been implicated in food-borne disease transmission?
7. Why is the spermosphere important for pathogen survival in sprouts?

Food-Borne Intoxications

Microbial growth in food products also can result in a **food intoxication,** as summarized in table 39.5 (see *pp. 928–29*). Intoxication produces symptoms shortly after the food is consumed because growth of the disease-causing microorganism is not required. Toxins produced in the food can be associated with microbial cells or can be released from the cells.

Most *Staphylococcus aureus* strains cause a staphylococcal enteritis related to the synthesis of extracellular toxins (*see section 39.4*). These are heat-resistant proteins, and heating will not usually render the food safe. The effects of the toxins are quickly felt, with disease symptoms occurring within 2 to 6 hours. The main reservoir of *S. aureus* is the human nasal cavity. Frequently *S. aureus* is transmitted to a person's hands and then is introduced into food during preparation. Growth and enterotoxin production usually occur when contaminated foods are held at room temperature for several hours.

Three gram-positive rods are known to cause food intoxications: *Clostridium botulinum, C. perfringens,* and *Bacillus cereus* (*see table 39.5*). *C. botulinum* poisoning is discussed in chapter 39, and *C. perfringens* intoxication is described here.

Clostridium perfringens food poisoning is one of the more widespread food intoxications. These microorganisms, which produce exotoxins, must grow to levels of approximately 10^6 bacteria per gram or higher in a food to cause disease. At least 10^8 bacteria must be ingested. They are common inhabitants of soil, water, food, spices, and the intestinal tract. Upon ingestion the cells sporulate in the intestine. The enterotoxin is a spore-specific protein and is produced during the sporulation process. Enterotoxin can be detected in the feces of affected individuals. *Clostridium perfringens* food poisoning is common and occurs after meat products are heated, which results in O_2 depletion. If the foods are cooled slowly, growth of the microorganism can occur. At 45°C, enterotoxin can be detected 3 hours after growth is initiated. Onset of the symptoms—watery diarrhea, nausea, and abdominal cramps—usually occurs in about 8 to 16 hours.

Baked potatoes served in aluminum foil can provide a unique environment for pathogenic microorganisms. Potatoes, even after washing, are covered by *Clostridium botulinum,* which naturally occurs in the soil. If the aluminum foil-covered potatoes are not heated sufficiently in the baking process, surviving clostridia can proliferate after removal of the potatoes from the oven and rapidly produce toxins.

Bacillus cereus also is of concern in starchy foods. It can cause two distinct types of illnesses depending on the type of toxin produced: an emetic illness characterized by nausea and vomiting with an incubation time of 1 to 6 hours, and a diarrheal type, with an incubation of 4 to 16 hours. The emetic type is often associated with boiled or fried rice, while the diarrheal type is associated with a wider range of foods.

1. What are some of the major genera involved in food-borne intoxications?
2. How does a food-borne intoxication differ from a food-borne infection?

41.5 Detection of Food-Borne Pathogens

A major problem in maintaining food safety is the need to rapidly detect microorganisms in order to curb outbreaks that can affect large populations. This is especially important because of widescale distribution of perishable foods. Standard culture techniques (*see chapter 5*) may require days to weeks for positive identification of pathogens. Identification is often complicated by the low numbers of pathogens compared with the background microflora. Furthermore, the varied chemical and physical composition of foods can make isolation difficult. Fluorescent antibody, enzyme-linked immunoassays (ELISAs), and radioimmunoassay techniques have proven of value (*see section 33.3*). These can be used to detect small amounts of pathogen-specific antigens.

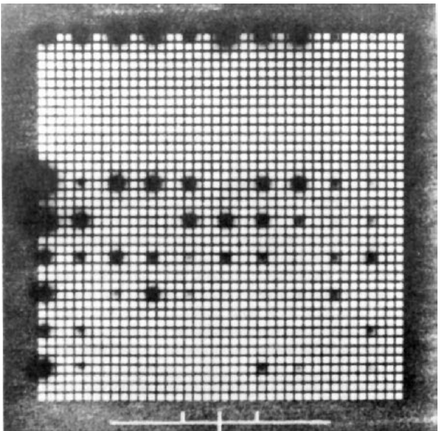

Figure 41.11 Molecular Probes and Food Microbiology. Molecular techniques are finding increasing use in microbial analysis of foods. Autoradiogram of a radioactive-labeled *Listeria monocytogenes* probe against 100 *Listeria* cultures. Only the *Listeria monocytogenes* cultures show sequence homology and binding with the DNA probe, darkening the autoradiogram film. The other *Listeria* spp. do not react with the probe.

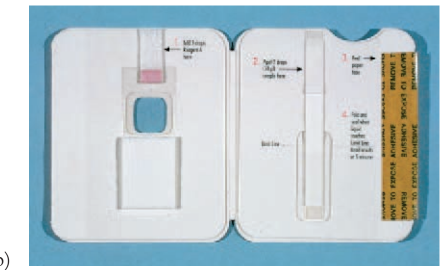
Molecular techniques also are increasingly used in identification. The basic methods of analysis and manipulation of DNA and RNA are discussed in chapter 14. These methods are valuable for three purposes: (1) to detect the presence of a single, specific pathogen; (2) to detect viruses that cannot be grown conveniently; and (3) to identify slow-growing or noncultured pathogens.

Pathogens now can be identified by detecting specific DNA or RNA base sequences with **probes.** These usually are 14 to 40 bases in length. They may be created by generating fragments with restriction endonucleases or through direct chemical synthesis. Probes are labeled by linking them to a variety of enzymatic, isotopic, chromogenic, or luminescent/fluorescent markers. A major advantage of their use is the speed with which specific microorganisms can be detected in a set of cultures, as shown in **figure 41.11.** In this example, a hydrophobic grid-membrane system has been used. The *Listeria monocytogenes* cultures are radioactive, indicating that they have bound the probe, while other *Listeria* species do not show probe binding.

Another example of the use of molecular techniques is provided by pathogenic *E. coli.* Currently *E. coli* O157:H7 is isolated and identified using selective culture media, rapid identification kits (*see* **figure 41.12**), rapid probe-based identification procedures, serotype-specific probes, and PCR techniques. These tech-

(a)



(b)

Figure 41.12 A Rapid Test Kit for the Identification of *Escherichia coli* O157:H7 after Growth in an Enrichment Medium. (**a**) Complete test kit containing the immunochromatic membrane assay; (**b**) interior with sample analysis instructions.

niques also have been extended to allow the detection of a few target cells in large populations of background microorganisms. For example, by using the polymerase chain reaction, as few as 10 toxin-producing *E. coli* cells can be detected in a population of 100,000 cells isolated from soft-cheese samples.

As few as two colony forming units of *Salmonella* can be detected with a special PCR system (**figure 41.13**). This procedure makes it possible to confirm *Salmonella* presence within 24 to 48 hours, whereas 3 to 4 days is needed for presumptive identification with standard culture procedures. Confirmation of *Salmonella* presence would then require additional time. Frequently, to improve the sensitivity and increase the speed of this method, a preenrichment step will be used before PCR. In this type of analysis, especially for well-characterized pathogens, all culture and PCR reagents are provided in "pill" form to speed the entire process. PCR is now being used for rapid detection of food-borne pathogens. In recent studies, the construction of specific 159 and 1,223 base pair PCR products, which can be separated electrophoretically, has made it possible to detect *Campylobacter jejuni* and *Arcobacter butzleri* in the same sample within 8 hours.

A major advance in the detection of food-borne pathogens is the use of standardized pathogen DNA patterns, or "food-borne pathogen fingerprinting." The Centers for Disease Control and Prevention in the United States has established a new program, called **PulseNet,** in which pulsed-field gel electrophoresis (PFGE) is used under carefully controlled and duplicated conditions to determine the distinctive DNA pattern of each bacterial pathogen. With this uniform procedure, it is possible to link pathogens associated with disease outbreaks in different parts of the world to a specific food source. Data from around the world are being used in **FoodNet,** an active surveillance network, to follow nine major food-borne diseases. Using the FoodNet approach, it is possible to trace the course and cause of infection in days and not weeks. As an example, a *Shigella* outbreak in three different areas of North America was traced to Mexican parsley that had been tainted with polluted irrigation water. This program has resulted in more rapid establishment of epidemiological linkages and a decreased occurrence of many of these important food-borne diseases.

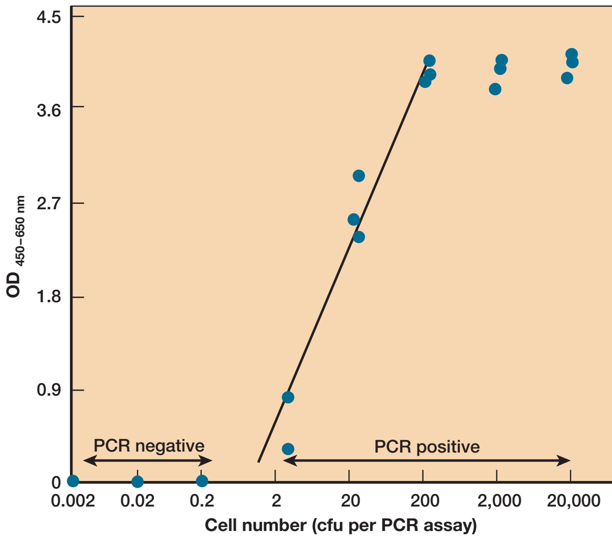


Figure 41.13 Polymerase Chain Reaction (PCR)-Based Pathogen Detection. Comparison of PCR sensitivity and growth for *Salmonella agona* detection. The Probalia™ PCR system can detect as few as two colony forming units (CFU) of the pathogen. OD = optical density.

1. What is a "probe" and how is it used for detection of food-borne pathogens?
2. How is the polymerase chain reaction used in pathogen detection?
3. How are PulseNet and FoodNet used in the surveillance of food-borne diseases?

41.6 Microbiology of Fermented Foods

Over the last several thousand years, fermentation has been a major way of preserving food. Microbial growth, either of natural or inoculated populations, causes chemical and/or textural changes to form a product that can be stored for extended periods. The fermentation process also is used to create new, pleasing food flavors and odors.

The major fermentations used in food microbiology are the lactic, propionic, and ethanolic fermentations, as discussed in section 9.3. These fermentations are carried out with a wide range of cultures, many of which have not been characterized.

Fermented Milks

Throughout the world, at least 400 different fermented milks are produced. These fermentations are carried out by mesophilic, thermophilic, and therapeutic lactic acid bacteria, as well as by yeasts and molds as noted in **table 41.7.** Only major examples of these fermentation types will be discussed in this section.

Table 41.7 Major Categories and Examples of Fermented Milk Products

Category	Typical Examples
I. Lactic fermentations	
Mesophilic	Buttermilk
	Cultured buttermilk
	Långofil
	Tëtmjolk
	Ymer
Thermophilic	Yogurt, laban, zabadi, labneh, skyr
	Bulgarian buttermilk
Therapeutic	Biogarde®, Bifighurt®
	Acidophilus milk, yakult
	Cultura-AB®
II. Yeast-lactic fermentations	Kefir, koumiss, acidophilus-yeast milk
III. Mold-lactic fermentations	Viili

Source: Table 3.1, p. 58. In B. A. Law, editor. 1997. *Microbiology and Biochemistry of cheese and fermented milk,* 2nd ed. New York: Chapman and Hall.

Mesophilic

Mesophilic milk fermentations result from similar manufacturing techniques, in which acid produced through microbial activity causes protein denaturation. To carry out the process, one usually inoculates milk with the desired starter culture (**Box 41.3**); incubates it at optimum temperature (approximately 20 to 30°C), and then stops microbial growth by cooling. *Lactobacillus* spp. and *Lactococcus lactis* cultures are used for aroma and acid production. The organism *Lactococcus lactis* subsp. *diacetilactis* converts milk citrate to diacetyl, which gives a special buttery flavor to the finished product. The use of these microorganisms with skim milk produces cultured buttermilk, and when cream is used, sour cream is the result. The genus Lactobacillus (pp. 529–30); The genus Lactococcus (pp. 531–33)

Thermophilic

In addition to mesophilic milk fermentations, thermophilic fermentations can be carried out at temperatures around 45°C. An important example is yogurt production. **Yogurt** is made using a special starter culture in which two major bacteria are present in a 1:1 ratio: *S. thermophilus* and *L. bulgaricus.* With these organisms growing in concert, acid is produced by *Streptococcus,* and aroma components are formed by the *Lactobacillus.* Freshly prepared yogurt contains 10^9 bacteria per gram.

Therapeutic

Fermented milks may have beneficial therapeutic effects. Acidophilus milk is produced by using *Lactobacillus acidophilus.*

Box 41.3

Starter Cultures, Bacteriophage Infections, and Plasmids

Cultures of lactic acid bacteria, called **starter cultures,** are added to milk during the preparation of many dairy products. For example, *Streptococcus lactis* and *S. cremoris* are used in the production of cheese. One of the greatest problems for the dairy industry is the presence of bacteriophages that destroy these starter cultures. Lactic acid production by a heavily phage-infected starter culture can come to a halt within 30 minutes. The industry has tried to overcome this problem by practicing aseptic techniques in order to reduce phage contamination, and by selecting for phage-resistant bacterial cultures.

Most efforts at control have not been successful in the longer term. It has been found that the very aseptic techniques and phage-resistant pure cultures used to attempt to solve this problem actually were parts of the problem. The most stable and dependable cultures, called P starter cultures, contain the bacteriophages in a pseudolysogenic state. When cultures are grown without phages or under aseptic conditions (L starters), they lose their phage resistance. The key to this riddle appears to be plasmids, which can block phage adsorption. The loss of the plasmids in a subpopulation of the bacteria allows the phage carrier state to be established. New phages can develop by acquiring restriction enzymes (*see section 14.1*) from plasmids. These modified phages again become lytic, establishing a new equilibrium in the population.

Other control approaches are being tested. Antisense RNA is now being used in an attempt to provide an agent against bacteriophage genes to help in the constant struggle between lactic acid bacteria and their phages.

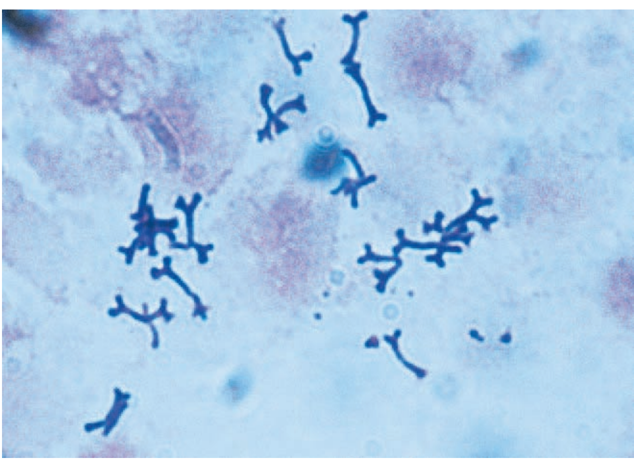

Figure 41.14 Bifidobacteria. Cultured milks are increasing in popularity. A light micrograph of *Bifidobacterium,* a microorganism suggested to provide many health benefits.

Figure 41.15 Examples of Bifid-Amended Dairy Products. These are produced in many countries.

L. acidophilus may modify the microbial flora in the lower intestine, thus improving general health, and it often is used as a dietary adjunct. Many microorganisms in fermented dairy products stabilize the bowel microflora, and some appear to have antimicrobial properties. The exact nature and extent of health benefits are still unclear but may involve minimizing lactose intolerance, lowering serum cholesterol, and possibly exhibiting anticancer activity. Several lactobacilli have antitumor compounds in their cell walls. Such findings suggest that diets including lactic acid bacteria, especially *L. acidophilus,* may contribute to the control of colon cancer.

Another interesting group used in milk fermentations are the bifidobacteria. The genus *Bifidobacterium* contains irregular, nonsporing, gram-positive rods that may be club-shaped or forked at the end (**figure 41.14**). Bifidobacteria are nonmotile, anaerobic, and ferment lactose and other sugars to acetic and lactic acids. They are typical residents of the human intestinal tract and were discovered in 1906. Many beneficial properties are attributed to them. Bifidobacteria are thought to help maintain the normal intestinal balance, while improving lactose tolerance; to possess antitumorigenic activity; and to reduce serum cholesterol levels. In addition, some believe that they promote calcium absorption and the synthesis of B-complex vitamins. It has also been suggested that bifidobacteria reduce or prevent the excretion of rotaviruses, a cause of diarrhea among children. Bifid-amended fermented milk products are now available in various parts of the world (**figure 41.15**).

Yeast Lactic

Yeast-lactic fermentations include **kefir,** a product with an ethanol concentration of up to 2%. This unique fermented milk originated in the Caucasus Mountains and it is produced east into Mongolia. Kefir products tend to be foamy and frothy, due to active carbon dioxide production. This process is based on the use of kefir "grains" as an inoculum. These are coagulated lumps of casein that contain yeasts, lactic acid bacteria, and acetic acid bacteria (**figure 41.16**). In this fermentation, the grains are used to inoculate the fresh milk and then recovered at the end of the fermentation. Originally, kefir was produced in leather sacks hung by the front door during the day, and passersby were expected to push and knead the sack to mix and stimulate the fermentation. Fresh milk could be added occasionally to maintain activity.

Mold Lactic

Mold-lactic fermentation results in a unique Finnish fermented milk called viili. The milk is placed in a cup and inoculated with a mixture of the fungus *Geotrichium candidum* and lactic acid bacteria. The cream rises to the surface, and after incubation at 18 to 20°C for 24 hours, lactic acid reaches a concentration of 0.9%. The fungus forms a velvety layer across the top of the final product, which also can be made with a bottom fruit layer to add extra flavor.

1. What are the major types of milk fermentations?
2. Briefly describe how buttermilk, sour cream, and yogurt are made.
3. What is unique about the morphology of *Bifidobacterium?* Why is it used in milk?
4. How and where are kefir and viili made?

Cheese Production

Cheese is one of the oldest human foods and is thought to have been developed approximately 8,000 years ago. About 2,000 distinct varieties of cheese are produced throughout the world,

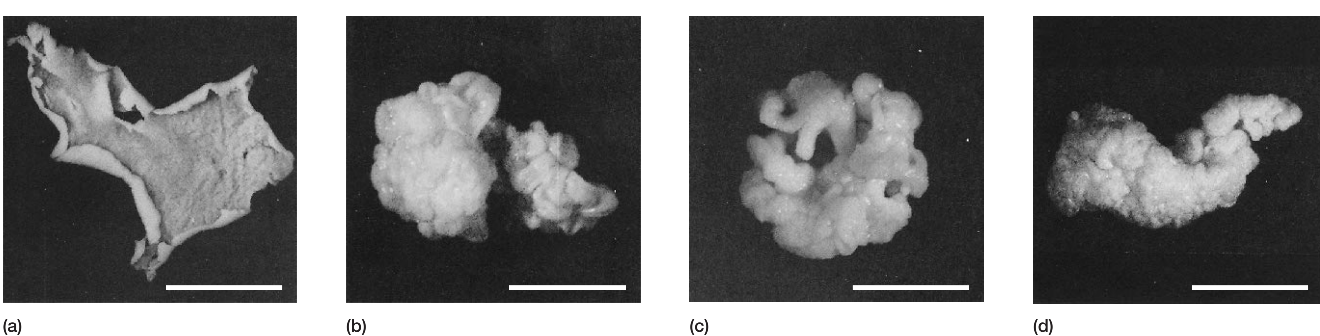

Figure 41.16 Kefir Grains Used to Inoculate Milk for a Yeast-Lactic Fermentation. The kefir grains are dried milk solids that contain a variety of desired bacteria and yeasts for production of kefir. After the fermentation is completed, the grains are recovered, washed, and used to inoculate another batch of fresh milk. Bars = 1 cm.

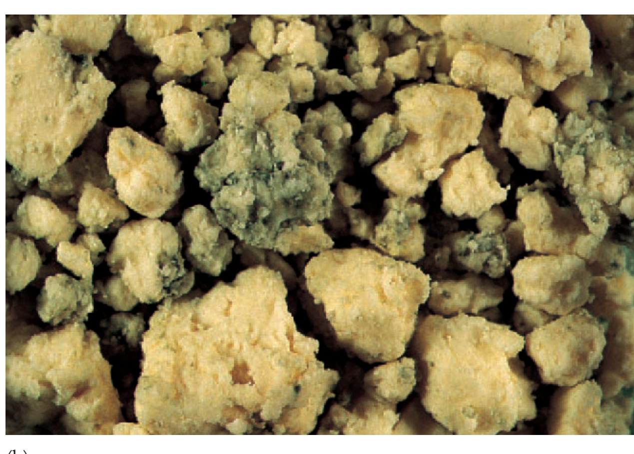
Table 41.8 Major Types of Cheese and Microorganisms Used in Their Production

Cheese (Country of Origin)	*Contributing Microorganisms*[a] Earlier Stages of Production	Later Stages of Production
Soft, unripened		
Cottage	*Lactococcus lactis*	*Leuconostoc cremoris*
Cream	*L. cremoris, L. diacetylactis, S. thermophilus, L. bulgaricus*	
Mozzarella (Italy)	*S. thermophilus, L. bulgaricus*	
Soft, ripened		
Brie (France)	*Lactococcus lactis, L. cremoris*	*Penicillium camemberti, P. candidum, Brevibacterium linens*
Camembert (France)	*L. lactis, L. cremoris*	*Penicillium camemberti, Brevibacterium linens*
Semisoft		
Blue, Roquefort (France)	*Lactococcus lactis, L. cremoris*	*Penicillium roqueforti*
Brick, Muenster (United States)	*L. lactis, L. cremoris*	*Brevibacterium linens*
Limburger (Belgium)	*L. lactis, L. cremoris*	*Brevibacterium linens*
Hard, ripened		
Cheddar, Colby (Britain)	*Lactococcus lactis, L. cremoris*	*Lactobacillus casei, L. plantarum*
Swiss (Switzerland)	*L. lactis, L. helveticus, S. thermophilus*	*Propionibacterium shermanii, P. freudenreichii*
Very hard, ripened		
Parmesan (Italy)	*Lactococcus lactis, L. cremoris, S. thermophilus*	*Lactobacillus bulgaricus*

[a]*Lactococcus lactis* stands for *L. lactis* subsp. *lactis*. *Lactococcus cremoris* is *L. lactis* subsp. *cremoris*, and *Lactococcus diacetilactis* is *L. lactis* subsp. *diacetilactis*.

representing approximately 20 general types (**table 41.8** and **figure 41.17**). Often cheeses are classified based on texture or hardness as soft cheeses (cottage, cream, Brie), semisoft cheeses (Muenster, Limburger, blue), hard cheeses (cheddar, Colby, Swiss), or very hard cheeses (Parmesan). All cheese results from a lactic acid fermentation of milk, which results in coagulation of milk proteins and formation of a curd. Rennin, an enzyme from calf stomachs, but now produced by genetically engineered microorganisms, can also be used to promote curd formation. After the curd is formed, it is heated and pressed to

(a)



(b)

(c)

(d)

(e)

Figure 41.17 Cheese. A bewildering array of cheeses are produced around the world using microorganisms. (**a**) Gouda (top left) and cheddar cheese (lower right). Note the typical indentations on the surface of Gouda caused by the cheesecloth and red wax covering. (**b**) Roquefort cheese crumbled for use in salad dressing. The dark areas are the result of extensive *Penicillium* growth. (**c**) Swiss cheese. This hard, ripened cheese contains holes formed by carbon dioxide from a *Propionibacterium* fermentation. (**d**) Brie (left) and Limburger (right) cheeses are soft, ripened cheeses. Ripening results from the surface growth of microorganisms like *Penicillium camemberti* (Brie) and *Brevibacterium linens* (Limburger). (**e**) Cottage cheese and cream cheese (spread on crackers) are soft, unripened cheeses. They are sold immediately after production, and the curd is consumed without further modification by microorganisms.

Figure 41.18 Cheddar Cheese Production. Cheddar, a village in England, has given its name to a cheese made in many parts of the world. "Cheddaring" is the process of turning and piling the curd to express whey and develop desired cheese texture.

remove the watery part of the milk or whey, salted, and then usually ripened (**figure 41.18**). The cheese curd can be packaged for ripening with or without additional microorganisms. Cheese curd inoculation is used in the manufacture of Roquefort and blue cheese. In this case *Penicillium roqueforti* spores are added to the curds just before the final cheese processing. Sometimes the surface of an already formed cheese is inoculated at the start of ripening; for example, Camembert cheese is inoculated with spores of *Penicillium camemberti.* The final hardness of the cheese is partially a function of the length of ripening. Soft cheeses are ripened for only about 1 to 5 months, whereas hard cheeses need 3 to 12 months, and very hard cheeses like Parmesan require 12 to 16 months ripening.

The ripening process also is critical for Swiss cheese. Gas production by *Propionibacterium* contributes to final flavor development and hole or eye formation in this cheese. Some cheeses are soaked in brine to stimulate the development of specific fungi and bacteria; Limburger is one such cheese.

Meat and Fish

Besides the fermentation of dairy products, a variety of meat products, especially sausage, can be fermented: country-cured hams, summer sausage, salami, cervelat, Lebanon bologna, fish sauces (processed by halophilic *Bacillus* species), izushi, and katsuobushi. *Pediococcus cerevisiae* and *Lactobacillus plantarum* are most often involved in sausage fermentations. Izushi is based on the fermentation of fresh fish, rice, and vegetables by *Lactobacillus* spp.; katsuobushi results from the fermentation of tuna by *Aspergillus glaucus.* Both meat fermentations originated in Japan.

1. What major steps are used to produce cheese? How is the cheese curd formed in this process? What is whey? How does Swiss cheese get its holes?
2. Which fungal genus is often used in cheese making? What cheeses are produced using this genus?
3. Give a microbial genus used in meat fermentations.

Production of Alcoholic Beverages

A variety of plants that contain adequate carbohydrates can be used to produce alcoholic beverages. When carbohydrates are available in readily fermentable form, the fermentation can be started immediately. For example, grapes are crushed to release the juice or **must,** which can be allowed to ferment without further delay. The must also can be sterilized by pasteurization or the use of sulfur dioxide, and then the desired microbial culture added.

In contrast, before cereals and other starchy materials can be used as substrates for the production of alcohol, their complex carbohydrates must be hydrolyzed. They are mixed with water and incubated in a process called **mashing.** The insoluble material is then removed to yield the **wort,** a clear liquid containing fermentable sugars and other simple molecules. Much of the art of beer and ale production involves the controlled hydrolysis of protein and carbohydrates to provide the desired body and flavor of the final product.

Wines and Champagnes

Wine production, or the science of **enology** [Greek *oinos,* wine, and *ology,* the science of], starts with the collection of grapes, continues with their crushing and the separation of the liquid (must) before fermentation, and concludes with a variety of storage and aging steps (**figure 41.19**). All grapes have white juices. To make a red wine from a red grape, the grape skins are allowed to remain in contact with the must before fermentation to release their skin-coloring components. Wines can be created by using the natural grape skin microorganisms. This natural mixture of bacteria and yeasts gives unpredictable fermentation results. To avoid such problems, one can treat the fresh must with a sulfur dioxide fumigant and add a desired strain of *Saccharomyces cerevisiae* or *S. ellipsoideus.* After inoculation the juice is fermented for 3 to 5 days at temperatures varying between 20 and 28°C. Depending on the alcohol tolerance of the yeast strain, the final product may contain 10 to 18% alcohol. Clearing and development of flavor occur during the aging process. Yeasts (pp. 554, 560–63)

A critical part of wine making involves the choice of whether to produce a dry (no remaining free sugar) or a sweeter (varying amounts of free sugar) wine. This can be controlled by regulating the initial must sugar concentration. With higher levels of sugar, alcohol will accumulate and inhibit the fermentation before the sugar can be completely used, thus producing a sweeter wine. During final fermentation in the aging process, flavoring compounds accumulate and influence the bouquet of the wine.

Microbial growth during the fermentation process produces sediments, which are removed during **racking.** Racking can be carried out at the time the fermented wine is transferred to bottles or casks for aging or even after the wine is placed in bottles.

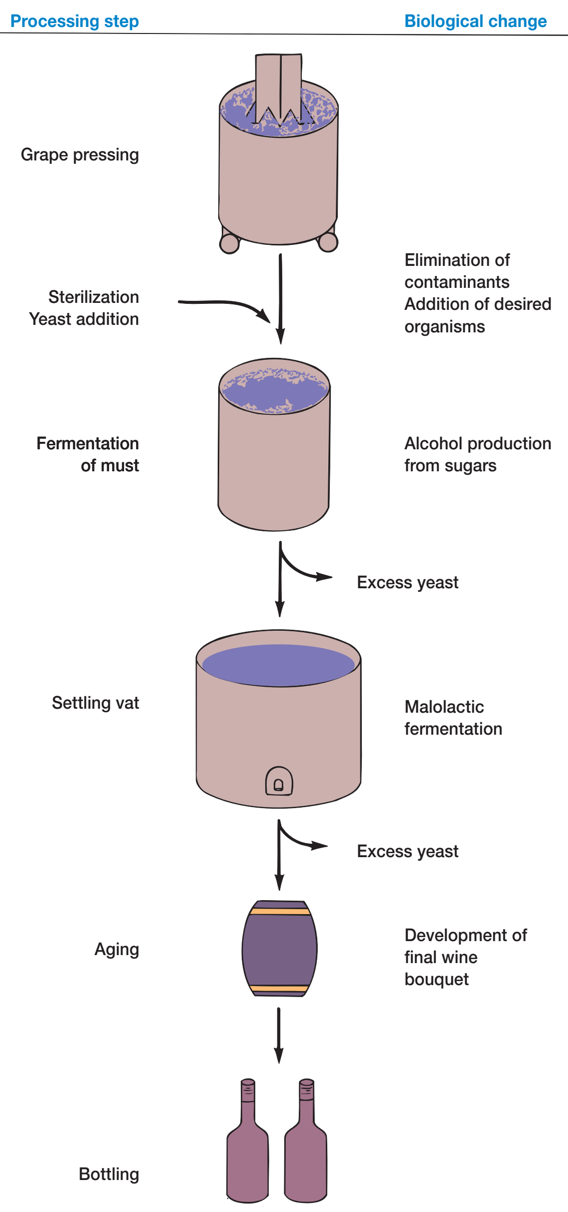


Figure 41.19 Wine Making. Once grapes are pressed, the sugars in the juice (the must) can be immediately fermented to produce wine. Must preparation, fermentation, and aging are critical steps.

Many processing variations can be used during wine production. The wine can be distilled to make a "burned wine" or brandy. *Acetobacter* and *Gluconobacter* can be allowed to oxidize the ethanol to acetic acid and form a **wine vinegar.** In the past an acetic acid generator was used to recirculate the wine over a bed of wood chips, where the desired microorganisms developed as a surface growth. Today the process is carried out in large aerobic submerged cultures under much more controlled conditions.

Natural champagnes are produced by continuing the fermentation in bottles to produce a naturally sparkling wine. Sediments that remain are collected in the necks of inverted champagne bottles after the bottles have been carefully turned. The necks of the bottles are then frozen and the corks removed to disgorge the accumulated sediments. The bottles are refilled with clear champagne from another disgorged bottle, and the product is ready for final packaging and labeling.

Beers and Ales

Beer and ale production uses cereal grains such as barley, wheat, and rice. The complex starches and proteins in these grains must be changed to a more readily usable mixture of simpler carbohydrates and amino acids. This process, shown in **figure 41.20,** involves germination of the barley grains and activation of their enzymes to produce a **malt.** The malt is then mixed with water and the desired grains, and the mixture is transferred to the mash tun or cask in order to hydrolyze the starch to usable carbohydrates. Once this process is completed, the **mash** is heated with hops (dried flowers of the female vine *Humulus lupulis*), which were originally added to the mash to inhibit spoilage microorganisms. The hops also provide flavor and assist in clarification of the wort. In this heating step the hydrolytic enzymes are inactivated and the wort can be **pitched**—inoculated—with the desired yeast.

Most beers are fermented with **bottom yeasts,** related to *Saccharomyces carlsbergensis,* which settle at the bottom of the fermentation vat. The beer flavor also is influenced by the production of small amounts of glycerol and acetic acid. Bottom yeasts produce beer with a pH of 4.1 to 4.2 and requiring 7 to 12 days of fermentation (**figure 41.21**). With a top yeast, such as *Saccharomyces cerevisiae,* the pH is lowered to 3.8 to produce ales. Freshly fermented (green) beers are aged or **lagered,** and when they are bottled, CO_2 is usually added. Beer can be pasteurized at 140°F or higher or sterilized by passage through membrane filters to minimize flavor changes.

In many places there is increased interest in specialty beers. Local "Braumeisters" develop unique products with special brewing techniques and ingredients. Often unusual names are given to these creations. This has led to local tasting festivals and increased interest in the art and craft of brewing.

Distilled Spirits

Distilled spirits are produced by an extension of beer production processes. The fermented liquid is boiled, and the volatile components are condensed to yield a product with a higher alcohol content than beer. Rye and bourbon are examples of whiskeys. Rye whiskey must contain at least 51% rye grain, and bourbon must contain at least 51% corn. Scotch whiskey is made primarily of barley. Usually a **sour mash** is used; the mash is inoculated with a homolactic (lactic acid is the major fermentation product) bacterium such as *Lactobacillus delbrueckii,* which can lower the mash pH to around 3.8 in 6 to 10 hours. This limits the development of undesirable organisms. Vodka and grain alcohols are also produced by distillation. Gin is vodka to which resinous flavoring

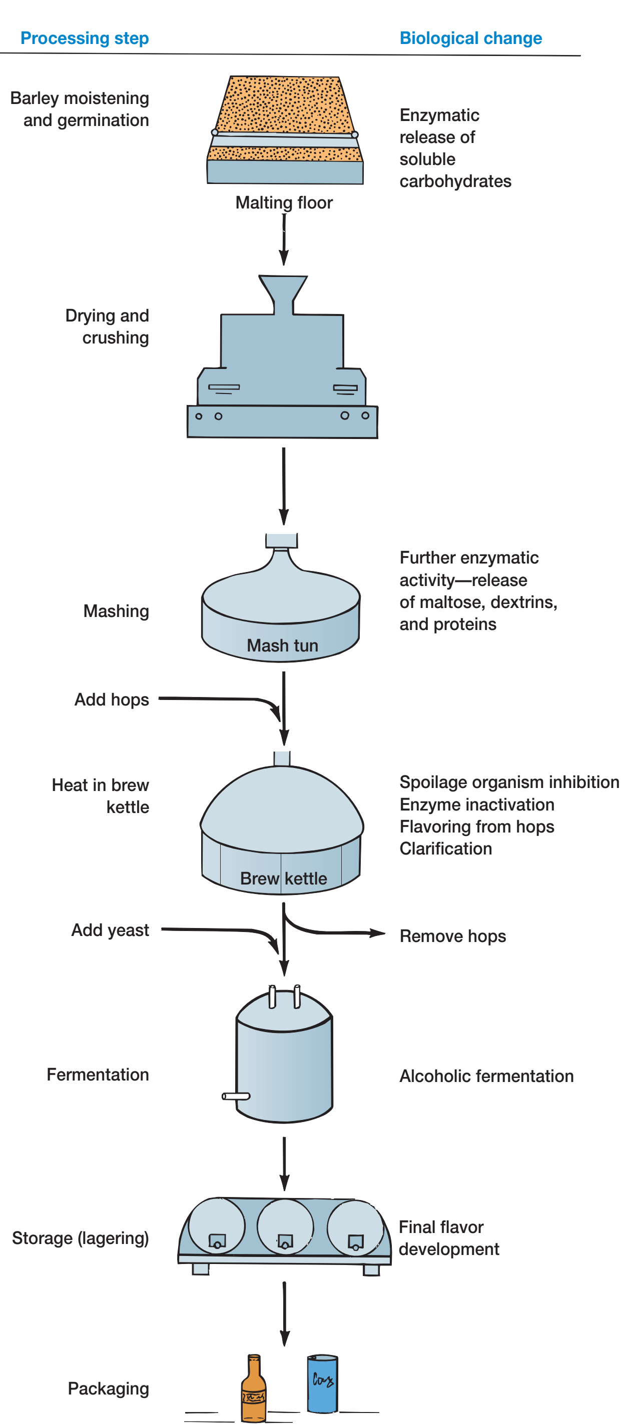

Figure 41.20 Producing Beer. To make beer, the complex carbohydrates in the grain must first be transformed into a fermentable substrate. Beer production thus requires the important steps of malting, and the use of hops and boiling for clarification, flavor development, and inactivation of malting enzymes. Only after completion of these steps can the actual fermentation be carried out.

Figure 41.21 Beer Fermentation. Beer making can be carried out on a large scale or in the kitchen. In large-scale processes, copper brewing vats are often used, as shown here in the Carlsberg Brewery, Copenhagen, Denmark.

agents—often juniper berries—have been added to provide a unique aroma and flavor.

Production of Breads

Bread is one of the most ancient of human foods, and is produced with the help of microorganisms. The use of yeasts to leaven bread is carefully depicted in paintings from ancient Egypt. A bakery at the Giza Pyramid area, from the year 2575 B.C., has been excavated. It is estimated that 30,000 people a day were provided with bread from this bakery. Samples of bread from 2100 B.C. are on display in the British Museum. In breadmaking, yeast growth is carried out under aerobic conditions. This results in increased CO_2 production and minimum alcohol accumulation. The fermentation of bread involves several steps: alpha- and beta-amylases present in the moistened dough release maltose and sucrose from starch. Then a baker's strain of the yeast *Saccharomyces cerevisiae,* which contains maltase, invertase, and zymase enzymes, is added. The CO_2 produced by the yeast results in the light texture of many breads, and traces of fermentation products contribute to the final flavor. Usually bakers add sufficient yeast to allow the bread to rise within 2 hours—the longer the rising time, the more additional growth by contaminating bacteria and fungi can occur, making the product less desirable.

By using more complex assemblages of microorganisms, bakers can produce special breads such as sour doughs. The yeast *Saccharomyces exiguus,* together with a *Lactobacillus* species, produces the characteristic acidic flavor and aroma of such breads.

Bread products can be spoiled by *Bacillus* species that produce ropiness. If the dough is baked after these organisms have grown, stringy and ropy bread will result, leading to decreased consumer acceptance.

Table 41.9 Fermented Foods Produced from Fruits, Vegetables, Beans, and Related Substrates

Foods	Raw Ingredients	Fermenting Microorganisms	Area
Coffee	Coffee beans	*Erwinia dissolvens, Saccharomyces* spp.	Brazil, Congo, Hawaii, India
Gari	Cassava	*Corynebacterium manihot, Geotrichum* spp.	West Africa
Kenkey	Corn	*Aspergillus* spp., *Penicillium* spp., Lactobacilli, yeasts	Ghana, Nigeria
Kimchi	Cabbage and other vegetables	Lactic acid bacteria	Korea
Miso	Soybeans	*Aspergillus oryzae, Zygosaccharomyces rouxii*	Japan
Ogi	Corn	*Lactobacillus plantarum, Lactococcus lactis, Zygosaccharomyces rouxii*	Nigeria
Olives	Green olives	*Leuconostoc mesenteroides, Lactobacillus plantarum*	Worldwide
Ontjom	Peanut presscake	*Neurospora sitophila*	Indonesia
Peujeum	Cassava	Molds	Indonesia
Pickles	Cucumbers	*Pediococcus cerevisiae, L. plantarum*	Worldwide
Poi	Taro roots	Lactic acid bacteria	Hawaii
Sauerkraut	Cabbage	*L. mesenteroides, L. plantarum*	Worldwide
Soy sauce	Soybeans	*Aspergillus oryzae* or *A. soyae, Z. rouxii, Lactobacillus delbrueckii*	Japan
Sufu	Soybeans	*Mucor* spp.	China
Tao-si	Soybeans	*A. oryzae*	Philippines
Tempeh	Soybeans	*Rhizopus oligosporus, R. oryzae*	Indonesia, New Guinea, Surinam

Other Fermented Foods

Many other plant products can be fermented, as summarized in **table 41.9.** These include sufu, which is produced by the fermentation of tofu, a chemically coagulated soybean milk product. To carry out the fermentation, the tofu curd is cut into small chunks and dipped into a solution of salt and citric acid. After the cubes are heated to pasteurize their surfaces, *Actinimucor elegans* and other *Mucor* species are added. When a white mycelium develops, the cubes, now called pehtze, are aged in salted rice wine. This product has achieved the status of a delicacy in many parts of the Western world. Another popular product is tempeh, a soybean mash fermented by *Rhizopus* (**figure 41.22**).

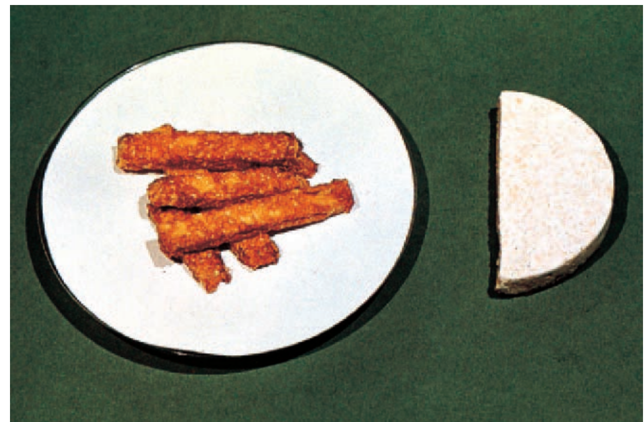

Figure 41.22 Fermented Soybean Products. Microorganisms also can be used to process soybean products. Tempeh is produced from soybeans and *Rhizopus.* Both the raw cake and the fried food are shown.

Sauerkraut or sour cabbage, is produced from wilted, shredded cabbage, as shown in **figure 41.23.** Usually the mixed microbial community of the cabbage is used. A concentration of 2.2 to 2.8% sodium chloride restricts the growth of gram-negative bacteria while favoring the development of the lactic acid bacteria. The primary microorganisms contributing to this product are *Leuconostoc mesenteroides* and *Lactobacillus plantarum.* A predictable microbial succession occurs in sauerkraut's development. The activities of the lactic acid-producing cocci usually cease when the acid content reaches 0.7 to 1.0%. At this point *Lactobacillus plantarum* and *Lactobacillus brevis* continue to function. The final acidity is generally 1.6 to 1.8, with lactic acid comprising 1.0 to 1.3% of the total acid in a satisfactory product.

Pickles are produced by placing cucumbers and such components as dill seeds in casks filled with a brine. The sodium chloride concentration begins at 5% and rises to about 16% in 6 to 9 weeks. The salt not only inhibits the growth of undesirable bacteria but also extracts water and water-soluble constituents from the cucumbers. These soluble carbohydrates are converted to lactic acid. The fermentation, which can require 10 to 12 days, involves the development of *Leuconostoc mesenteroides, Enterococcus faecalis, Pediococcus cerevisiae, Lactobacillus brevis,* and *L. plantarum. L. plantarum* plays the dominant role in this fermentation process. Sometimes, to achieve more uniform pickle quality, natural microorganisms are first destroyed and the cucumbers are fermented using pure cultures of *P. cerevisiae* and *L. plantarum.*

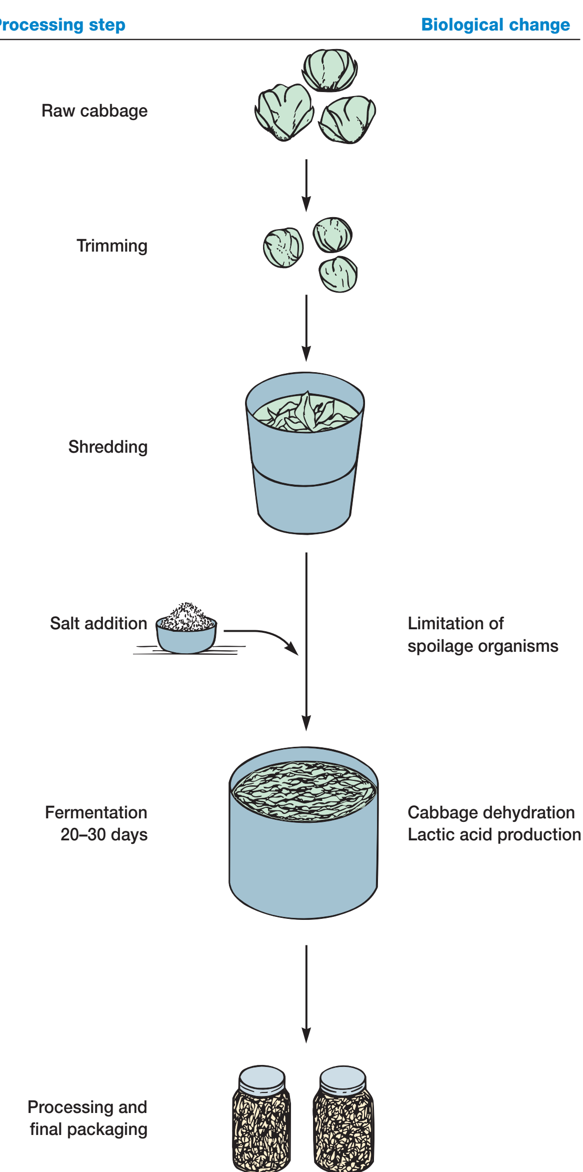

Figure 41.23 Sauerkraut. Sauerkraut production employs a lactic acid fermentation. The basic process involves fermentation of shredded cabbage in the presence of 2.25–2.5% by weight of salt to inhibit spoilage organisms.

Grass, chopped corn, and other fresh animal feeds, if stored under moist anaerobic conditions, will undergo a lactic-type mixed fermentation that produces pleasant-smelling **silages.** Trenches or more traditional vertical steel or concrete silos are used to store the silage. The accumulation of organic acids in silage can cause rapid deterioration of these silos. Older wooden stave silos, if not properly maintained, allow the outer portions of the silage to become aerobic, resulting in spoilage of a large portion of the plant material.

Figure 41.24 Mushroom Farming. Growing mushrooms requires careful preparation of the growth medium and control of environmental conditions. The mushroom bed is a carefully developed compost, which can be steam sterilized to improve mushroom growth.

1. Describe and contrast the processes of wine and beer production. How are red wines produced when the juice of all grapes is white?
2. How do champagnes differ from wines?
3. Describe how distilled spirits like whiskey are produced.
4. How are bread, sauerkraut, and pickles produced? What microorganisms are most important in these fermentations?

41.7 Microorganisms as Foods and Food Amendments

Besides microorganisms' actions in fermentation as agents of physical and biological change, they themselves can be used as a food source. A variety of bacteria, yeasts, and other fungi have been used as animal and human food sources. Mushrooms (*Agaricus bisporus*) are one of the most important fungi used directly as a food source. Large caves are used to maintain optimal conditions for the production of this delicacy (**figure 41.24**). Microorganisms can be used directly as a food source or as a supplement to other foods and are then called single-cell protein. One of the more popular microbial food supplements is the cyanobacterium *Spirulina.* It is used as a food source in Africa and is now being sold in United States health food stores as a dried cake or powdered product.

Microorganisms such as *Lactobacillus* and *Bifidobacterium* are being used in the rapidly developing area of **probiotics,** the addition of microorganisms to the diet in order to provide health benefits beyond basic nutritive value. These supplements may be called **microbial dietary adjuvants.** Many of the claims for the value of probiotics in the past were not based on strong scientific investigations, and were more the stuff of tradition and hearsay. This is changing, as recent work in this area is based on a more

scientific foundation. For example, scientists have created a *S*imulated *H*uman *I*ntestinal *M*icrobial *E*cosystem or **SHIME system,** to better understand the effects of adding probiotic organisms. Probiotics (Box 31.1)

In addition, there is a greater appreciation of the role of oligosaccharide polymers or **prebiotics,** which are not processed until they enter the large intestine. The combination of prebiotics and probiotic microorganisms is described as a **synbiotic** system. This synbiotic combination can result in an increase in the levels of butyric and propionic acids, as well as an increase in *Bifidobacterium* in the human intestine. The butyrate, especially, may play a role in the possible beneficial effects of probiotics on intestinal processes.

Probiotics are being used successfully with poultry. Recently, the USDA has designated a probiotic *Bacillus* strain for use with chickens as "Generally Recognized As Safe" or GRAS. Feeding chickens a strain of *Bacillus subtilis* (Calsporin) led to increased body weight and feed conversion. There was also a reduction in coliforms and *Campylobacter* in the processed carcasses. It has been suggested that this probiotic decreases the need for antibiotics in poultry production and pathogen levels on farms. *Salmonella* can be controlled by spraying a patented blend of 29 bacteria, isolated from the chicken cecum, on day-old chickens. As they preen themselves, the chicks ingest the bacterial mixture, establishing a functional microbial community in the cecum and limiting *Salmonella* colonization of the gut in a process called **competitive exclusion.** In 1998, this product, called PREEMPT™, was approved for use in the United States by the Food and Drug Administration.

1. What conditions are needed to have most efficient production of edible mushrooms? What is the scientific name of the most important fungus used for this purpose?
2. A cyanobacterium is widely used as a food supplement. What is this genus, and in what part of the world was it first used as a significant food source?
3. What are prebiotics, probiotics, and synbiotics?
4. What probiotic has recently been recognized as "Generally Recognized As Safe" or GRAS?

Summary

1. Most foods, especially when raw, provide an excellent environment for microbial growth. This growth can lead to spoilage or preservation, depending on the microorganisms present and environmental conditions.
2. The course of microbial development in a food is influenced by the intrinsic characteristics of the food itself—pH, salt content, substrates present, water presence and availability—and extrinsic factors, including temperature, relative humidity, and atmospheric composition (**figure 41.1**).
3. Microorganisms can spoil meat, dairy products, fruits, vegetables, and canned goods in several ways. Spices, with their antimicrobial compounds, sometimes protect foods.
4. Modified atmosphere packaging (MAP) is being used to control microbial growth in foods and to extend product shelf life. This process involves decreasing oxygen and increased carbon dioxide levels in the space between the food surface and the wrapping material.
5. Food spoilage is a major concern throughout the world. This can occur at any point in the food production process: growth, harvesting, transport, storage, or final preparation. Spoilage also can occur if foods are not stored properly.
6. Fungi, if they can grow in foods, especially cereals and grains, can produce important disease-causing chemicals, including aflatoxins and fumonisins (carcinogens), and ergot alkaloids (mind-altering drugs).
7. Prior illness with hepatitis B can increase susceptibility to liver cancer from aflatoxins. Control of hepatitis B is suggested to be more critical than control of aflatoxins.
8. Algal toxins can be transmitted to humans through the food chain via marine products. These can have severe amnesic, diarrhetic and neurotoxic effects.
9. Foods can be preserved in a variety of physical and chemical ways, including filtration, alteration of temperature (cooling, pasteurization, sterilization), drying, the addition of chemicals, radiation, and fermentation (**table 41.4**).
10. There is an increasing interest in using bacteriocins for food preservation. Nisin, a product of *Streptococcus lactis,* is the major substance approved for use in foods. Bacteriocins are especially important for control of *Listeria monocytogenes.*
11. Foods can be contaminated by pathogens at any point in the food production, storage, or preparation processes. Pathogens such as *Salmonella, Campylobacter, Listeria,* and *E. coli* can be transmitted by the food to the susceptible consumer, where they grow and cause disease, or a food-borne infection (**table 41.6**). If the pathogen grows in the food before consumption and forms toxins that affect the food consumer without further microbial growth, the disease is a food-borne intoxication. Examples are intoxications caused by *Staphylococcus, Clostridium,* and *Bacillus.*
12. Norwalk-type viruses, *Campylobacter,* and *Salmonella* are thought to be the most important causes of food-borne illness. The cause of most food-borne illnesses is not known.
13. *E. coli* O157:H7 is an enterohemorrhagic bacterium that apparently can produce shigalike verocytotoxins, which especially affect the young. Proper food handling and thorough cooking are critical in control.
14. New variant Creutzfeldt-Jakob disease (vCJD) is of increasing worldwide concern as a possible food-borne infectious agent, which is related to the occurrence of "mad cow disease." The major means of vCJD transmission between animals is the use of mammalian tissue in ruminant animal feeds. There are difficulties in detecting such prohibited animal products in ruminant feeds.
15. The increasing popularity of raw foods such as sprouts, seafood, and raspberries has provided new routes for disease transmission. Increases in the international shipment of fresh foods contribute to this problem. *Cyclospora* is a protozoan of concern, and the major source is contaminated waters.
16. Detection of food-borne pathogens is a major part of food microbiology. The use of immunological and molecular techniques such as probes, PCR, and pulsed field electrophoresis is making it possible to link disease occurrences to a common infection source (**figure 41.13**). PulseNet and InfoNet programs are being used to coordinate these control efforts.
17. Dairy products can be fermented to yield a wide variety of cultured milk products (**table 41.7**). These include mesophilic, therapeutic, thermophilic, lacto-ethanolic, and mold-lactic products.

18. Growth of lactic acid–forming bacteria, often with the additional use of rennin, can coagulate milk solids. These solids can be processed to yield a wide variety of cheeses, including soft unripened, soft ripened, semisoft, hard, and very hard types (**table 41.8** and **figure 41.17**). Both bacteria and fungi are used in these cheese production processes.
19. Wines are produced from pressed grapes and can be dry or sweet, depending on the level of free sugar that remains at the end of the alcoholic fermentation (**figure 41.19**). Champagne is produced when the fermentation, resulting in CO_2 formation, is continued in the bottle.
20. Beer and ale are produced from cereals and grains. The starches in these substrates are hydrolyzed, in the processes of malting and mashing, to produce a fermentable wort. *Saccharomyces cerevisiae* is a major yeast used in the production of beer and ale (**figure 41.20**).
21. Many plant products can be fermented with bacteria, yeasts, and fungi. Important products are breads, soy sauce, sufu, and tempeh (**table 41.9**). Sauerkraut and pickles are produced in a fermentation process in which natural populations of lactobacilli play a major role (**figure 41.23**).
22. Microorganisms themselves can serve as an important food source. Mushrooms (*Agaricus bisporus*) are one of the most important fungi used as a food source. *Spirulina,* a cyanobacterium, also is a popular food source sold in specialty stores.
23. Many microorganisms, including some of those used to ferment milks, can be used as food amendments or microbial dietary adjuvants. Microorganisms such as *Lactobacillus* and *Bifidobacterium,* termed probiotics, can be used with oligopolysaccharides, termed prebiotics, to yield synbiotics. Several types of probiotic microorganisms are being used successfully in poultry production.

Key Terms

aflatoxin *967*
algal toxin *968*
bacteriocin *972*
bottom yeast *983*
canning *970*
competitive exclusion *987*
enology *982*
ergotism *967*
extrinsic factor *964*
food-borne infection *973*
food intoxication *975*
FoodNet *977*
fumonisin *968*
GRAS *972*
intrinsic factor *964*
kefir *979*
lager *983*
malt *983*
mash 983
mashing *982*
microbial dietary adjuvant *986*
modified atmosphere packaging (MAP) *966*
must *982*
osmophilic microorganism *965*
pasteurization *970*

starter culture *978*
synbiotic *987*
wine vinegar *983*
wort *982*
xerophilic microorganism *965*
yogurt *978*

Questions for Thought and Review

1. You are going through a salad line in a cafeteria at the end of the day. Which types of foods would you tend to avoid, and why?
2. Why does the law only allow foods to be pasteurized a single time? What could be the consequences of repeated pasteurization?
3. Why is it recommended that frozen foods, once thawed, not be frozen again? Suggest some of the reasons for this important principle of food handling.
4. Hamburger is notorious for having relatively high populations of microorganisms. How can these populations be controlled in preparation and storage?
5. Coffee cream is now packaged in small-portion servings that can be held at room temperature for extended periods. How do you think this product is produced and packaged?
6. What factors might limit the application of DNA- and RNA-based molecular techniques to the detection of pathogens in foods? How might these problems be overcome?
7. Why were aflatoxins not discovered before the 1960s? Do you think this was the first time they had grown in a food product to cause disease?
8. What advantage might the shiga-like toxin give *E. coli* O157:H7? Can we expect to see other "new" pathogens appearing, and what should we do, if anything?
9. Because of the possible beneficial effects of probiotic microorganisms on the intestinal microflora, scientists are becoming increasingly interested in their use as dietary supplements. How might modern biotechnology be used to improve the effectiveness of these microorganisms?
10. "New" food-borne pathogens continue to be discovered. How much of this phenomenon do you think is due to new techniques for recognizing existing organisms rather than the actual appearance of new organisms? How would you sort out the answer to this question?
11. How might microbial ecology be used to better protect humans from food-borne diseases?

Critical Thinking Questions

1. Fresh lemon slices are often served with raw or steamed seafood (oysters, crab, shrimp). From a food microbiology perspective, provide an explanation for their being served. Are there other examples in either the cooking or the serving of foods that not only enhance flavor, but might have an antimicrobial strategy? Consider the example of marinades.
2. Keep a record of what you eat for a day or two. Determine if the food, beverages, and snacks you ate could have been produced (at any level) without the aid of microorganisms. Indicate at what level(s) microorganisms were deliberately used. Be sure to consider ingredients such as citric acid, which is produced at the industrial level by several species of fungi.
3. Colonization of a susceptible human is critical to food-borne disease microorganisms. How might it be possible to modify foods to decrease these attachment processes?

CHAPTER 42

Industrial Microbiology and Biotechnology

Biodegradation often can be facilitated by changing environmental conditions. Polychlorinated biphenyls (PCBs) are widespread industrial contaminants that accumulate in anaerobic river muds. Although reductive dechlorination occurs under these anaerobic conditions, oxygen is required to complete the degradation process. In this experiment, muds are being aerated to allow the final biodegradation steps to occur.

42.6 Impacts of Microbial Biotechnology 1022

Concepts

1. Microorganisms are used in industrial microbiology and biotechnology to create a wide variety of products and to assist in maintaining and improving the environment.
2. Most work in industrial microbiology has been carried out using microorganisms isolated from nature or modified through mutations. In modern biotechnology, microorganisms with specific genetic characteristics can be constructed to meet desired objectives.
3. Most microorganisms have not been grown or described. A major challenge in biotechnology is to be able to grow and characterize these observed but uncultured microorganisms in what is called "bioprospecting."
4. Forced evolution and adaptive mutations now are part of modern biotechnology. These can be carried out in processes termed "natural genetic engineering."
5. The development of growth media and specific conditions for the growth of microorganisms is a large part of industrial microbiology and biotechnology. Microorganisms can be grown in controlled environments with specific limitations to maximize the synthesis of desired products.
6. Microbial growth in soils, waters, and other environments, where complex microbial communities already are present, cannot be completely controlled, and it is not possible to precisely define limiting factors or physical conditions.
7. Microbial growth in controlled environments is expensive; it is used to synthesize high-value microbial metabolites and other products for use in animal and human health. In comparison, microbial growth in natural environments usually does not involve the creation of specific microbial products; microorganisms are used to carry out lower-value environmental and agriculture-related processes.
8. In controlled growth systems, different products are synthesized during growth and after growth is completed. Most antibiotics are produced after the completion of active growth.
9. Antibiotics and other microbial products continue to contribute to animal and human welfare. Newer products include anticancer drugs. Combinatorial biology is making it possible to produce hybrid antibiotics with unique properties.
10. The products of industrial microbiology impact all aspects of our lives. These often are bulk chemicals that are used as food supplements and acidifying agents. Other products are used as biosurfactants and emulsifiers in a wide variety of applications.
11. Degradation is critical for understanding microbial contributions to natural environments. The chemical structure of substrates and microbial community characteristics play important roles in determining the fate of chemicals. Anaerobic degradation processes are important for the initial modification of many compounds, especially those with chlorine and other halogenated functions. Degradation can produce simpler or modified compounds that may not be less toxic than the original compound.
12. Biosensors are undergoing rapid development, which is limited only by the advances that are occurring in molecular biology and other areas of science. It is now possible, especially with streptavidin-biotin-linked systems, to have essentially real-time detection of important pathogens.
13. Gene arrays, based on recombinant DNA technology, allow gene expression to be monitored. These systems are being used in the analysis of complex microbial systems.
14. Bacteria, fungi, and viruses are increasingly employed as biopesticides, thus reducing dependence on chemical pesticides.
15. Application of microorganisms and their technology has both positive and negative aspects. Possible broader impacts of applications of industrial microbiology and biotechnology should be considered in the application of this rapidly expanding area.

The microbe will have the last word.

—Louis Pasteur

Industrial microbiology and biotechnology both involve the use of microorganisms to achieve specific goals, whether creating new products with monetary value or improving the environment. Industrial microbiology, as it has traditionally developed, focuses on products such as pharmaceutical and medical compounds (antibiotics, hormones, transformed steroids), solvents, organic acids, chemical feedstocks, amino acids, and enzymes that have direct economic value. The microorganisms employed by industry have been isolated from nature, and in many cases, were modified using classic mutation-selection procedures.

The era of biotechnology has developed rapidly in the last several decades, and is characterized by the modification of microorganisms through the use of molecular biology, including the use of recombinant DNA technology (*see chapter 14*). It is now possible to manipulate genetic information and design products such as proteins, or to modify microbial gene expression. In addition, genetic information can be transferred between markedly different groups of organisms, such as between bacteria and plants.

Selection and use of microorganisms in industrial microbiology and biotechnology are challenging tasks that require a solid understanding of microorganism growth and manipulation, as well as microbial interactions with other organisms. The use of microorganisms in industrial microbiology and biotechnology follows a logical sequence. It is necessary first to identify or create a microorganism that carries out the desired process in the most efficient manner. This microorganism then is used, either in a controlled environment such as a fermenter or in complex systems such as in soils or waters to achieve specific goals.

42.1 Choosing Microorganisms for Industrial Microbiology and Biotechnology

The first task for an industrial microbiologist is to find a suitable microorganism for use in the desired process. A wide variety of alternative approaches are available, ranging from isolating microorganisms from the environment to using sophisticated molecular techniques to modify an existing microorganism.

Finding Microorganisms in Nature

Until relatively recently, the major sources of microbial cultures for use in industrial microbiology were natural materials such as soil samples, waters, and spoiled bread and fruit. Cultures from all areas of the world were examined in an attempt to identify strains with desirable characteristics. Interest in "hunting" for new microorganisms continues unabated.

Because only a minor portion of the microbial species in most environments has been isolated or cultured (**table 42.1**), there is a continuing effort throughout the world to find new microorganisms, even using environments that have been examined for decades. In spite of these long-term efforts, few microorganisms have been cultured and studied; most microbes

Box 42.1

The Potential of Archaea from High-Temperature Environments for Use in Biotechnology

There is great interest in the characteristics of archaeans isolated from the outflow mixing regions above deep hydrothermal vents that release water at 250 to 350°C. This is because these hardy organisms can grow at temperatures as high as 113°C. The problems in growing these microorganisms are formidable. For example, to grow some of them, it will be necessary to use special culturing chambers and other specialized equipment to maintain water in the liquid state at these high temperatures.

Such microorganisms, termed hyperthermophiles, with optimum growth temperatures of 80°C or above (*see p. 126*), confront unique challenges in nutrient acquisition, metabolism, nucleic acid replication, and growth. Many of these are anaerobes that depend on elemental sulfur as an oxidant and reduce it to sulfide. Enzyme stability is critical. Some DNA polymerases are inherently stable at 140°C, whereas many other enzymes are stabilized in vivo with unique thermoprotectants. When these enzymes are separated from their protectant, they lose their unique thermostability.

These enzymes may have important applications in methane production, metal leaching and recovery, and for use in immobilized enzyme systems. In addition, the possibility of selective stereochemical modification of compounds normally not in solution at lower temperatures may provide new routes for directed chemical syntheses. This is an exciting and expanding area of the modern biological sciences to which environmental microbiologists can make significant contributions.

Table 42.1 Estimated Total and Known Species from Different Microbial Groups

Group	Estimated Total Species	Known Species[a]	Percent Known
Viruses	130,000[b]	5,000	[4][c]
Archaea	?[d]	<500	?
Bacteria	40,000[b]	4,800	[12]
Fungi	1,500,000	69,000	5
Algae	60,000	40,000	67

[a]Mid-1990 values and should be increased 10–50%.

[b]These values are substantially underestimated, perhaps by 1–2 orders of magnitude.

[c][ ] indicates that these values are probably gross overestimates.

[d]Small subunit (SSU) rRNA data indicate much higher in situ diversity than given by culture-based studies.

Table 42.2 Estimates of the Percent "Cultured" Microorganisms in Various Environments

Environment	Estimated Percent Cultured
Seawater	0.001–0.100
Fresh water	0.25
Mesotrophic lake	0.1–1.0
Unpolluted estuarine waters	0.1–3.0
Activated sludge	1–15
Sediments	0.25
Soil	0.3

Source: D. A. Cowan. 2000. Microbial genomes—the untapped resource. *Tibtech* 18:14–16. Table 2, p. 15.

that can be observed in nature have not been cultured or identified, although molecular techniques are making it possible to obtain information on these uncultured microorganisms (**table 42.2**). With increased interest in microbial diversity and microbial ecology, and especially in microorganisms from extreme environments (**Box 42.1**), microbiologists are rapidly expanding the pool of known microorganisms with characteristics desirable for use in industrial microbiology and biotechnology. They are also identifying microorganisms involved in mutualistic and protocooperative relationships with other microorganisms and with higher plants and animals. There is continuing interest in bioprospecting in all areas of the world, and major companies have been organized to continue to explore microbial diversity and identify microorganisms with new capabilities. Uncultured microorganisms and microbial diversity (section 6.5)

Genetic Manipulation of Microorganisms

Genetic manipulations are used to produce microorganisms with new and desirable characteristics. The classical methods of microbial genetics (*see chapter 13*) play a vital role in the development of cultures for industrial microbiology.

Mutation

Once a promising culture is found, a variety of techniques can be used for culture improvement, including chemical mutagens and ultraviolet light (*see chapter 11*). As an example, the first cultures of *Penicillium notatum,* which could be grown only under static conditions, yielded low concentrations of penicillin. In 1943 a strain of *Penicillium chrysogenum* was isolated—

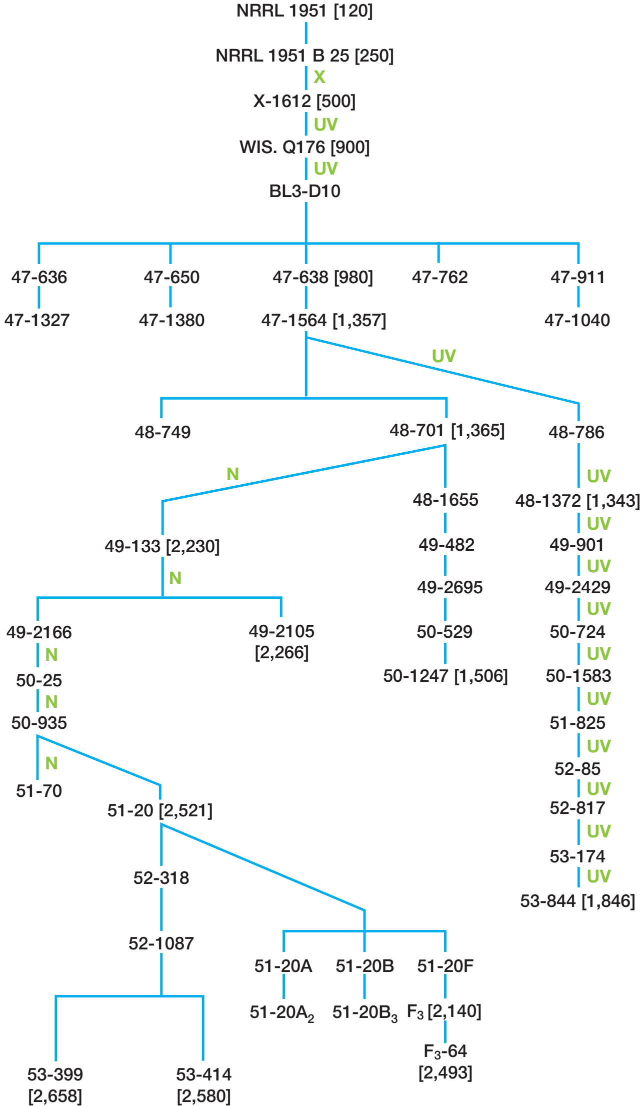

Figure 42.1 Mutation Makes It Possible to Increase Fermentation Yields. A "genealogy" of the mutation processes used to increase penicillin yields with *Penicillium chrysogenum* using X-ray treatment (X), UV treatment (UV), and mustard gas (N). By use of these mutational processes, the yield was increased from 120 International Units (IU) to 2,580 IU, a 20-fold increase. Unmarked transfers were used for mutant growth and isolation. Yields in international units/ml in brackets.

strain NRRL 1951—which was further improved through mutation (**figure 42.1**). Today most penicillin is produced with *Penicillium chrysogenum,* grown in aerobic stirred fermenters, which gives 55-fold higher penicillin yields than the original static cultures.

Protoplast Fusion

Protoplast fusion is now widely used with yeasts and molds. Most of these microorganisms are asexual or of a single mating type, which decreases the chance of random mutations that could lead to strain degeneration. To carry out genetic studies with these microorganisms, protoplasts are prepared by growing the cells in an isotonic solution while treating them with enzymes, including cellulase and beta-galacturonidase. The protoplasts are then regenerated using osmotic stabilizers such as sucrose. If fusion occurs to form hybrids, desired recombinants are identified by means of selective plating techniques. After regeneration of the cell wall, the new protoplasm fusion product can be used in further studies.

A major advantage of the protoplast fusion technique is that protoplasts of different microbial species can be fused, even if they are not closely linked taxonomically. For example, protoplasts of *Penicillium roquefortii* have been fused with those of *P. chrysogenum.* Even yeast protoplasts and erythrocytes can be fused.

Insertion of Short DNA Sequences

Short lengths of chemically synthesized DNA sequences can be inserted into recipient microorganisms by the process of **site-directed mutagenesis.** This can create small genetic alterations leading to a change of one or several amino acids in the target protein. Such minor amino acid changes have been found to lead, in many cases, to unexpected changes in protein characteristics, and have resulted in new products such as more environmentally resistant enzymes and enzymes that can catalyze desired reactions. These approaches are part of the field of **protein engineering.**
Site-directed mutagenesis (p. 323)

Enzymes and bioactive peptides with markedly different characteristics (stability, kinetics, activities) can be created. The molecular basis for the functioning of these modified products also can be better understood. One of the most interesting areas is the design of enzyme-active sites to promote the modification of "unnatural substrates." This approach may lead to improved transformation of recalcitrant materials, or even the degradation of materials that have previously not been amenable to biological processing.

1. How are industrial microbiology and biotechnology similar and different?
2. Based on recent estimates, what portion of the microorganisms have been cultured from soils and from aquatic and marine environments?
3. What is protoplast fusion and what types of microorganisms are used in this process?
4. Describe site-directed mutagenesis and how it is used in biotechnology.
5. What is protein engineering?

Table 42.3 Combinatorial Biology in Biotechnology: The Expression of Genes in Other Organisms to Improve Processes and Products

Property or Product Transferred	Microorganism Used	Combinatorial Process
Ethanol production	*Escherichia coli*	Integration of pyruvate decarboxylase and alcohol dehydrogenase II from *Zymomonas mobilis.*
1,3-Propanediol production	*E. coli*	Introduction of genes from the *Klebsiella pneumoniae* dha region into *E. coli* made possible anaerobic 1,3-propanediol production.
Cephalosporin precursor synthesis	*Penicillium chrysogenum*	Production 7-ADC and 7-ADCA[a] precursors by incorporation of the expandase gene of *Cephalosoporin acremonium* into *Penicillium* by transformation.
Lactic acid production	*Saccharomyces cerevisiae*	A muscle bovine lactate dehydrogenase gene (LDH-A) expressed in *S. cerevisiae.*
Xylitol production	*S. cerevisiae*	95% xylitol conversion from xylose was obtained by transforming the XYLI gene of *Pichia stipitis* encoding a xylose reductase into *S. cerevisiae,* making this organism an efficient organism for the production of xylitol, which serves as a sweetener in the food industry.
Creatininase[b]	*E. coli*	Expression of the creatininase gene from *Pseudomonas putida* R565. Gene inserted with a pUC18 vector.
Pediocin[c]	*S. cerevisiae*	Expression of bacteriocin from *Pediococcus acidilactici* in *S. cerevisiae* to inhibit wine contaminants.
Acetone and butanol production	*Clostridium acetobutylicum*	Introduction of a shuttle vector into *C. acetobutylicum* by an improved electrotransformation protocol, which resulted in acetone and butanol formation.

[a] 7-ACA = 7-aminocephalosporanic acid; 7-ADCA = 7-aminodecacetoxycephalosporonic acid.

Transfer of Genetic Information between Different Organisms

New alternatives have arisen through the transfer of nucleic acids between different organisms, which is part of the rapidly developing field of **combinatorial biology** (**table 42.3**). This involves the transfer of genes for the synthesis of a specific product from one organism into another, giving the recipient varied capabilities such as an increased capacity to carry out hydrocarbon degradation. An important early example of this approach was the creation of the "superbug," patented by A. M. Chakarabarty in 1974, which had an increased capability of hydrocarbon degradation. The genes for antibiotic production can be transferred to a microorganism that produces another antibiotic, or even to a non-antibiotic-producing microorganism. For example, the genes for synthesis of bialophos (an antibiotic herbicide) were transferred from *Streptomyces hygroscopicus* to *S. lividans.* Other examples are the expression in *E. coli,* of the enzyme creatininase from *Pseudomonas putida* and the production of pediocin, a bacteriocin, in a yeast used in wine fermentation for the purpose of controlling bacterial contaminants. Bacteriocins (pp. 297, 712)

DNA expression in different organisms can improve production efficiency and minimize the purification steps required before the product is ready for use. For example, recombinant baculoviruses (*see p. 415*) can be replicated in insect larvae to achieve rapid large-scale production of a desired virus or protein. Transgenic plants (*discussed on pp. 335–36*) may be used to manufacture large quantities of a variety of metabolic products. A most imaginative way of incorporating new DNA into a plant is to simply shoot it in using DNA-coated microprojectiles and a gene gun (*see section 14.6*).

A wide range of genetic information also can be inserted into microorganisms using vectors and recombinant DNA techniques. Vectors (*see section 14.5*) include artificial chromosomes such as those for yeasts (YACs), bacteria (BACs), P1 bacteriophage-derived chromosomes (PACs), and mammalian artificial chromosomes (MACs). YACs are especially valuable because large DNA sequences (over 100 kb) can be maintained in the YAC as a separate chromosome in yeast cells. A good example of vector use is provided by the virus that causes foot-and-mouth disease of cattle and other livestock. Genetic information for a foot-and-mouth disease virus antigen can be incorporated into *E. coli,* followed by the expression of this genetic information and synthesis of the gene product for use in vaccine production (**figure 42.2**).

Genetic information transfer allows the production of specific proteins and peptides without contamination by similar products that might be synthesized in the original organism. This approach can decrease the time and cost of recovering and purifying a product. Another major advantage of peptide production with modern biotechnology is that only biologically active stereoisomers are produced. This specificity is required to avoid the possible harmful side effects of inactive stereoisomers, as occurred in the thalidomide disaster.

In summary, modern gene-cloning techniques provide a considerable range of possibilities for manipulation of microorganisms and the use of plants and animals (or their cells) as factories for the expression of recombinant DNA. Newer molecular techniques continue to be discovered and applied to transfer genetic information and to construct microorganisms with new capabilities.

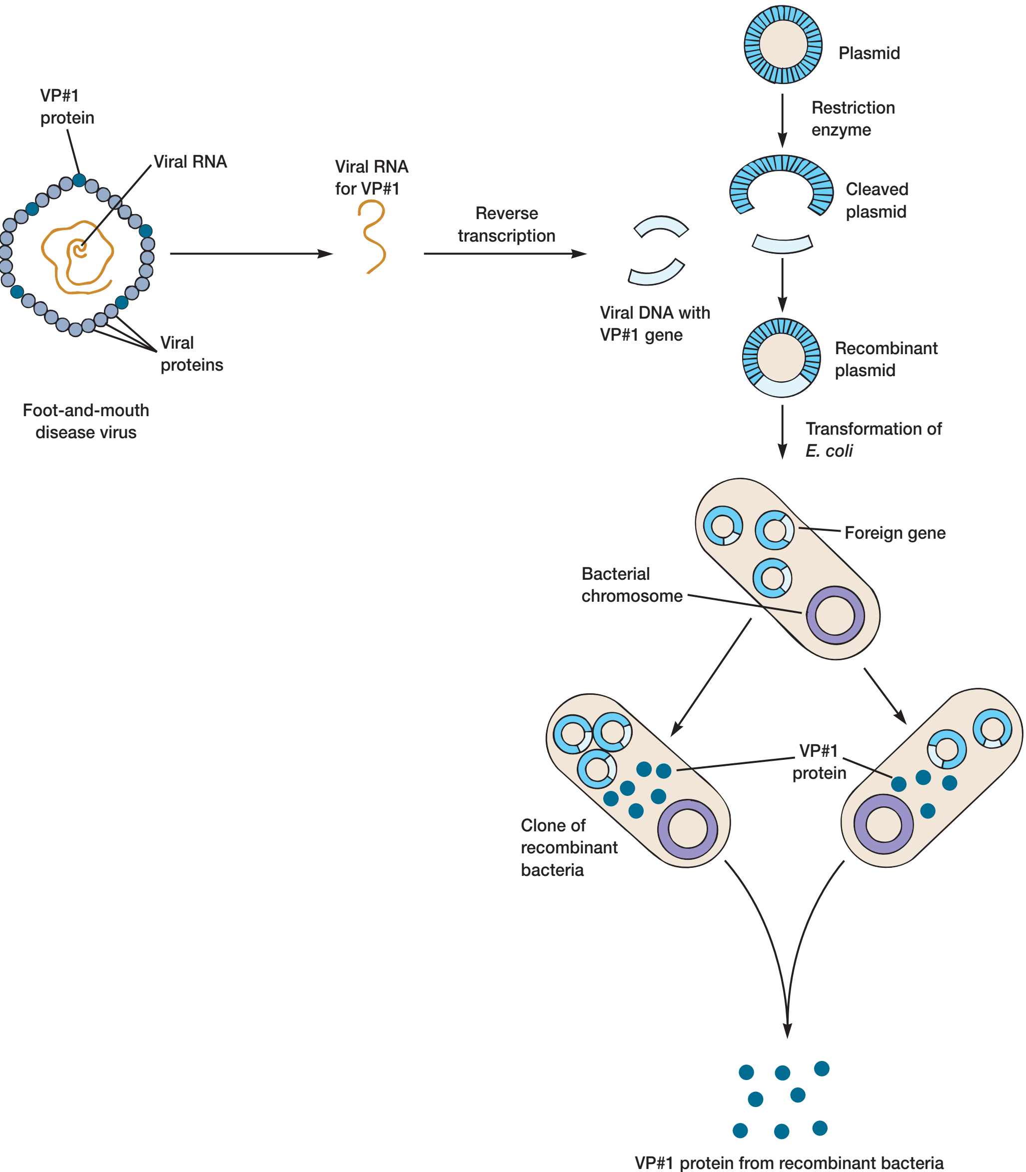

Figure 42.2 Recombinant Vaccine Production. Genes coding for desired products can be expressed in different organisms. By the use of recombinant DNA techniques, a foot-and-mouth disease vaccine is produced through cloning the vaccine genes into *Escherichia coli.*

Table 42.4 Examples of Recombinant DNA Systems Used to Modify Gene Expression

Product	Microorganism	Change
Actinorhodin	*Streptomyces coelicolor*	Modification of gene transcription
Cellulase	*Clostridium* genes in *Bacillus*	Amplification of secretion through chromosomal DNA amplification
Recombinant protein albumin	*Saccharomyces cerevisiae*	Fusion to a high-production protein
Heterologous protein	*Saccharomyces cerevisiae*	Use of the inducible strong hybrid promoter UAS_{gal}/CYCl
Enhanced growth rate[a]	*Aspergillus nidulans*	Overproduction of glyceraldehyde-3-phosphate dehydrogenase
Amino acids[b]	*Corynebacterium*	Isolation of biosynthetic genes that lead to enhanced enzyme activities or removal of feedback regulation

[a,b]S. Ostergaard; L. Olsson; and J. Nielson. 2000. Metabolic engineering of *Saccharomyces cerevisiae*. *Microbiol. Mol. Biol. Rev.* 64(1):34–50. Table 1, p. 35

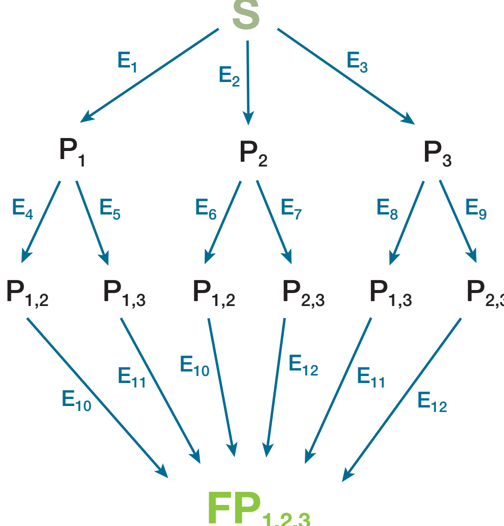

Figure 42.3 Pathway Architecture, a Critical Factor in Metabolic Engineering. Alternative steps for addition of three functional groups to a basic chemical skeleton may have different efficiencies, and it is critical to choose the most efficient combination of enzymatic steps or pathway to yield the desired product. E1 → E12 = different enzymes; P = intermediary products after the addition of the first and second functional groups, and FP = final product.

1. What is combinatorial biology and what is the basic approach used in this technique?
2. What types of major products have been created using combinatorial biology?
3. Why might one want to insert a gene in a foreign cell and how is this done?
4. Why is it important to produce specific isomers of products for use in animal and human health?

Modification of Gene Expression

In addition to inserting new genes in organisms, it also is possible to modify gene regulation by changing gene transcription, fusing proteins, creating hybrid promoters, and removing feedback regulation controls. These approaches make it possible to overproduce a wide variety of products, as shown in **table 42.4.** As a further example, genes for the synthesis of the antibiotic actinorhodin have been transferred into strains producing another antibiotic, resulting in the production of two antibiotics by the same cell.

This approach of modifying gene expression also can be used to intentionally alter metabolic pathways by inactivation or deregulation of specific genes, which is the field of **pathway architecture,** as shown in **figure 42.3.** Alternative routes can be used to add three functional groups to a molecule. Some of these pathways may be more efficient than the others. Understanding pathway architecture makes it possible to design a pathway that will be most efficient by avoiding slower or energetically more costly routes. This approach has been used to improve penicillin production by ***m**etabolic **p**athway **e**ngineering* **(MPE).**

An interesting recent development in modifying gene expression, which illustrates **metabolic control engineering,** is that of altering controls for the synthesis of lycopene, an important antioxidant normally present at high levels in tomatoes and tomato products. In this case, an engineered regulatory circuit was designed to control lycopene synthesis in response to the internal metabolic state of *E. coli.* An artificially engineered region that controls two key lycopene synthesis enzymes is stimulated by excess glycolytic activity and influences acetyl phosphate levels, thus allowing a significant increase in lycopene production while reducing negative impacts of metabolic imbalances.

Another recent development is the use of modified gene expression to produce variants of the antibiotic erythromycin. Blocking specific biochemical steps (**figure 42.4**) in pathways for the synthesis of an antibiotic precursor resulted in modified final products. These altered products, which have slightly different structures, can be tested for their possible antimicrobial effects. In addition, by the use of this approach, it is possible to better establish the structure-function relationships of antibiotics. Procedures for using microorganisms in the production of chemical feedstocks also have been developed using this MPE approach. By turning on and off

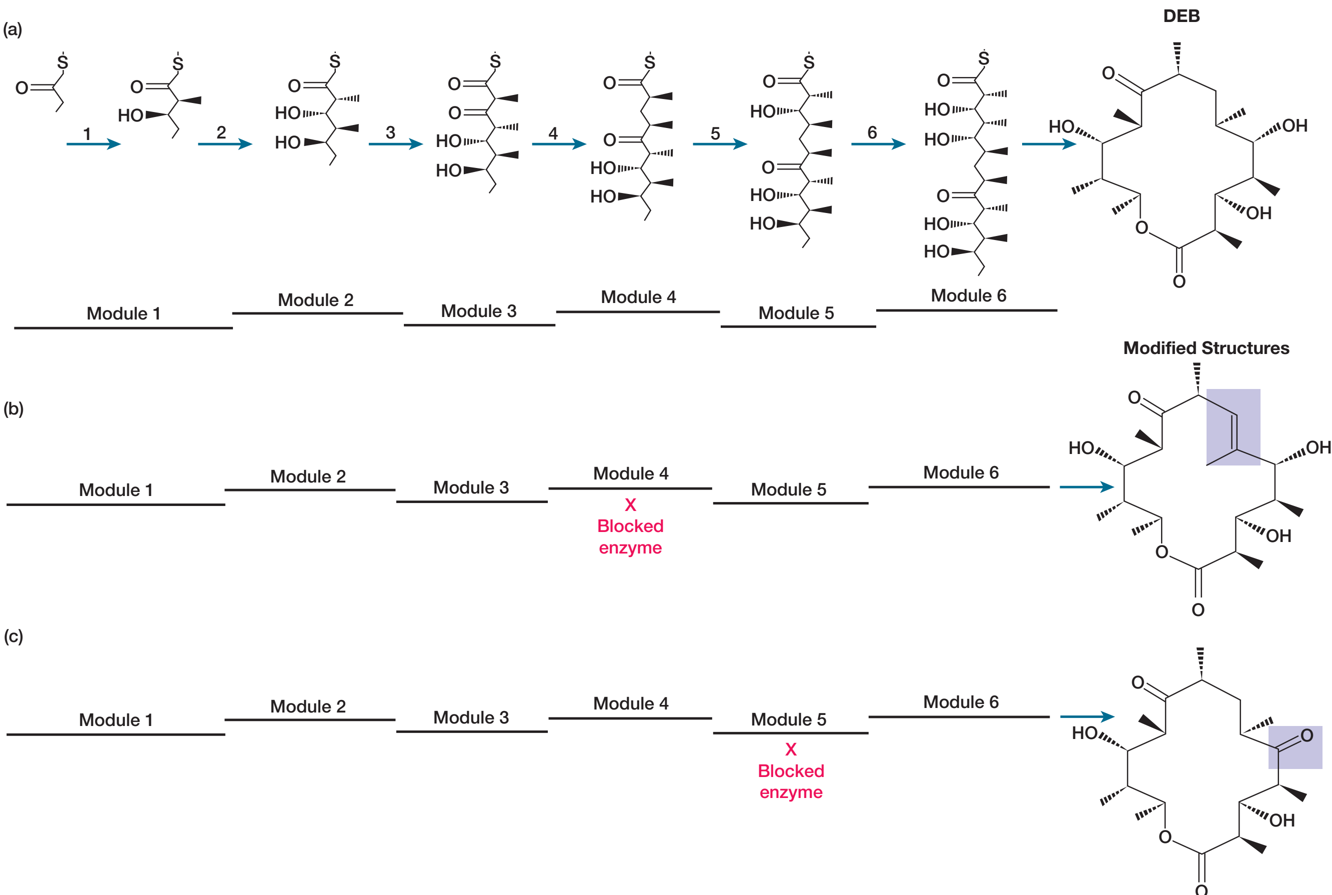

Figure 42.4 Metabolic Engineering to Create Modified Antibiotics. (**a**) Model for six elongation cycles (modules) in the normal synthesis of 6-deoxyerythonilide B (DEB), a precursor to the important antibiotic erythromycin. (**b**) Changes in structure that occur when the enoyl reductase enzyme of module 4 is blocked. (**c**) Changes in structure that occur when the keto reductase enzyme of module 5 is blocked. These changed structures (the highlighted areas) may lead to the synthesis of modified antibiotics with improved properties.

specific genes, feedstock chemicals such as 1,2-propanediol and 1,3-propanediol can be produced at high levels (**figure 42.5**). These particular chemicals are used in semimoist dog foods!

Other examples include the increased synthesis of antibiotics and cellulases, modification of gene expression, DNA amplification, greater protein synthesis, and interactive enzyme overproduction or removal of feedback inhibition. Recombinant plasminogen, for example, may comprise 20 to 40% of the soluble protein in a modified strain, a tenfold increase in concentration over that in the original strain.

Natural Genetic Engineering

The newest approach for creating new metabolic capabilities in a given microorganism is the area of **natural genetic engineering,** which employs **forced evolution** and **adaptive mutations** (*see p. 246*). This is the process of using specific environmental stresses to "force" microorganisms to mutate and adapt, thus creating microorganisms with new biological capabilities. The mechanisms of these adaptive mutational processes include DNA rearrangements in which transposable elements and various types of recombination play critical roles, as shown in **table 42.5.**

Studies on natural genetic engineering are in a state of flux. It may be that "forced processes of evolution" are more effective than rational design in some cases. Such "environmentally directed" mutations have the potential of producing microbes with new degradative or biosynthetic capabilities.

Although there is much controversy concerning this area, the responses of microorganisms to stress provide the potential of generating microorganisms with new microbial capabilities for use in industrial microbiology and biotechnology.

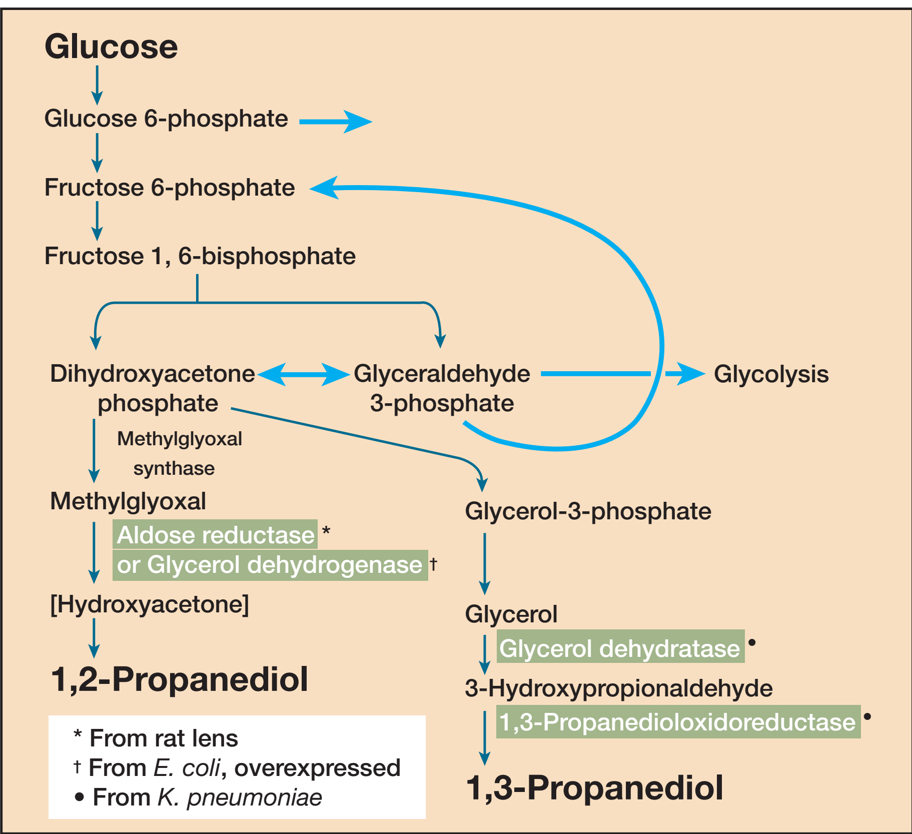

Figure 42.5 Use of Combinatorial Biology to Produce Propanediol in *E. coli.* Either an aldose reductase enzyme from rat lens or an overexpressed *E. coli* glycerol dehydrogenase enzyme and two enzymes from *Klebsiella pneumoniae,* glycerol dehydrogenase and 1,3-propanedioloxidoreductase (all green), are used to shift the intermediary metabolism of *E. coli* to the production of propanediols.

Table 42.5 Natural Genetic Engineering Systems in Bacteria

Genetic Engineering Mechanisms	DNA Changes Mediated
Localized SOS mutagenesis	Base substitutions, frameshifts
Adapted frameshifting	−1 frameshifting
Tn*5*, Tn*9*, Tn*10* precise excision	Reciprocal recombination of flanking 8/9 bp repeats; restores original sequence
In vivo deletion, inversion, fusion, and duplication formation	Generally reciprocal recombination of short sequence repeats; occasionally nonhomologous
Type II topoisomerase recombination	Deletions and fusions by nonhomologous recombination, sometimes at short repeats
Site-specific recombination (type I topoisomerases)	Insertions, excisions/deletions, inversions by concerted or successive cleavage-ligation reactions at short sequence repeats; tolerates mismatches
Transposable elements (many species)	Insertions, transpositions, replicon fusions, adjacent deletions/excisions, adjacent inversions by ligation of 3′ OH transposon ends of 5′ PO_4 groups from staggered cuts at nonhomologous target sites
DNA uptake (transformation competence)	Uptake of single strand independent of sequence, or of double-stranded DNA carrying species identifier sequence

Adapted from J. A. Shapiro. 1999. Natural genetic engineering, adaptive mutation, and bacterial evolution. In *microbial ecology of infectious disease,* E. Rosenberg, editor, 259–75. Washington, D.C.: American Society for Microbiology. Derived from Table 2, pp. 263–64.

Preservation of Microorganisms

Once a microorganism or virus has been selected or created to serve a specific purpose, it must be preserved in its original form for further use and study. Periodic transfers of cultures have been used in the past, although this can lead to mutations and phenotypic changes in microorganisms. To avoid these problems, a variety of culture preservation techniques may be used to maintain desired culture characteristics (**table 42.6**). **Lyophilization,** or freeze-drying, and storage in liquid nitrogen are frequently employed with microorganisms. Although lyophilization and liquid

Table 42.6 Methods Used to Preserve Cultures of Interest for Industrial Microbiology and Biotechnology

Method	Comments
Periodic transfer	Variables of periodic transfer to new media include transfer frequency, medium used, and holding temperature; this can lead to increased mutation rates and production of variants
Mineral oil slant	A stock culture is grown on a slant and covered with sterilized mineral oil; the slant can be stored at refrigerator temperature
Minimal medium, distilled water, or water agar	Washed cultures are stored under refrigeration; these cultures can be viable for 3 to 5 months or longer
Freezing in growth media	Not reliable; can result in damage to microbial structures; with some microorganisms, however, this can be a useful means of culture maintenance
Drying	Cultures are dried on sterile soil (soil stocks), on sterile filter paper disks, or in gelatin drops; these can be stored in a desiccator at refrigeration temperature, or frozen to improve viability
Freeze-drying (lyophilization)	Water is removed by sublimation, in the presence of a cryoprotective agent; sealing in an ampule can lead to long-term viability, with 30 years having been reported
Ultrafreezing	Liquid nitrogen at –196°C is used, and cultures of fastidious microorganisms have been preserved for more than 15 years

nitrogen storage are complicated and require expensive equipment, they do allow microbial cultures to be stored for years without loss of viability or an accumulation of mutations.

1. What types of recombinant DNA techniques are being used to modify gene expression in microorganisms?
2. Define metabolic control engineering, metabolic pathway engineering, forced evolution, and adaptive mutations.
3. Why might natural genetic engineering be useful in modern microbial biotechnology?
4. What approaches can be used for the preservation of microorganisms?

42.2 Microorganism Growth in Controlled Environments

For many industrial processes, microorganisms must be grown using specifically designed media under carefully controlled conditions, including temperature, aeration, and nutrient feeding during the course of the fermentation. The growth of microorganisms under such controlled environments is expensive, and this approach is used only when the desired product can be sold for a profit. These high costs arise from the expense of development of the particular microorganism to be used in a large-scale fermentation, the equipment, medium preparation, product purification and packaging, and marketing efforts. In addition, if this is a product to be used in animal or human health care, literally millions of dollars must be spent conducting trials and obtaining regulatory approval before even a dollar of income is available to investors. Patents are obtained whenever possible to assure that investment costs can be recovered over a longer time period. Clearly products that are brought to market must have a high monetary value. The development of appropriate culture media and the growth of microorganisms under industrial conditions are the subjects of this section.

Table 42.7 Fermentation: A Word with Many Meanings for the Microbiologist

1. Any process involving the mass culture of microorganisms, either aerobic or anaerobic
2. Any biological process that occurs in the absence of O_2
3. Food spoilage
4. The production of alcoholic beverages
5. Use of an organic substrate as the electron donor and acceptor
6. Use of an organic substrate as a reductant, and of the same partially degraded organic substrate as an oxidant
7. Growth dependent on substrate-level phosphorylation

Before proceeding, it is necessary to clarify terminology. The term **fermentation,** used in a physiological sense in earlier sections of the book, is employed in a much more general way in relation to industrial microbiology and biotechnology. As noted in **table 42.7,** the term can have several meanings, including the mass culture of microorganisms (or even plant and animal cells). The development of industrial fermentations requires appropriate culture media and the large-scale screening of microorganisms. Often years are needed to achieve optimum product yields. Many isolates are tested for their ability to synthesize a new product in the desired quantity. Few are successful. Fermentation as a physiological process (pp. 179–81)

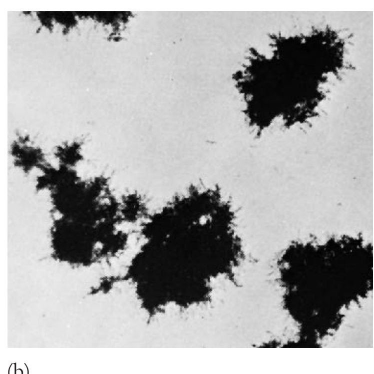
Medium Development

The medium used to grow a microorganism is critical because it can influence the economic competitiveness of a particular process. Frequently, lower-cost crude materials are used as sources of carbon, nitrogen, and phosphorus (**table 42.8**). Crude plant hydrolysates often are used as complex sources of carbon, nitrogen, and growth factors. By-products from the brewing industry frequently are employed because of their lower cost and greater availability. Other useful carbon sources include molasses and whey from cheese manufacture. Microbial growth media (pp. 104–6)

Table 42.8 Major Components of Growth Media Used in Industrial Processes

Source	Raw Material	Source	Raw Material
Carbon and energy	Molasses Whey	Vitamins	Crude preparations of plant and animal products
	Grains	Iron, trace salts	Crude inorganic chemicals
	Agricultural wastes (corncobs)	Buffers	Chalk or crude carbonates Fertilizer-grade phosphates
Nitrogen	Corn-steep liquor Soybean meal Stick liquor (slaughterhouse products) Ammonia and ammonium salts Nitrates Distiller's solubles	Antifoam agents	Higher alcohols Silicones Natural esters Lard and vegetable oils

(a)



(b)

Figure 42.6 Filamentous Growth During Fermentation. Filamentous fungi and actinomycetes can change their growth form during the course of a fermentation. The development of pelleted growth by fungi has major effects on oxygen transfer and energy required to agitate the culture. (**a**) Initial culture. (**b**) after 18 hours growth.

The levels and balance of minerals (especially iron) and growth factors can be critical in medium formulation. For example, biotin and thiamine, by influencing biosynthetic reactions, control product accumulation in many fermentations. The medium also may be designed so that carbon, nitrogen, phosphorus, iron, or a specific growth factor will become limiting after a given time during the fermentation. In such cases the limitation often causes a shift from growth to production of desired metabolites.

Growth of Microorganisms in an Industrial Setting

Once a medium is developed, the physical environment for microbial functioning in the mass culture system must be defined. This often involves precise control of agitation, temperature, pH changes, and oxygenation. Phosphate buffers can be used to control pH while also functioning as a source of phosphorus. Oxygen limitations, especially, can be critical in aerobic growth processes. The O_2 concentration and flux rate must be sufficiently high to have O_2 in excess within the cells so that it is not limiting. This is especially true when a dense microbial culture is growing. When filamentous fungi and actinomycetes are cultured, aeration can be even further limited by filamentous growth (**figure 42.6**). Such filamentous growth results in a viscous, plastic medium, known as a **non-Newtonian broth,** which offers even more resistance to stirring and aeration. To minimize this problem, cultures can be grown as pellets or flocs or bound to artificial particles.

It is essential to assure that these physical factors are not limiting microbial growth. This is most critical during **scaleup,** where a successful procedure developed in a small shake flask is modified for use in a large fermenter. One must understand the microenvironment of the culture and maintain similar conditions near the individual cell despite increases in the culture volume. If a successful transition can be made from a process originally developed in a 250 ml Erlenmeyer flask to a 100,000 liter reactor, then the process of scaleup has been carried out properly.

Microorganisms can be grown in culture tubes, shake flasks, and stirred fermenters or other mass culture systems. Stirred fermenters can range in size from 3 or 4 liters to 100,000 liters or larger, depending on production requirements (**figure 42.7**). A typical industrial stirred fermentation unit is illustrated in figure 42.7*b*. This unit requires a large capital investment and skilled operators. All required steps in the growth and harvesting of products must be carried out under aseptic conditions. Not only must the medium be sterilized but aeration, pH adjustment, sampling, and process monitoring must be carried out under rigorously controlled conditions. When required, foam control agents must be added, especially with high-protein media. Computers are commonly used to monitor outputs from probes that determine microbial biomass, levels of critical metabolic

This unit can be run under aerobic or anaerobic conditions, and nutrient additions, sampling, and fermentation monitoring can be carried out under aseptic conditions. Biosensors and infrared monitoring can provide real-time information on the course of the fermentation. Specific substrates, metabolic intermediates, and final products can be detected.

products, pH, input and exhaust gas composition, and other parameters. Such information is needed for precise process and product control. Environmental conditions can be changed or held constant over time, depending on the goals for the particular process.

Frequently a critical component in the medium, often the carbon source, is added continuously—**continuous feed**—so that the microorganism will not have excess substrate available at any given time. An excess of substrate can cause undesirable metabolic waste products to accumulate. This is particularly important with glucose and other carbohydrates. If excess glucose is present at the beginning of a fermentation, it can be catabolized to yield ethanol, which is lost as a volatile product and reduces the final yield. This can occur even under aerobic conditions.

Besides the traditional stirred aerobic or anaerobic fermenter, other approaches can be used to grow microorganisms. These alternatives, illustrated in **figure 42.8,** include lift-tube fermenters (figure 42.8*a*), which eliminate the need for stirrers that can be fouled by filamentous fungi. Also available is solid-state fermentation (figure 42.8*b*), in which the substrate is not diluted in water. In various types of fixed- (figure 42.8*c*) and fluidized-bed reactors (figure 42.8*d*), the microorganisms are associated with inert surfaces as biofilms (*see pp. 620–22*), and medium flows past the fixed or suspended particles.

Dialysis culture units also can be used (figure 42.8*e*). These units allow toxic waste metabolites or end products to diffuse away from the microbial culture and permit new substrates to diffuse through the membrane toward the culture. Continuous culture techniques using chemostats (figure 42.8*f*) can markedly improve cell outputs and rates of substrate use because microorganisms can be maintained in a continuous logarithmic phase. However, continuous maintenance of an organism in an active growth phase is undesirable in many industrial processes.

Microbial products often are classified as primary and secondary metabolites. As shown in **figure 42.9, primary metabolites** consist of compounds related to the synthesis of microbial cells in the growth phase. They include amino acids, nucleotides, and fermentation end products such as ethanol and organic acids. In addition, industrially useful enzymes, either associated with the microbial cells or exoenzymes, often are synthesized by microorganisms during growth. These enzymes find many uses in food production and textile finishing.

Secondary metabolites usually accumulate during the period of nutrient limitation or waste product accumulation that follows the active growth phase. These compounds have no direct relationship to the synthesis of cell materials and normal growth. Most antibiotics and the mycotoxins fall into this category.

Figure 42.8 Alternate Methods for Mass Culture. In addition to stirred fermenters, other methods can be used to culture microorganisms in industrial processes. In many cases these alternate approaches will have lower operating costs and can provide specialized growth conditions needed for product synthesis.

1. How is the cost of media reduced during industrial operations? Discuss the effect of changing balances in nutrients such as minerals, growth factors, and the sources of carbon, nitrogen, and phosphorus.
2. What factors increase the costs of microbial products, such as antibiotics, used in animal and human health?
3. What are non-Newtonian broths, and why are these important in fermentations?
4. Discuss scaleup and the objective of the scaleup process.
5. What parameters can be monitored in a modern, large-scale industrial fermentation?
6. Besides the aerated, stirred fermenter, what other alternatives are available for the mass culture of microorganisms in industrial processes? What is the principle by which a dialysis culture system functions?

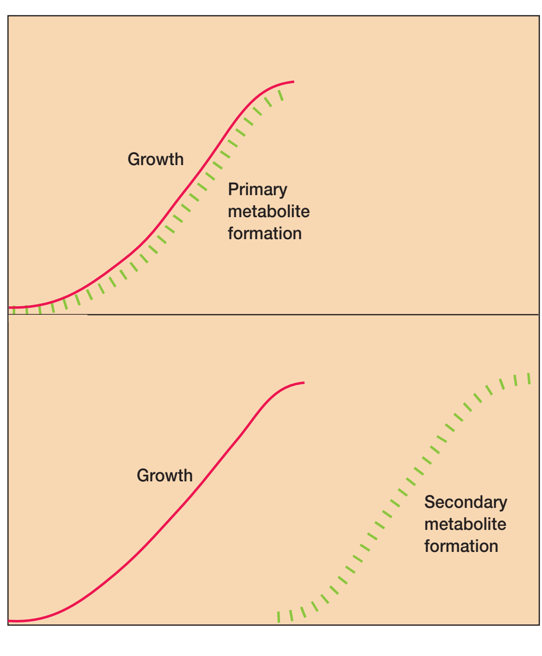

Figure 42.9 Primary and Secondary Metabolites. Depending on the particular organism, the desired product may be formed during or after growth. Primary metabolites are formed during the active growth phase, whereas secondary metabolites are formed after growth is completed.

42.3 Major Products of Industrial Microbiology

Industrial microbiology has provided products that have impacted our lives in many direct and often not appreciated ways. These products have profoundly changed our lives and life spans. They include industrial and agricultural products, food additives, medical products for human and animal health, and biofuels (**table 42.9**). Particularly, in the last few years, nonantibiotic compounds used in medicine and health have made major contributions to the improved well-being of animal and human populations. Only major products in each category will be discussed here.

Antibiotics

Many antibiotics are produced by microorganisms, predominantly by actinomycetes in the genus *Streptomyces* and by filamentous fungi (*see table 35.2*). In this chapter, the synthesis of several of the most important antibiotics will be discussed to illustrate the critical role of medium formulation and environmental control in the production of these important compounds. Antibiotics in medicine (chapter 35)

Penicillin

Penicillin, produced by *Penicillium chrysogenum,* is an excellent example of a fermentation for which careful adjustment of the medium composition is used to achieve maximum yields. Rapid production of cells, which can occur when high levels of glucose are used as a carbon source, does not lead to maximum antibiotic

Table 42.9 Major Microbial Products and Processes of Interest in Industrial Microbiology and Biotechnology

Substances	Microorganisms
Industrial Products	
Ethanol (from glucose)	*Saccharomyces cerevisiae*
Ethanol (from lactose)	*Kluyveromyces fragilis*
Acetone and butanol	*Clostridium acetobutylicum*
2,3-butanediol	*Enterobacter, Serratia*
Enzymes	*Aspergillus, Bacillus, Mucor, Trichoderma*
Agricultural Products	
Gibberellins	*Gibberella fujikuroi*
Food Additives	
Amino acids (e.g., lysine)	*Corynebacterium glutamicum*
Organic acids (citric acid)	*Aspergillus niger*
Nucleotides	*Corynebacterium glutamicum*
Vitamins	*Ashbya, Eremothecium, Blakeslea*
Polysaccharides	*Xanthomonas*
Medical Products	
Antibiotics	*Penicillium, Streptomyces, Bacillus*
Alkaloids	*Claviceps purpurea*
Steroid transformations	*Rhizopus, Arthrobacter*
Insulin, human growth hormone, somatostatin, interferons	*Escherichia coli, Saccharomyces cerevisiae,* and others (recombinant DNA technology)
Biofuels	
Hydrogen	Photosynthetic microorganisms
Methane	*Methanobacterium*
Ethanol	*Zymomonas, Thermoanaerobacter*

yields. Provision of the slowly hydrolyzed disaccharide lactose, in combination with limited nitrogen availability, stimulates a greater accumulation of penicillin after growth has stopped (**figure 42.10**). The same result can be achieved by using a slow continuous feed of glucose. If a particular penicillin is needed, the specific precursor is added to the medium. For example, phenylacetic acid is added to maximize production of penicillin G, which has a benzyl side chain (*see figure 35.7*). This "steering" process is used to maximize the production of desired compounds. The fermentation pH is maintained around neutrality by the addition of sterile alkali, which assures maximum stability of the newly synthesized penicillin. Once the fermentation is completed, normally in 6 to 7 days, the broth is separated from the fungal mycelium and processed by absorption, precipitation, and crystallization to yield the final product. This basic product can then be modified by chemical procedures to yield a variety of **semisynthetic penicillins.**

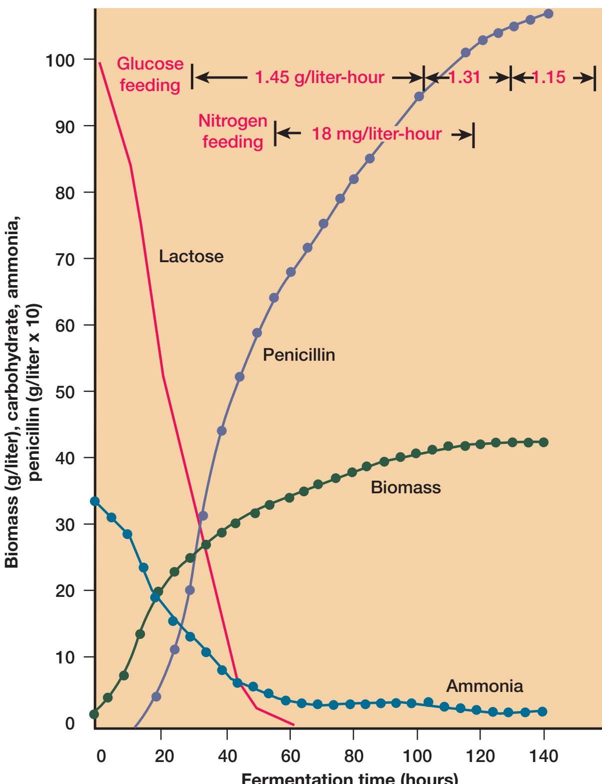

Figure 42.10 Penicillin Fermentation Involves Precise Control of Nutrients. The synthesis of penicillin begins when nitrogen from ammonia becomes limiting. After most of the lactose (a slowly catabolized disaccharide) has been degraded, glucose (a rapidly used monosaccharide) is added along with a low level of nitrogen. This stimulates maximum transformation of the carbon sources to penicillin.

Streptomycin

Streptomycin is a secondary metabolite produced by *Streptomyces griseus,* for which changes in environmental conditions and substrate availability also influence final product accumulation. In this fermentation a soybean-based medium is used with glucose as a carbon source. The nitrogen source is thus in a combined form (soybean meal), which limits growth. After growth the antibiotic levels in the culture begin to increase (**figure 42.11**) under conditions of controlled nitrogen limitation.

The field of antibiotic development continues to expand. At present, 6,000 antibiotics have been described, with 4,000 of these derived from actinomycetes. About 300 new antibiotics are being discovered per year.

Amino Acids

Amino acids such as lysine and glutamic acid are used in the food industry as nutritional supplements in bread products and as flavor-enhancing compounds such as monosodium glutamate (MSG).

Amino acid production is typically carried out by means of **regulatory mutants,** which have a reduced ability to limit synthesis of an end product. The normal microorganism avoids overproduction of biochemical intermediates by the careful regulation of cellular metabolism. Production of glutamic acid and several other amino acids in large quantities is now carried out using mutants of

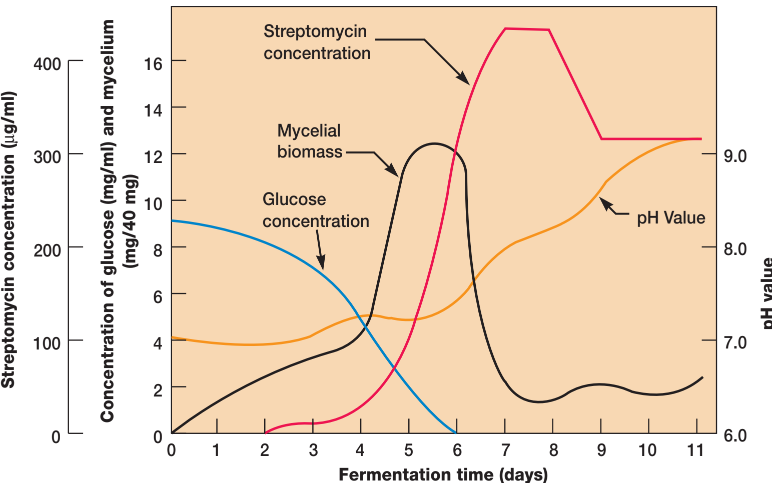

Figure 42.11 Streptomycin Production by *Streptomyces griseus*. Depletion of glucose leads to maximum antibiotic yields.

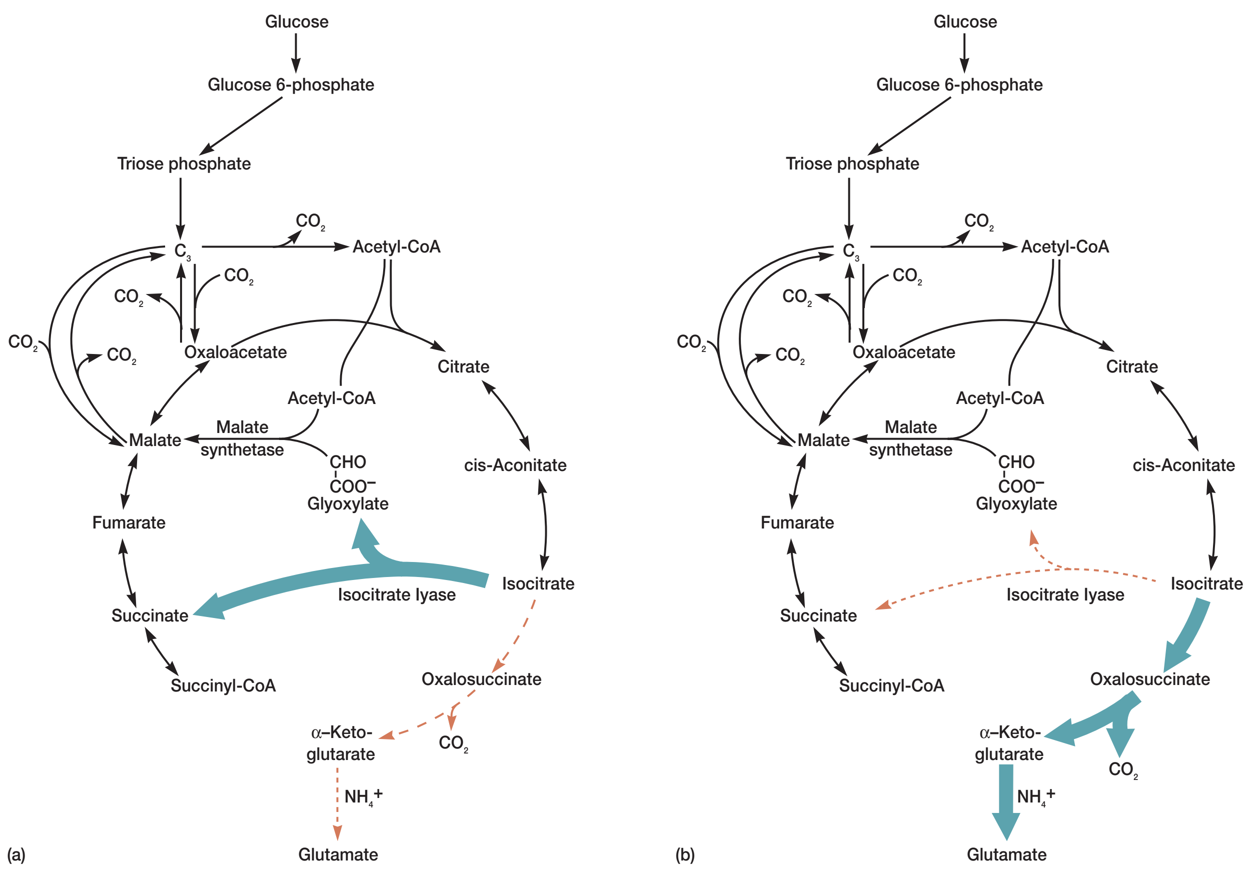

Figure 42.12 Glutamic Acid Production. The sequence of biosynthetic reactions leading from glucose to the accumulation of glutamate by *Corynebacterium glutamicum.* Major carbon flows are noted by bold arrows. (**a**) Growth with use of the glyoxylate bypass to provide critical intermediates in the TCA cycle. (**b**) After growth is completed, most of the substrate carbon is processed to glutamate (note shifted bold arrows). The dashed lines indicate reactions that are being used to a lesser extent.

Corynebacterium glutamicum that lack, or have only a limited ability to process, the TCA cycle intermediate α-ketoglutarate (*see appendix II*) to succinyl-CoA as shown in **figure 42.12.** A controlled low biotin level and the addition of fatty acid derivatives results in increased membrane permeability and excretion of high concentrations of glutamic acid. The impaired bacteria use the glyoxylate pathway (*see section 10.6*) to meet their needs for essential biochemical intermediates, especially during the growth phase. After growth becomes limited because of changed nutrient availability, an almost complete molar conversion (or 81.7% weight conversion) of isocitrate to glutamate occurs.

Lysine, an essential amino acid used to supplement cereals and breads, was originally produced in a two-step microbial process. This has been replaced by a single-step fermentation in which the bacterium *Corynebacterium glutamicum,* blocked in the synthesis of homoserine, accumulates lysine. Over 44 g/liter can be produced in a 3 day fermentation.

Although not used extensively in the United States, microorganisms with related regulatory mutations have been employed to produce a series of 5′ purine nucleotides that serve as flavor enhancers for soups and meat products.

Organic Acids

Organic acid production by microorganisms is important in industrial microbiology and illustrates the effects of trace metal levels and balances on organic acid synthesis and excretion. Citric, acetic, lactic, fumaric, and gluconic acids are major products (**table 42.10**). Until microbial processes were developed, the major source of citric acid was citrus fruit from Italy. Today most citric acid is produced by microorganisms; 70% is used in the food and beverage industry, 20% in pharmaceuticals, and the balance in other industrial applications.

The essence of citric acid fermentation involves limiting the amounts of trace metals such as manganese and iron to stop *As-*

Table 42.10 Major Organic Acids Produced by Microbial Processes

Product	Microorganism Used	Representative Uses	Fermentation Conditions
Acetic acid	*Acetobacter* with ethanol solutions	Wide variety of food uses	Single-step oxidation, with 15% solutions produced; 95–99% yields
Citric acid	*Aspergillus niger* in molasses-based medium	Pharmaceuticals, as a food additive	High carbohydrate concentrations and controlled limitation of trace metals; 60–80% yields
Fumaric acid	*Rhizopus nigricans* in sugar-based medium	Resin manufacture, tanning, and sizing	Strongly aerobic fermentation; carbon-nitrogen ratio is critical; zinc should be limited; 60% yields
Gluconic acid	*Aspergillus niger* in glucose-mineral salts medium	A carrier for calcium and sodium	Uses agitation or stirred fermenters; 95% yields
Itaconic acid	*Aspergillus terreus* in molasses-salts medium	Esters can be polymerized to make plastics	Highly aerobic medium, below pH 2.2; 85% yields
Kojic acid	*Aspergillus flavus-oryzae* in carbohydrate-inorganic N medium	The manufacture of fungicides and insecticides when complexed with metals	Iron must be carefully controlled to avoid reaction with kojic acid after fermentation
Lactic acid	Homofermentative *Lactobacillus delbrueckii*	As a carrier for calcium and as an acidifier	Purified medium used to facilitate extraction

pergillus niger growth at a specific point in the fermentation. The medium often is treated with ion exchange resins to ensure low and controlled concentrations of available metals. Citric acid fermentation, which earlier was carried out by means of static surface growth, now takes place in aerobic stirred fermenters. Generally, high sugar concentrations (15 to 18%) are used, and copper has been found to counteract the inhibition of citric acid production by iron above 0.2 ppm. The success of this fermentation depends on the regulation and functioning of the glycolytic pathway and the tricarboxylic acid cycle (*see section 9.4*). After the active growth phase, when the substrate level is high, citrate synthase activity increases and the activities of aconitase and isocitrate dehydrogenase decrease. This results in citric acid accumulation and excretion by the stressed microorganism.

In comparison, the production of gluconic acid involves a single microbial enzyme, glucose oxidase, found in *Aspergillus niger. A. niger* is grown under optimum conditions in a corn-steep liquor medium. Growth becomes limited by nitrogen, and the resting cells transform the remaining glucose to gluconic acid in a single-step reaction. Gluconic acid is used as a carrier for calcium and iron and as a component of detergents.

Specialty Compounds for Use in Medicine and Health

In addition to the bulk products that have been produced over the last 30 to 40 years, such as antibiotics, amino acids, and organic acids, microorganisms are used for the production of nonantibiotic specialty compounds. These include sex hormones, antitumor agents, ionophores, and special compounds that influence bacteria, fungi, amoebae, insects, and plants (**table 42.11**). In all cases, it is necessary to produce and recover the products under carefully controlled conditions to assure that these medically important compounds reach the consumer in a stable, effective condition.

1. Approximately how many new antibiotics are being discovered per year? What portion of these are derived from actinomycetes?
2. What is the principal limitation created to stimulate citric acid accumulation by *Aspergillus niger?*
3. What types of nutrient limitations are often used in carrying out a successful fermentation? Consider carbon and nitrogen sources.
4. What critical limiting factors are used in the penicillin and streptomycin fermentations?
5. Give some important specialty compounds that are produced by the use of microorganisms.

Biopolymers

Biopolymers are microbially produced polymers used to modify the flow characteristics of liquids and to serve as gelling agents. These are employed in many areas of the pharmaceutical and food industries. The advantage of using microbial biopolymers is that production is independent of climate, political events that can limit raw material supplies, and the depletion of natural resources. Production facilities also can be located near sources of inexpensive substrates (e.g., near agricultural areas). Bacterial exopolysaccharides (p. 61)

At least 75% of all polysaccharides are used as stabilizers, for the dispersion of particulates, as film-forming agents, or to promote water retention in various products. Polysaccharides help maintain the texture of many frozen foods, such as ice cream, that are subject to drastic temperature changes. These polysaccharides must maintain their properties under the pH conditions in the particular food and be compatible with other polysaccharides. They should not lose their physical characteristics if heated.

Biopolymers include (1) dextrans, which are used as blood expanders and absorbents; (2) *Erwinia* polysaccharides that are in

Table 42.11 Nonantibiotic Specialty Compounds Produced by Microorganisms

Compound Type	Source	Specific Product	Process/Organism Affected
Polyethers	*Streptomyces cinnamonensis*	Monensin	Coccidiostat, rumenal growth promoter
	S. lasaliensis	Lasalocid	Coccidiostat, ruminal growth promoter
	S. albus	Salinomycin	Coccidiostat, ruminal growth promoter
Avermectins	*S. avermitilis*		Helminths and arthropods
Statins	*Aspergillus terreus*	Lovastatin	Cholesterol-lowering agent
	Penicillium citrinum + actinomycete[a]	Pravastatin	Cholesterol-lowering agent
Enzyme inhibitors	*S. clavaligerus*	Clavulanic acid	Penicillinase inhibitor
	Actinoplanes sp.	Acarbose	Intestinal glucosidase inhibitor (decreases hyperglycemia and triglyceride synthesis)
Bioherbicide	*S. hygroscopicus*	Bialaphos	
Immunosuppressants	*Tolypocladium inflatum*	Cyclosporin A	Organ transplants
	S. tsukabaensis	FK-506	Organ transplants
	S. hygroscopicus	Rapamycin	Organ transplants
Anabolic agents	*Gibberella zeae*	Zearalenone	Farm animal medication
Uterocontractants	*Claviceps purpurea*	Ergot alkaloids	Induction of labor
Antitumor agents	*S. peuceticus* subsp. *caesius*	Doxorubicin	Cancer treatment
	S. peuceticus	Daunorubicin	Cancer treatment
	S. caespitosus	Mitomycin	Cancer treatment
	S. verticillus	Bleomycin	Cancer treatment

[a]Compactin, produced by *Penicillium citrinum,* is changed to pravastatin by an actinomycete bioconversion.

Biotechnol.* 52:455–463; G. Lancini; A. L. Demain. 1999. Secondary metabolism in bacteria: Antibiotic pathways regulation, and function. In *Biology of the prokaryotes,* J. W. Lengeler, G. Drews, and H. G. Schlegel, editors, 627–51. New York: Thieme.

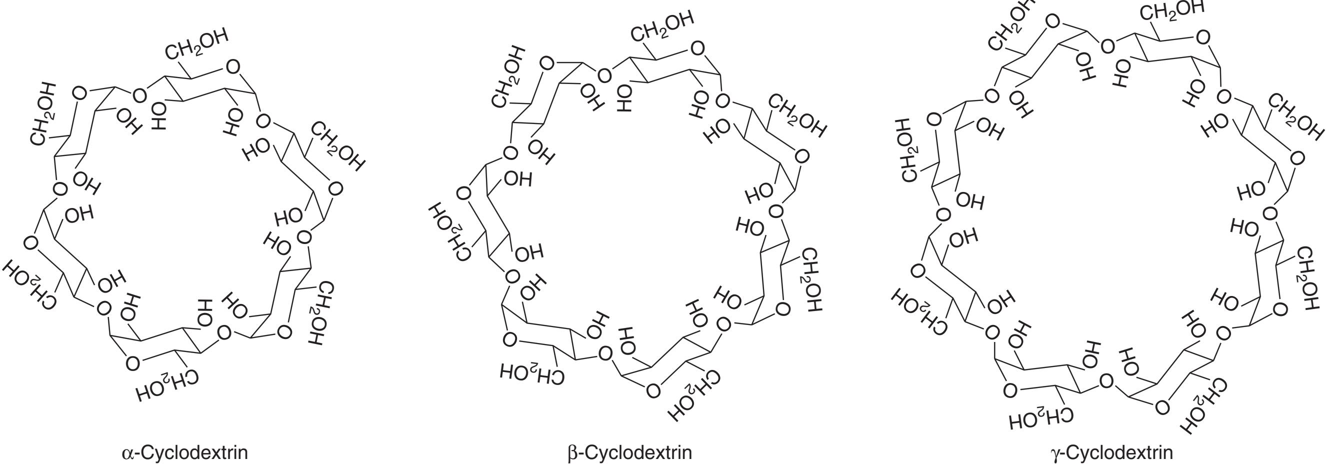

Figure 42.13 Cyclodextrins. The basic structures of cyclodextrins produced by *Thermoanaerobacter* are illustrated here. These unique oligopolysaccharides have many applications in medicine and industry.

paints; and (3) polyesters, derived from *Pseudomonas oleovorans,* which are a feedstock for specialty plastics. Cellulose microfibrils, produced by an *Acetobacter* strain, are used as a food thickener. Polysaccharides such as scleroglucan are used by the oil industry as drilling mud additives. Xanthan polymers enhance oil recovery by improving water flooding and the displacement of oil. This use of xanthan gum, produced by *Xanthomonas campestris,* represents a large potential market for this microbial product.

The cyclodextrins have a unique structure, as shown in **figure 42.13.** They are cyclic oligosaccharides whose sugars are joined by α-1,4 linkages. Cyclodextrins can be used for a wide variety of purposes because these cyclical molecules bind with

substances and modify their physical properties. For example, cyclodextrins will increase the solubility of pharmaceuticals, reduce their bitterness, and mask chemical odors. Cyclodextrins also can be used as selective adsorbents to remove cholesterol from eggs and butter or protect spices from oxidation.

Biosurfactants

Many surfactants that have been used for commercial purposes are products of synthetic chemistry. At the present time there is an increasing interest in the use of biosurfactants. These are especially important for environmental applications where biodegradability is a major requirement. Biosurfactants are used for emulsification, increasing detergency, wetting and phase dispersion, as well as for solubilization. These properties are especially important in bioremediation, oil spill dispersion, and enhanced oil recovery (EOR).

The most widely used microbially produced biosurfactants are glycolipids. These compounds have distinct hydrophilic and hydrophobic regions, and the final compound structure and characteristics depend on the particular growth conditions and the carbon source used. Good yields often are obtained with insoluble substrates. These biosurfactants are excellent dispersing agents and have been used with the *Exxon Valdez* oil spill.

Bioconversion Processes

Bioconversions, also known as **microbial transformations** or **biotransformations,** are minor changes in molecules, such as the insertion of a hydroxyl or keto function or the saturation/desaturation of a complex cyclic structure, that are carried out by nongrowing microorganisms. The microorganisms thus act as **biocatalysts.** Bioconversions have many advantages over chemical procedures. A major advantage is stereochemical; the biologically active form of a product is made. In contrast, most chemical syntheses produce racemic mixtures in which only one of the two isomers will be able to be used efficiently by the organism. Enzymes also carry out very specific reactions under mild conditions, and larger water-insoluble molecules can be transformed. Unicellular bacteria, actinomycetes, yeasts, and molds have been used in various bioconversions. The enzymes responsible for these conversions can be intracellular or extracellular. Cells can be produced in batch or continuous culture and then dried for direct use, or they can be prepared in more specific ways to carry out desired bioconversions.

A typical bioconversion is the hydroxylation of a steroid (**figure 42.14**). In this example, the water-insoluble steroid is dissolved in acetone and then added to the reaction system that contains the pregrown microbial cells. The course of the modification is monitored, and the final product is extracted from the medium and purified.

Biotransformations carried out by free enzymes or intact nongrowing cells do have limitations. Reactions that occur in the absence of active metabolism—without reducing power or ATP being available continually—are primarily exergonic reactions (*see section 8.3*). If ATP or reductants are required, an energy source such as glucose must be supplied under carefully controlled nongrowth conditions.

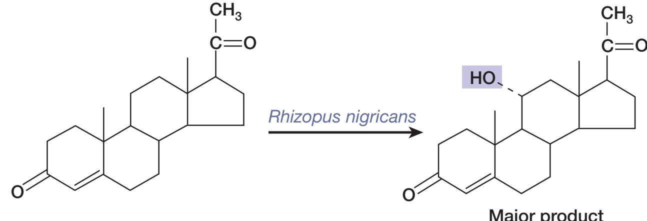

Figure 42.14 Biotransformation to Modify a Steroid. Hydroxylation of progesterone in the 11α position by *Rhizopus nigricans.* The steroid is dissolved in acetone before addition to the pregrown fungal culture.

When freely suspended vegetative cells or spores are employed, the microbial biomass usually is used only once. At the end of the process, the cells are discarded. Cells often can be used repeatedly after attaching them to ion exchange resins by ionic interactions or immobilizing them in a polymeric matrix. Ionic, covalent, and physical entrapment approaches can be used to immobilize microbial cells, spores, and enzymes. Microorganisms also can be immobilized on the inner walls of fine tubes. The solution to be modified is then simply passed through the microorganism-lined tubing; this approach is being applied in many industrial and environmental processes. These include bioconversions of steroids, degradation of phenol, and the production of a wide range of antibiotics, enzymes, organic acids, and metabolic intermediates. One application of cells as biocatalysts is the recovery of precious metals from dilute-process streams.

1. Discuss the major uses for biopolymers and biosurfactants.
2. What are cyclodextrins and why are they important additives?
3. What are bioconversions or biotransformations? Describe the changes in molecules that result from these processes.

42.4 Microbial Growth in Complex Environments

Industrial microbiology and biotechnology also can be carried out in complex natural environments such as waters, soils, or high organic matter–containing composts. In these complex environments, the physical and nutritional conditions for microbial growth cannot be completely controlled, and a largely unknown microbial community is present. These applications of industrial microbiology and biotechnology usually are lower cost, larger volume processes, where no specific commercial microbial product is created. Examples are (1) the use of microbial communities to carry out biodegradation, bioremediation, and environmental maintenance processes; and (2) the addition of microorganisms to soils or plants for the improvement of crop production. Both of these applications will be discussed in this section.

© The McGraw–Hill Companies, 2002

(a) Minor change (dehalogenation)

(b) Fragmentation

(c) Mineralization

Figure 42.15 Biodegradation Has Several Meanings. Biodegradation is a term that can be used to describe three major types of changes in a molecule. (**a**) A minor change in the functional groups attached to an organic compound, as the substitution of a hydroxyl group for a chlorine group. (**b**) An actual breaking of the organic compound into organic fragments in such a way that the original molecule could be reconstructed. (**c**) The complete degradation of an organic compound to minerals.

Biodegradation Using Natural Microbial Communities

Before discussing **biodegradation** processes carried out by natural microbial communities, it is important to consider definitions. Biodegradation has at least three definitions (**figure 42.15**): (1) a minor change in an organic molecule leaving the main structure still intact, (2) fragmentation of a complex organic molecule in such a way that the fragments could be reassembled to yield the original structure, and (3) complete mineralization. As mentioned previously (*see p. 613*), mineralization is the transformation of organic molecules to mineral forms, including carbon dioxide or methane, plus inorganic forms of other elements that might have been contained in the original structures.

Originally it was assumed, given time and the almost infinite variety of microorganisms, that all organic compounds, including those synthesized in the laboratory, would eventually degrade. Observations of natural and synthetic organic compound accumulation in natural environments, however, began to raise questions about the ability of microorganisms to degrade these varied substances and the role of the environment (clays, anaerobic conditions) in protecting some chemicals. With the development of synthetic pesticides, it became distressingly evident that not all organic compounds are immediately biodegradable. This chemical **recalcitrance** (resisting authority or control) resulted from the apparent fallibility of microorganisms, or their inability to degrade some industrially synthesized chemical compounds.

Degradation of a complex compound takes place in several stages. In the case of halogenated compounds, dehalogenation often occurs early in the overall process. Dehalogenation of many compounds containing chlorine, bromine, or fluorine occurs faster under anaerobic than under aerobic conditions. The study of **reductive dehalogenation,** especially its commercial applications, is expanding rapidly. Research on the dehalogenation of PCBs shows that this coreductive process can use electrons derived from water; other studies indicate that hydrogen can be the source of reductant for the dehalogenation of different chlorinated compounds. Major genera that carry out this process include *Desulfitobacterium, Dehalospirillum,* and *Desulfomonile.*

Humic acids, brownish polymeric residues of lignin decomposition that accumulate in soils and waters, have been found to play a role in anaerobic biodegradation processes. They can serve as electron acceptors under what are called "humic-acid-reducing conditions." The use of humic acids as electron acceptors has been observed with the anaerobic dechlorination of vinyl chloride and dichloroethylene.

Once the anaerobic dehalogenation steps are completed, degradation of the main structure of many pesticides and other xenobiotics often proceeds more rapidly in the presence of O_2.

Structure and stereochemistry are critical in predicting the fate of a specific chemical in nature. When a constituent is in the meta as opposed to the ortho position, the compound will be degraded at a much slower rate. The ***meta* effect** is shown in **figure 42.16.** This stereochemical difference is the reason that the common lawn herbicide 2,4-dichlorophenoxyacetic acid (2,4-D), with a chlorine in the ortho position, will be largely degraded in a single summer. In contrast, 2,4,5-trichlorophenoxyacetic acid, with a constituent in the meta position, will persist in the soils for several years, and thus is used for long-term brush control. Check out the labels on herbicide preparations the next time you go to the garden store!

An important aspect of managing biodegradation is the recognition that many of the compounds that are added to environments are **chiral,** or possess asymmetry and handedness. Microorganisms often can degrade only one isomer of a substance; the other isomer will remain in the environment. At least 25% of herbicides are chiral (**figure 42.17**). Thus it is critical to add the herbicide isomer that is effective and also degradable. Recent studies have shown that microbial communities in different environments will degrade dif-

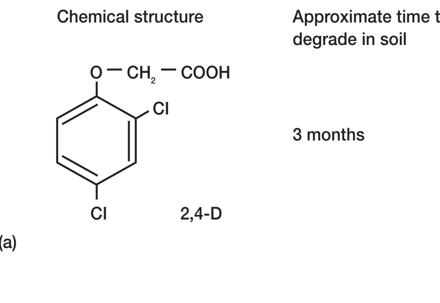

Figure 42.16 The *Meta* Effect and Biodegradation. Minor structural differences can have major effects on the biodegradability of chemicals. The *meta* effect is an important example. (**a**) Readily degradable 2,4-dichlorophenoxyacetic acid (2,4-D) with an exposed meta position on the ring degrades in several months; (**b**) recalcitrant 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) with the blocked meta group, can persist for years.

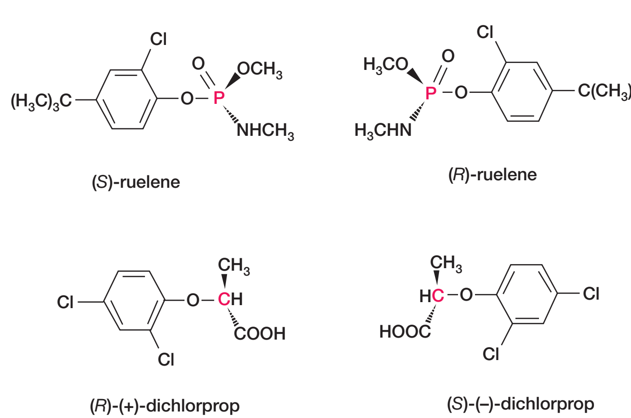

Figure 42.17 Chirality, or Handedness, Is Important in Degradation. It is now recognized that one enantiomer form of a chemical may be more effective, and also may differ in degradability. Enantiomers of the herbicides ruelene and dichlorprop are shown. It is critical to add the isomers that are effective and biodegradable.

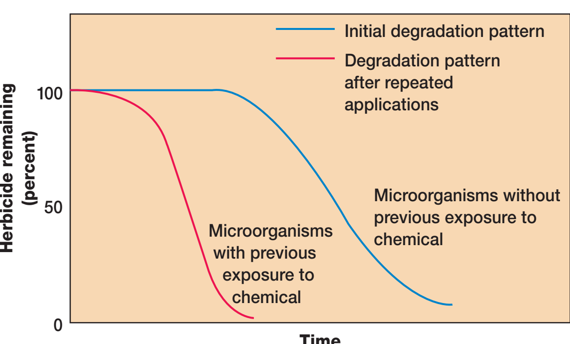

Figure 42.18 Repeated Exposure and Degradation Rate. Addition of an herbicide to a soil can result in changes in the degradative ability of the microbial community. Relative degradation rates for an herbicide after initial addition to a soil, and after repeated exposure to the same chemical.

ferent enantiomers. Changes in environmental conditions and nutrient supplies can alter the patterns of chiral form degradation.

Microbial communities change their characteristics in response to physical changes such as mixing of soil or water to add oxygen, or after the addition of inorganic or organic substrates, which may stimulate different components of the microbial community. If a particular compound, such as a herbicide, is added repeatedly to a microbial community, the community adapts and faster rates of degradation can occur (**figure 42.18**). The adaptive process often is so effective that this enrichment culture-based approach, established on the principles elucidated by Beijerinck (*see p. 11*) can be used to isolate organisms with a desired set of capabilities. For example, a microbial community can become so efficient at rapid herbicide degradation that herbicide effectiveness is diminished. To counteract this process, herbicides can be changed to throw the microbial community off balance, thus preserving the effectiveness of the chemicals. The degradation of many pesticides may also result in the accumulation of organic fragments that bind with organic matter in the soil. The longer-term fate and possible effects of "bound" pesticide residues on the soil system, plants, and higher organisms are largely unknown.

Degradation processes that occur in soils also can be used in large-scale degradation of hydrocarbon wastes or of wastewater, particularly from agricultural operations, in a technique called **land farming.** The waste material is incorporated into the soil or allowed to flow across the soil surface, where degradation occurs.

It is important to emphasize that such degradation processes do not always reduce environmental problems. In fact, the partial degradation or modification of an organic compound may not lead to decreased toxicity. An example of this process is the microbial metabolism of 1,1,1-trichloro-2,2-*bis*-(p-chlorophenyl)ethane (DDT), a xenobiotic or foreign (chemically synthesized) organic compound. Degradation removes a chlorine function to give 1,1-dichloro-2,2-*bis*(p-chlorophenyl)ethylene (DDE), which is still of environmental concern. Another important example is the degradation of trichloroethylene (TCE), a widely used solvent. If this is degraded under anaerobic conditions, the dangerous carcinogen vinyl chloride can be synthesized.

$$Cl_2 = CHCl \rightarrow ClHC = CH_2$$

Biodegradation also can lead to widespread damages and financial losses. Metal corrosion is a particularly important example.

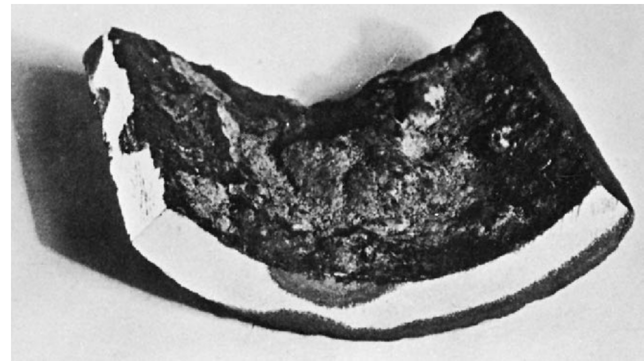
Box 42.2

Methanogens: A New Role for an Ancient Microbial Group

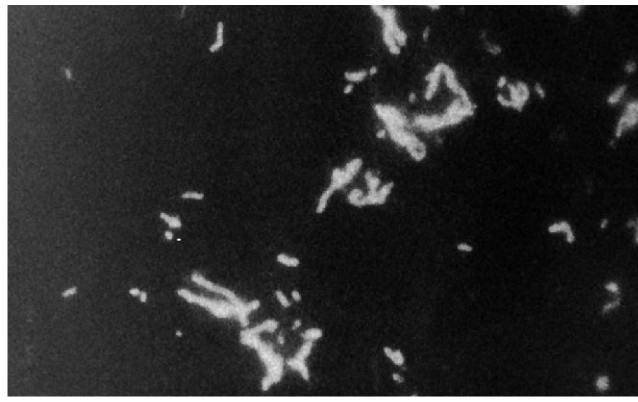
The methanogens, an important group of the archaea that can produce methane, are considered to be at least 3.5 billion years old. Despite intensive research, new discoveries are still being made concerning these microorganisms. Methanogens have now been found to contribute to the anaerobic corrosion of soft iron. Previously the microbial group usually considered the major culprit in the anaerobic corrosion process was the genus *Desulfovibrio,* which can use sulfate as an oxidant and hydrogen produced in the corrosion process as a reductant. Methanogens can use elemental iron as an electron source in their metabolism. It appears that corrosion may occur even without the presence of sulfate, which is required for functioning of *Desulfovibrio.* Rates of iron removal by the methanogens are around 79 mg/1,000 cm^2 of surface area in a 24 hour period. This may not seem a high rate, but in relation to the planned service life of metal structures in muds and subsurface soils—possibly years and decades—such corrosion can become a major problem. Continuous efforts to improve protection of iron structures will be required in view of the diversity of iron-corroding microorganisms.

The microbially mediated corrosion of metals is particularly critical where iron pipes are used in waterlogged anaerobic environments or in secondary petroleum recovery processes carried out at older oil fields. In these older fields water is pumped down a series of wells to force residual petroleum to a central collection point. If the water contains low levels of organic matter and sulfate, anaerobic microbial communities can develop in rust blebs or tubercles (**figure 42.19**), resulting in punctured iron pipe and loss of critical pumping pressure. Microorganisms that use elemental iron as an electron donor during the reduction of CO_2 in methanogenesis have recently been discovered (**Box 42.2**). Because of the wide range of interactions that occur between microorganisms and metals, the need to develop strategies to deal with corrosion problems is critical.

1. Give alternative definitions for the term biodegradation.
2. What is reductive dehalogenation? Describe humic acids and the role they can play in anaerobic degradation processes.
3. Discuss chirality and its importance for understanding degradation effects in the environment.
4. Why is the “meta effect” important for understanding biodegradation?
5. What is “land farming” and why is it important in waste degradation?



(a)



(b)

Figure 42.19 Microbial-Mediated Metal Corrosion. The microbiological corrosion of iron is a major problem. (**a**) The graphitization of iron under a rust bleb on the pipe surface allows microorganisms, including *Desulfovibrio,* to corrode the inner surface. (**b**) Evidence points to the importance of communities of microorganisms, as opposed to individual species acting alone, as a major factor in microbiologically influenced corrosion. This epifluorescence microscope view (×1,600) is of pipeline steel a few hours after colonization by sulfate-reducing and organic acid-producing bacteria such as species of *Enterobacter* and *Clostridium.*

Changing Environmental Conditions to Stimulate Biodegradation

Often natural microbial communities will not be able to carry out biodegradation processes at a desired rate due to limiting physical or nutritional factors. For example, biodegradation often will be limited by low oxygen levels. Hydrocarbons, nitrogen, phosphorus, and other needed nutrients also may be absent or available only at slow flux rates, thus limiting rates of degradation. In these cases, it is necessary to determine the limiting factors, based on Liebig’s and Shelford’s laws, and then to supply needed materials or modify the environment. Liebig’s and Shelford’s laws (p. 131)

Most of the early efforts to stimulate the degradative activities of microorganisms involved the modification of waters and soils by the addition of oxygen or nutrients, now called **engineered biore-**

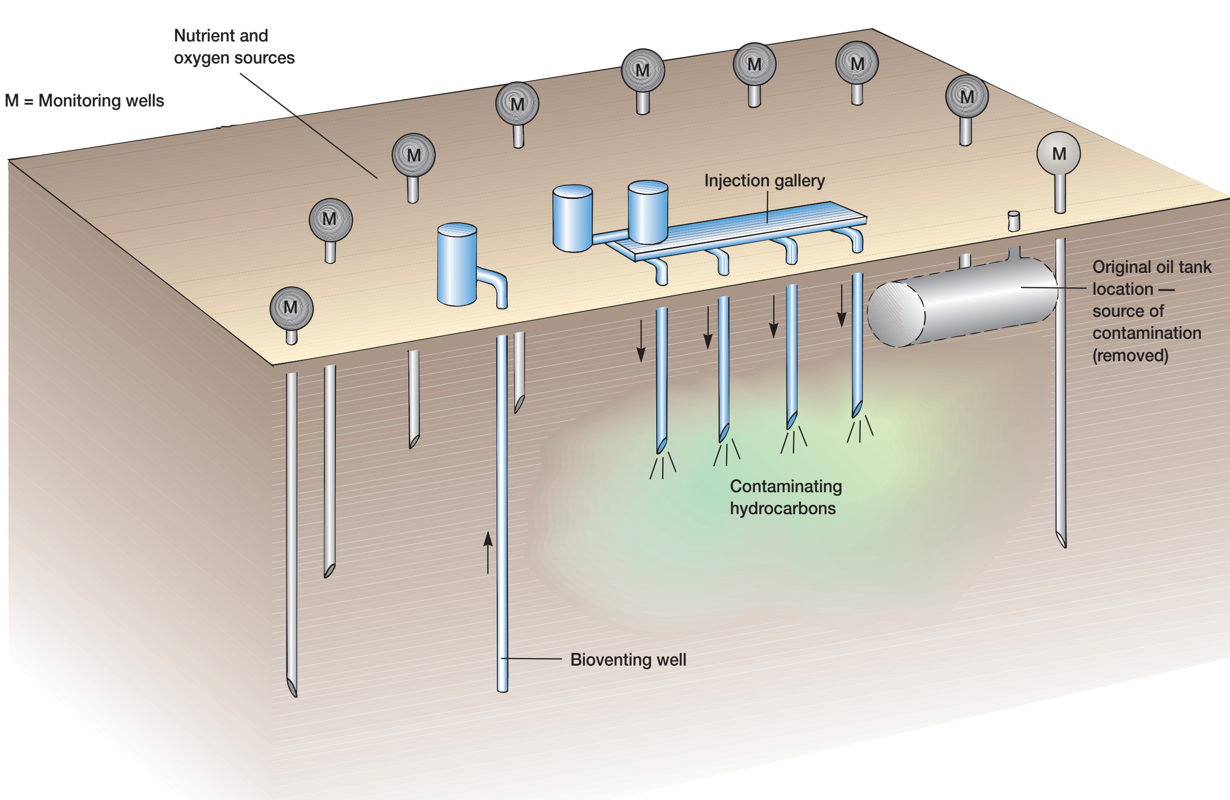


Figure 42.20 A Subsurface Engineered Bioremediation System. Monitoring and recovery wells are used to monitor the plume and its possible movement. Nutrients and oxygen (as peroxide or air) are added to the contaminated soil and groundwater. A bioventing well can be used to accelerate the removal of hydrocarbon vapors.

mediation. Contact between the microbes and the substrate; the proper physical environment, nutrients, oxygen (in most cases); and the absence of toxic compounds are critical in this managed process.

Often it is found that the addition of easily metabolized organic matter such as glucose increases biodegradation of recalcitrant compounds that are usually not used as carbon and energy sources by microorganisms. This process, termed **cometabolism,** is finding widespread applications in biodegradation management. Cometabolism can be carried out by simply adding easily catabolized organic matter such as glucose or cellulose and the compound to be degraded to a complex microbial community. Plants also may be used to provide the organic matter. Cometabolism is important in many different biodegradation systems, and it also is discussed in chapter 30.

Stimulating Hydrocarbon Degradation in Waters and Soils

Experiences with oil spills in marine environments illustrate these principles. When working with dispersed hydrocarbons in the ocean, contact between the microorganism, the hydrocarbon substrate, and other essential nutrients must be maintained. To achieve this, pellets containing nutrients and an oleophilic (hydrocarbon soluble) preparation have been used. This technique has accelerated the degradation of different crude oil slicks by 30 to 40%, in comparison with control oil slicks where the additional nutrients were not available.

A unique challenge for this technology was the *Exxon Valdez* oil spill, which occurred in Alaska in March 1989. Several different approaches were used to increase biodegradation. These included nutrient additions, chemical dispersants, biosurfactant additions, and the use of high-pressure steam. The use of a microbially produced glycolipid emulsifier has proven helpful.

The degradation of hydrocarbons and other chemical residues in contaminated subsurface environments presents special challenges. The major difference is that geological structures have limited permeability. Although subsurface regions in a pristine state often have O_2 concentrations approaching saturation, the penetration of small amounts of organic matter into these structures can quickly lead to O_2 depletion.

A typical approach that can be used to carry out in situ bioremediation in subsurface environments is shown in **figure 42.20.** Depending on the petroleum contamination and the geological

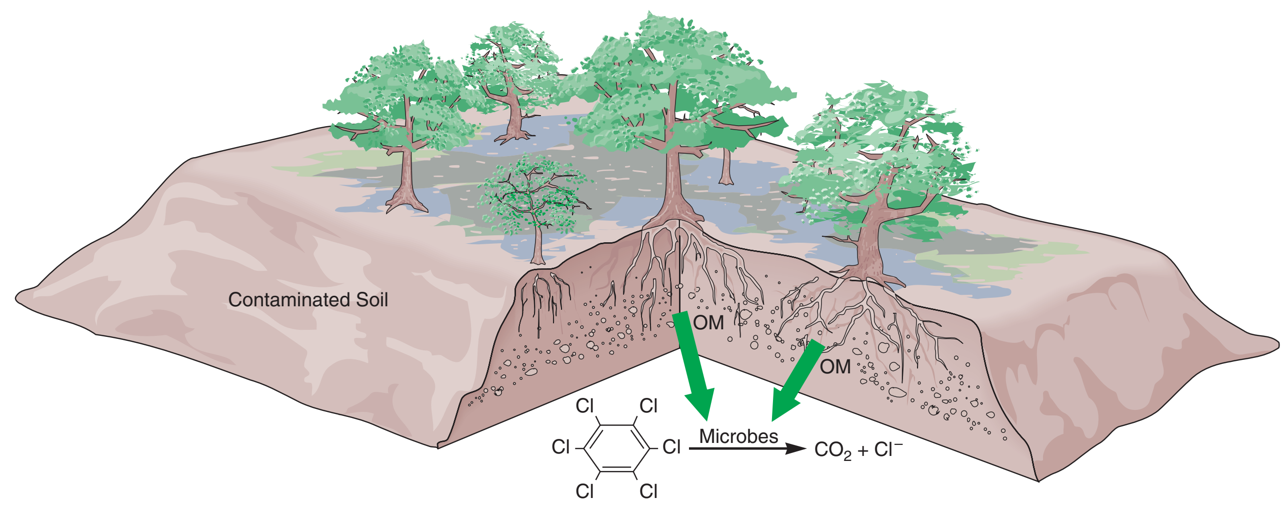

Figure 42.21 Phytoremediation. A conceptual view of a phytoremediation system, with a cut-away section of the root-soil zone. When organic matter (OM) is released from the plant roots, cometabolic processes can be carried out more efficiently by microbes, leading to enhanced degradation of contaminants. The degradation of hexachlorobenzene is shown as an example.

characteristics of the site, injection and monitoring wells can be installed. Nutrients and a source of oxygen (possibly compressed air or peroxide) also can be added. Often this process is combined with bioventing, the physical removal of vapors by a vacuum. Depending on the volume and the location of the contaminated soil, the process may require months or years to complete.

A unique two-stage process can be used to degrade PCBs in river sediments. First, partial dehalogenation of the PCBs occurs naturally under anaerobic conditions. Then the muds are aerated to promote the complete degradation of the less chlorinated residues produced by this intrinsic bioremediation process (chapter opening figure).

Stimulating Degradation with Plants

Phytoremediation, or the use of plants to stimulate the degradation, transformation, or removal of compounds, either directly or in conjunction with microorganisms, is becoming an important part of biodegradation technology. A plant provides nutrients that allow cometabolism to occur in the plant root zone or rhizosphere (**figure 42.21**). Phytoremediation also includes plant contributions to degradation, immobilization, and volatilization processes, as noted in **table 42.12.** Transgenic plants may be employed in phytoremediation. Using cloning techniques with *Agrobacterium* (*see pp. 340, 492–93, 684*), the *mer*A and *mer*B genes have been integrated into a plant (*Arabidopsis thaliana*), thus making it possible to transform extremely toxic organic mercury forms to elemental mercury, which is less of an environmental hazard. Recently transgenic tobacco plants have been constructed that express tetranitrate reductase, an enzyme from an explosive-degrading bacterium, thereby enabling the transgenic plants to degrade nitrate ester and nitro aromatic explosives. The genetically modified plants grow in solutions of explosives that control plants cannot tolerate. Other plants have been engineered in the same way to degrade trichloroethylene, an environmental contaminant of worldwide concern.

Table 42.12 Types of Phytoremediation

Process	Function
Phytoextraction	Use of pollutant-accumulating plants to remove metals or organics from soil by concentrating them in the harvestable plant parts
Phytodegradation	Use of plants and associated microorganisms to degrade organic pollutants
Rhizofiltration	Use of plant roots to absorb and adsorb pollutants, mainly metals, from water and aqueous waste streams
Phytostabilization	Use of plants to reduce the bioavailability of pollutants in the environment
Phytovolatilization	Use of plants to volatilize pollutants

Based on T. Macek; M. Mackova; and J. Kás. 2000. Exploitation of plants for the removal of organics in environmental remediation. *Biotechnol. Adv.* 18:23–34. P. 25.

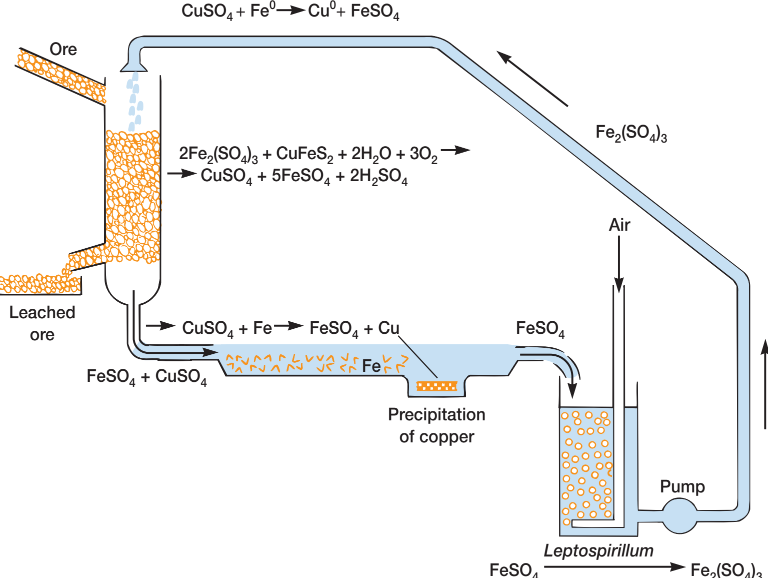

Figure 42.22 Copper Leaching from Low-Grade Ores. The chemistry and microbiology of copper ore leaching involve interesting complementary reactions. The microbial contribution is the oxidation of ferrous ion (Fe^{2+}) to ferric ion (Fe^{3+}). *Leptospirillum ferrooxidans* and related microorganisms are very active in this oxidation. The ferric ion then reacts chemically to solubilize the copper. The soluble copper is recovered by a chemical reaction with elemental iron, which results in an elemental copper precipitate.

Stimulation of Metal Bioleaching from Minerals

Bioleaching is the use of microorganisms, which produce acids from reduced sulfur compounds, to create acidic environments that solubilize desired metals for recovery. This approach is used to recover metals from ores and mining tailings with metal levels too low for smelting. Bioleaching carried out by natural populations of *Leptospirillum*-like species, *Thiobacillus thiooxidans,* and related thiobacilli, for example, allows recovery of up to 70% of the copper in low-grade ores. As shown in **figure 42.22,** this involves the biological oxidation of copper present in these ores to produce soluble copper sulfate. The copper sulfate can then be recovered by reacting the leaching solution, which contains up to 3.0 g/liter of soluble copper, with iron. The copper sulfate reacts with the elemental iron to form ferrosulfate, and the copper is reduced to the elemental form, which precipitates out in a settling trench. The process is summarized in the following reaction:

$$CuSO_4 + Fe^0 \rightarrow Cu^0 + FeSO_4$$

Bioleaching may require added phosphorus and nitrogen if these are limiting in the ore materials, and the same process can be used to solubilize uranium.

It is apparent that nature will assist in bioremediation if given a chance. The role of natural microorganisms in biodegradation is now better appreciated. An excellent example is the recent work with the very versatile fungus *Phanerochaete chrysosporium* (**Box 42.3**).

Often biodegradation and biodeterioration have major negative effects, and it becomes important to control and limit these processes by environmental management. Problems include unwanted degradation of paper, jet fuels, textiles, and leather goods. A global concern is microbial-based metal corrosion.

1. What factors must one consider when attempting to stimulate the microbial degradation of a massive oil spill in a marine environment?
2. What is cometabolism and why is this important for degradation processes?
3. How is in situ bioremediation carried out?
4. Describe the major types of phytoremediation. What is the role of microorganisms in each of these processes?
5. How is bioleaching carried out and what microbial genera are involved?
6. What is unique about *Phanerochaete chrysosporium?* What does its name mean?

Addition of Microorganisms to Complex Microbial Communities

Both in laboratory and field studies, attempts have been made to speed up existing microbiological processes by adding known active microorganisms to soils, waters, or other complex systems. The microbes used in these experiments have been isolated from contaminated sites, taken from culture collections, or derived from uncharacterized enrichment cultures. For example, commercial culture preparations are available to facilitate silage formation and to improve septic tank performance.

Addition of Microorganisms without Considering Protective Microhabitats

With the development of the "superbug" by A. M. Chakrabarty in 1974, there was initial excitement due to the hope that such

Box 42.3

Phanerochaete chrysosporium: A Wood-Degrading Fungus with a Voracious Appetite

The basidiomycete *Phanerochaete chrysosporium* (the scientific name means "visible hair, golden spore") is a fungus with unusual degradative capabilities. This organism is termed a "white rot fungus" because of its ability to degrade lignin, a randomly linked phenylpropane-based polymeric component of wood (*see section 28.3*). The cellulosic portion of wood is attacked to a lesser extent, resulting in the characteristic white color of the degraded wood. This organism also degrades a truly amazing range of xenobiotic compounds (nonbiological foreign chemicals) using both intracellular and extracellular enzymes.

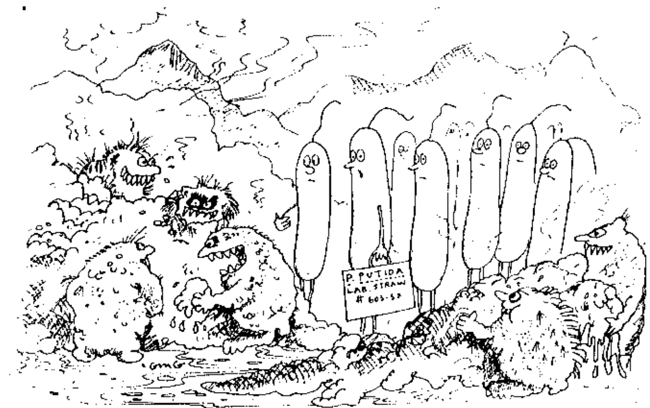
As examples, the fungus degrades benzene, toluene, ethylbenzene, and xylenes (the so-called BTEX compounds), chlorinated compounds such as 2,4,5-trichloroethylene (TCE), and trichlorophenols. The latter are present as contaminants in wood preservatives and also are used as pesticides. In addition, other chlorinated benzenes can be degraded with or without toluenes being present. Even the insecticide Hydramethylnon is degraded!

How does this microorganism carry out such feats? Apparently most degradation of these xenobiotic compounds occurs after active growth, during the secondary metabolic lignin degradation phase. Degradation of some compounds involves important extracellular enzymes including lignin peroxidase, manganese-dependent peroxidase, and glyoxal oxidase. A critical enzyme is pyranose oxidase, which releases H_2O_2 for use by the manganese-dependent peroxidase enzyme. The H_2O_2 also is a precursor of the highly reactive hydroxyl radical, which participates in wood degradation. Apparently the pyranose oxidase enzyme is located in the interperiplasmic space of the fungal cell wall, where it can function either as a part of the fungus or be released from the fungus and penetrate into the wood substrate. It appears that the nonspecific enzymatic system that releases these oxidizing products degrades many cyclic, aromatic, and chlorinated compounds related to lignins.

We can expect to continue hearing of many new advances in work with this organism. Potentially valuable applications being studied include growth in bioreactors where intracellular and extracellular enzymes can be maintained in the bioreactor while liquid wastes flow past the immobilized fungi.

---

an improved microorganism might be able to degrade hydrocarbon pollutants very effectively. A critical point, which was not considered, was the actual location, or microhabitat, where the microbe had to survive and function. Engineered microorganisms were added to soils and waters with the expectation that rates of degradation would be stimulated as these microorganisms established themselves. Generally such additions led to short-term increases in rates of the desired activity, but typically after a few days the microbial community responses were similar in treated and control systems. After many unsuccessful attempts, it was found that the lack of effectiveness of such added cultures was due to at least three factors: (1) the attractiveness of laboratory-grown microorganisms as a food source for predators such as soil protozoa, (2) the inability of these added microorganisms to contact the compounds to be degraded, and (3) the failure of the added microorganisms to survive and compete with indigenous microorganisms (**figure 42.23**). Such a modified microorganism may be less fit to compete and survive because of the additional energetic burden required to maintain the extra DNA.



"Oh dear! I didn't realize 'in the field' would be like this! We should have stayed in the laboratory."

Figure 42.23 A Cartoonist's View of Laboratory-Grown Microbes Returning to Their Original Environment. *Source:* Tibtech *1993 11:344–352.*

Attempts have been made to make such laboratory-grown cultures more capable of survival in a natural environment by growing them in low-nutrient media or starving the microorganisms before adding them to an environment. These "toughening" approaches have improved microbial survival and function somewhat, but have not solved the problem. In recent years, there has been less interest in simply adding microorganisms to environments without considering the specific niche or microenvironment in which they are to survive and function. This has led to the field of **natural attenuation,** which emphasizes the use of natural microbial communities in the environmental management of pollutants.

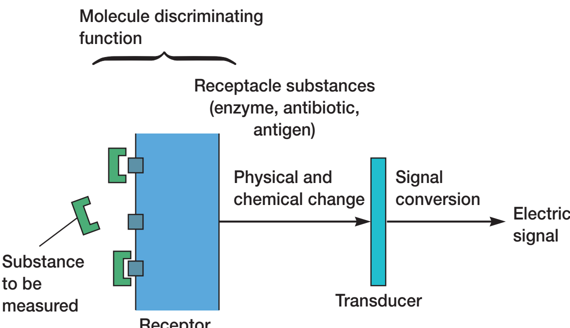


Figure 42.24 Biosensor Design. Biosensors are finding increasing applications in medicine, industrial microbiology, and environmental monitoring. In a biosensor a biomolecule or whole microorganism carries out a biological reaction, and the reaction products are used to produce an electrical signal.

Addition of Microorganisms Considering Protective Microhabitats

Microorganism additions to natural environments can be more successful if the microorganism is added together with a microhabitat that gives the organism physical protection, as well as possibly supplying nutrients. This makes it possible for the microorganism to survive in spite of the intense competitive pressures that exist in the natural environment, including pressure from protozoan predators such as ciliates, flagellates, and amoebae. Microhabitats may be either living or inert. Predation (pp. 607–9)

Living Microhabitats. Specialized living microhabitats include the surface of a seed, a root, or a leaf, which, with their higher nutrient flux rate and the chance for initial colonization by the added microorganisms, can protect the added microbe from the fierce competitive conditions in the natural environment. Examples include the use of *Rhizobium* and *Bacillus thuringiensis.* In order to ensure that *Rhizobium* is in close association with the legume, seeds are coated with the microbe using an oil-organism mixture, or *Rhizobium* is placed in a band under the seed where the newly developing primary root will penetrate. In contrast, *Bacillus thuringiensis* (BT) is placed on the surface of the plant leaf, or the plant is engineered to contain the BT genes that allow the production of the toxic protein in situ, once it is ingested. After ingestion by the target organism, the toxic protein will be within the digestive tract where it is most effective.
Bacillus thuringiensis (pp. 525, 1020–21); *Rhizobium* (sections 22.1 and 30.4)

Inert Microhabitats. Recently it has been found that microorganisms can be added to natural communities together with protective inert microhabitats! As an example, if microbes are added to a soil with microporous glass, the survival of added microorganisms can be markedly enhanced. Other microbes have been observed to create their own microhabitats! Microorganisms in the water column overlying PCB-contaminated sand-clay soils have been observed to create their own "clay hutches" by binding clays to their outer surfaces with exopolysaccharides. These illustrations show that with the application of principles of microbial ecology it may be possible to more successfully manage microbial communities in nature.

Table 42.13 Biosensors: Potential Biomedical, Industrial, and Environmental Applications

Clinical diagnosis and biomedical monitoring
Agricultural, horticultural, veterinary analysis
Detection of pollution, and microbial contamination of water
Fermentation analysis and control
Monitoring of industrial gases and liquids
Measurement of toxic gas in mining industries
Direct biological measurement of flavors, essences, and pheromones

1. What factors might limit the ability of microorganisms, after addition to a soil or water, to be able to persist and carry out desired functions?
2. What types of microhabitats can be used with microorganisms when they are added to a complex natural environment?
3. Why are plants inoculated with *Bacillus thuringiensis?*

42.5 Biotechnological Applications

Microorganisms and parts of microorganisms, especially enzymes, are used in a wide variety of biotechnological applications to monitor the levels of critical compounds in the environment and in animals and humans. These techniques have wide applications in environmental science, animal and human health, and in basic science.

Biosensors

A rapidly developing area of biotechnology, arousing intense international scientific interest, is that of **biosensor** production. In this field of bioelectronics, living microorganisms (or their enzymes or organelles) are linked with electrodes, and biological reactions are converted into electrical currents by these biosensors (**figure 42.24**). Biosensors are being developed to measure specific components in beer, to monitor pollutants, and to detect flavor compounds in food. It is possible to measure the concentration of substances from many different environments (**table 42.13**). Applications include the detection of glucose, acetic acid, glutamic acid, ethanol, and biochemical oxygen demand. In addition, the application of biosensors

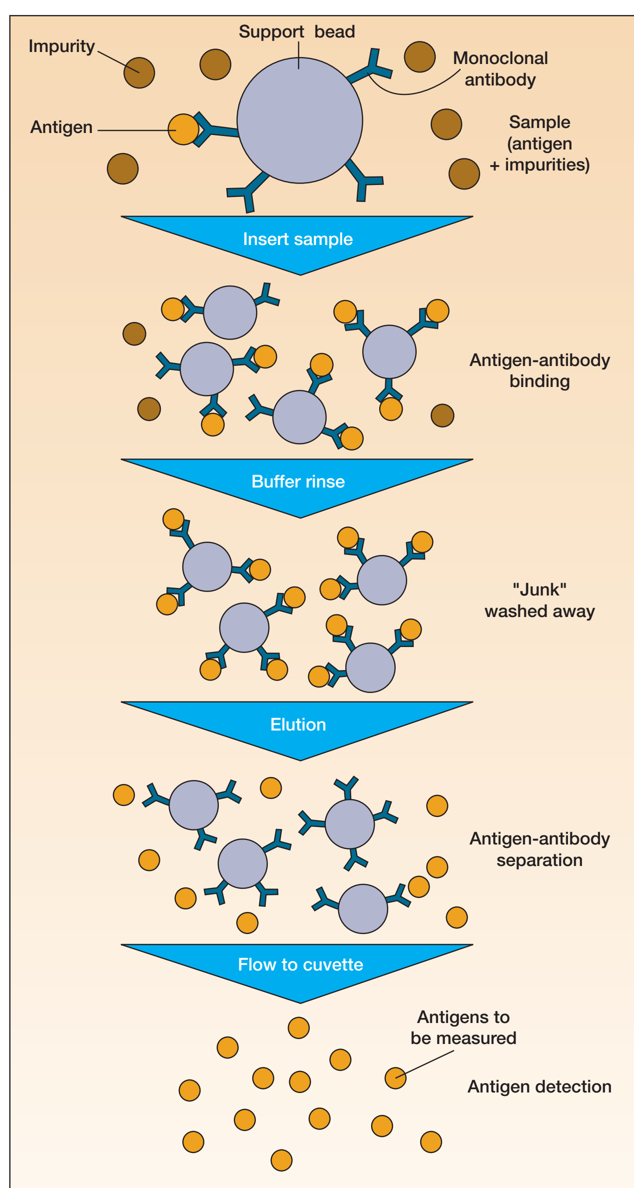

Figure 42.25 A Biosensor for Rapid Detection of a Pathogen. Basic reaction scheme for the immunochemical-based capture, purification, and detection of a pathogen based on a monoclonal antibody system. Detection can be carried out using a small portable instrument.

to measure cephalosporin, nicotinic acid, and several B vitamins has been described. Recently biosensors have been developed using immunochemical-based detection systems (**figure 42.25**). These new biosensors will detect pathogens, herbicides, toxins, proteins, and DNA. Many of these biosensors are based on the use of a streptavidin-biotin recognition system (**Box 42.4**).

One of the most interesting recent developments using these approaches is a handheld aflatoxin detection system for use in monitoring food quality. This automated unit, based on a new column-based immunoaffinity fluorometric procedure, can be used for 100 measurements before being recharged. The unit can detect from 0.1 to 50 ppb of aflatoxins in a 1.0 ml sample in less than 2 min. Aflatoxins (pp. 967–68)

Rapid advances are being made in all areas of biosensor technology. These include major improvements in the stability and durability of these units, which are being made more portable and sensitive. Microorganisms and metabolites such as glucose can be measured, thus meeting critical needs in modern medicine

Microarrays

A large part of the new and developing microbial biotechnology involves the use of DNA sequences in **gene arrays** to monitor gene expression in complex biological systems (*see section 15.6*). The rapid advances that have occurred in this area are the result of progress in genomics, recombinant DNA technology, optics, fluid flow systems, and high-speed data acquisition and processing. This **microarray technology** has been suggested to provide the equivalent of the chemist's periodic table. It offers the potential of assaying all genes used to assemble an organism and can monitor expression of tens of thousands of genes based on the principles shown in **figure 42.26.** In this technique, 100 to 200 μl volumes, containing desired sequences, are spotted onto glass slides or other inert materials and dried. These arrays are then mixing with cDNAs from gene expression (*see p. 321*). Binding of the cDNA for various genes is measured using rapid photometric monitoring techniques. Genomics (chapter 15); Nucleic acid hybridization (pp. 431–32)

Commercial microarray products are now available that contain 6,400 open frames for screening gene expression in *Saccharomyces cerevisiae.* For *E. coli,* 4,200 open reading frames can be scanned in a microarray format. These approaches, both now and in the future, make it possible to follow the expression of thousands of genes and study global regulation of microbial growth and responses to environmental changes.

1. What are biosensors and how do they detect substances?
2. What areas are biosensors being used in to assist in chemical and biological monitoring efforts?
3. Describe streptavidin-biotin systems and how they work. Why is this technique important?
4. What is a gene array? What basic techniques are used in this new procedure?

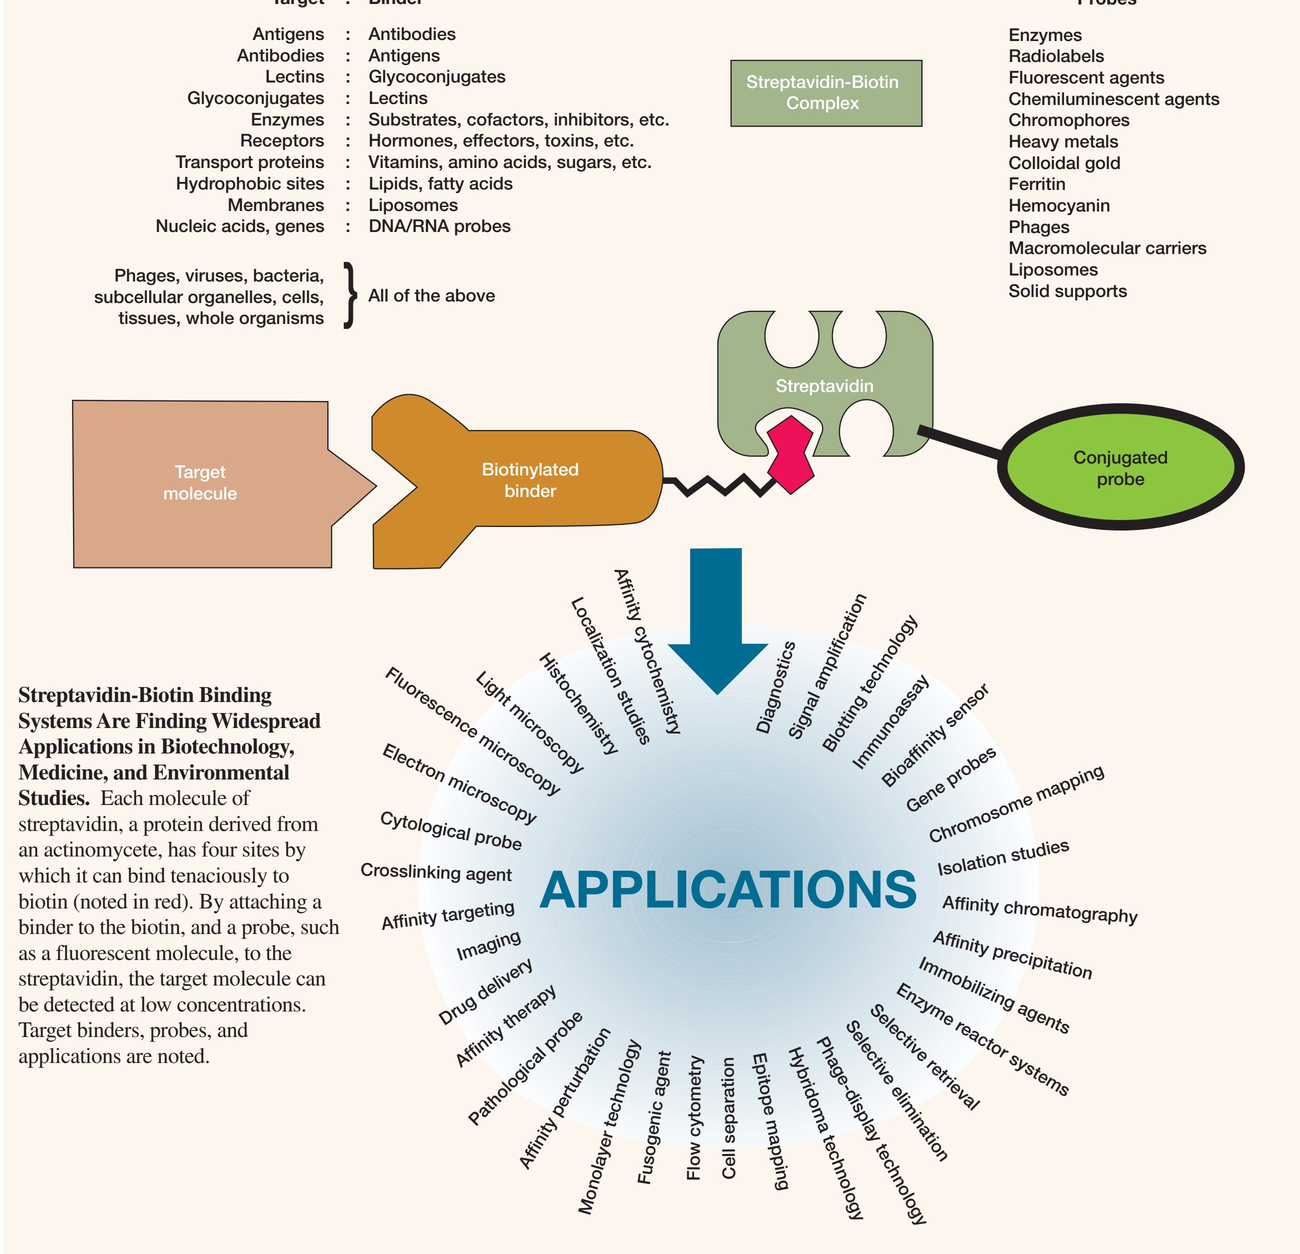
Biopesticides

There has been a long-term interest in the use of bacteria, fungi, and viruses as **bioinsecticides** and **biopesticides** (**table 42.14**). These are defined as biological agents, such as bacteria, fungi, viruses, or their components, which can be used to kill a susceptible insect. In this section, major uses of bacteria, fungi, and viruses to control populations of insects will be discussed.

Box 42.4

Streptavidin-Biotin Binding and Biotechnology

Egg white contains many proteins and glycoproteins with unique properties. One of the most interesting, which binds tenaciously to biotin, was isolated in 1963. This glycoprotein, called avidin due to its "avid" binding of biotin, was suggested to play an important role: making egg white antimicrobial by "tying up" the biotin needed by many microorganisms. Avidin, which functions best under alkaline conditions, has the highest known binding affinity between a protein and a ligand. Several years later, scientists at Merck & Co., Inc. discovered a similar protein produced by an actinomycete, *Streptomyces avidini,* which binds biotin at a neutral pH and which does not contain carbohydrates. These characteristics make streptavidin an ideal binding agent for biotin, and it has been used in an almost unlimited range of applications, as shown in the **Box figure.** The streptavidin protein is joined to a probe. When a sample is incubated with the biotinylated binder, the binder attaches to any available target molecules. The presence and location of target molecules can be determined by treating the sample with a streptavidin probe because the streptavidin binds to the biotin on the biotinylated binder, and the probe is then visualized. This detection system is being employed in a wide variety of biotechnological applications, including use as a nonradioactive probe in hybridization studies and as a critical component in biosensors for a wide range of environmental monitoring and clinical applications. Not bad for a protein from a "simple" filamentous bacterium!



Streptavidin-Biotin Binding Systems Are Finding Widespread Applications in Biotechnology, Medicine, and Environmental Studies. Each molecule of streptavidin, a protein derived from an actinomycete, has four sites by which it can bind tenaciously to biotin (noted in red). By attaching a binder to the biotin, and a probe, such as a fluorescent molecule, to the streptavidin, the target molecule can be detected at low concentrations. Target binders, probes, and applications are noted.

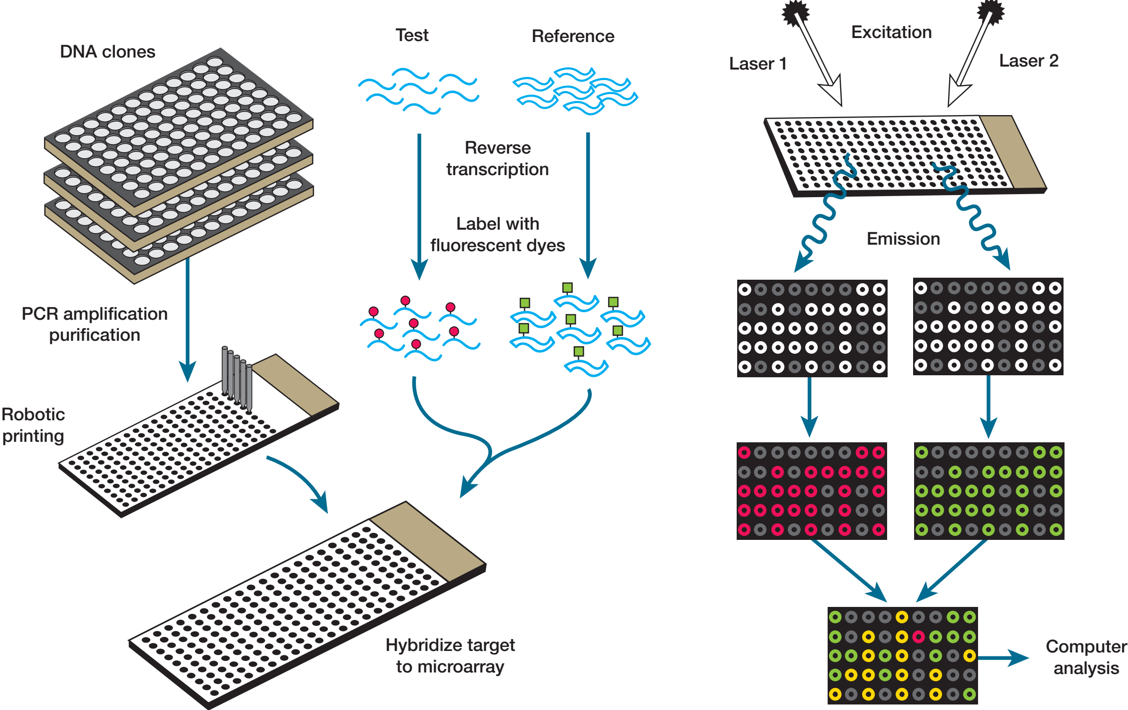


Figure 42.26 A Microarray System for Monitoring Gene Expression. Cloned genes from an organism are amplified by PCR, and after purification, samples are placed on a support in a pattern using a robotic printer. To monitor enzyme expression, RNA from test and reference cultures are converted to cDNA by a reverse transcriptase and labeled with two different fluor dyes. The labeled mixture is hybridized to the microarray and scanned using two lasers with different exciting wavelengths. After pseudocoloring, the fluorescence responses are measured as normalized ratios that show whether the test gene response is higher or lower than that of the reference.

Table 42.14 The Use of Bacteria, Viruses, and Fungi As Bioinsecticides: An Older Technology with New Applications

Microbial Group	Major Organisms and Applications
Bacteria	*Bacillus thuringiensis* and *Bacillus popilliae* are the two major bacteria of interest. *Bacillus thuringiensis* is used on a wide variety of vegetable and field crops, fruits, shade trees, and ornamentals. *B. popilliae* is used primarily against Japanese beetle larvae. Both bacteria are considered harmless to humans. *Pseudomonas fluorescens,* which contains the toxin-producing gene from *B. thuringiensis,* is used on maize to suppress black cutworms.
Viruses	Three major virus groups that do not appear to replicate in warm-blooded animals are used: nuclear polyhedrosis virus (NPV), granulosis virus (GV), and cytoplasmic polyhedrosis virus (CPV). These occluded viruses are more protected in the environment.
Fungi	Over 500 different fungi are associated with insects. Infection and disease occur primarily through the insect cuticle. Four major genera have been used. *Beauveria bassiana* and *Metarhizium anisopliae* are used for control of the Colorado potato beetle and the froghopper in sugarcane plantations, respectively. *Verticillium lecanii* and *Entomophthora* spp., have been associated with control of aphids in greenhouse and field environments.

Bacteria

Bacterial agents include a variety of *Bacillus* species, primarily *B. thuringiensis* (*see p. 525*). This bacterium is only weakly toxic to insects as a vegetative cell, but during sporulation, it produces an intracellular protein toxin crystal, the parasporal body, that can act as a microbial insecticide for specific insect groups.

The parasporal crystal, after exposure to alkaline conditions in the hindgut, fragments to release the protoxin. After this reacts with a protease enzyme, the active toxin is released (**figure 42.27**).

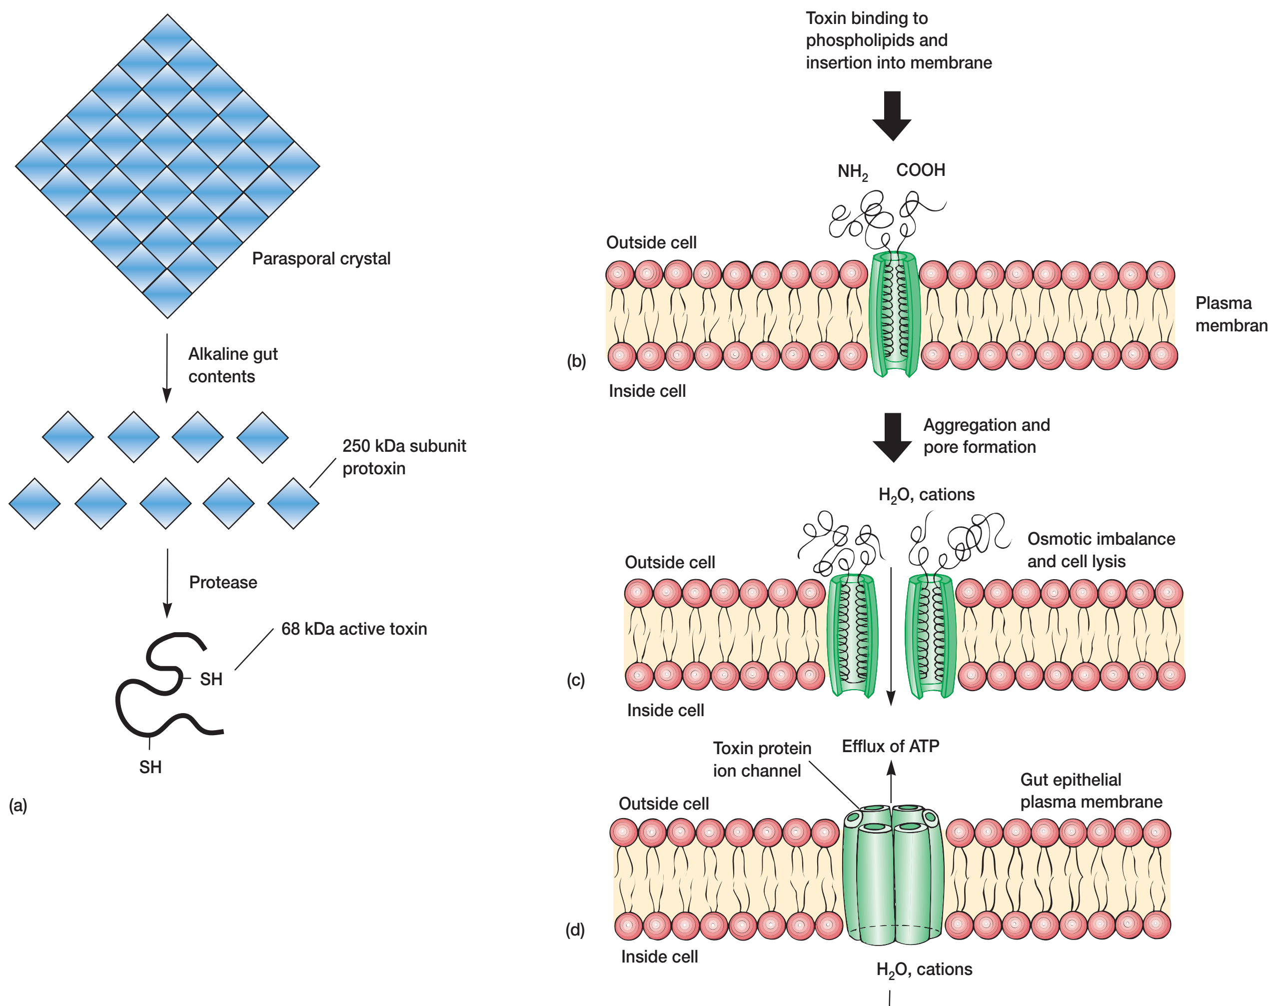

Figure 42.27 The Mode of Action of the *Bacillus thuringiensis* Toxin. (**a**) Release of the protoxin from the parasporal body and modification by proteases in the hindgut. (**b**) Insertion of the 68 kDa active toxin molecules into the membrane. (**c**) Aggregation and pore formation, showing a cross section of the pore. (**d**) Final creation of the hexagonal pore which causes an influx of water and cations as well as a loss of ATP, resulting in cell imbalance and lysis.

Six of the active toxin units integrate into the plasma membrane (figure 42.27*b,c*) to form a hexagonal-shaped pore through the midgut cell, as shown in figure 42.27*d.* This leads to the loss of osmotic balance and ATP, and finally to cell lysis.

The most recent advances in our understanding of *Bacillus thuringiensis* have involved the creation of pest-resistant plants. The first step in this work was to insert the toxin gene into *E. coli.* This work showed that the crystal protein could be expressed in another organism, and that the toxin was effective. This major scientific advance was followed in 1987 by the production of tomato plants that contained the toxin gene.

B. thuringiensis can be grown in fermenters. When the cells lyse, the spores and crystals are released into the medium. The medium is then centrifuged and made up as a dust or wettable powder for application to plants.

A related bacterium, *Bacillus popilliae,* is used to combat the Japanese beetle. This bacterium, however, cannot be grown in fermenters, and inocula must be grown in the living host. The microorganism controls development of larvae, but destruction of the adult beetle requires chemical insecticides.

Viruses

Viruses that are pathogenic for specific insects include nuclear polyhedrosis viruses (NPVs), granulosis viruses (GVs), and cytoplasmic polyhedrosis viruses (CPVs). Currently over 125 types of NPVs are

known, of which approximately 90% affect the *Lepidoptera*—butterflies and moths. Approximately 50 GVs are known, and they, too, primarily affect butterflies and moths. CPVs are the least host-specific viruses, affecting about 200 different types of insects. An important commercial viral pesticide is marketed under the trade name Elcar for control of the cotton bollworm *Heliothis zea.*

One of the most exciting advances involves the use of baculoviruses that have been genetically modified to produce a potent scorpion toxin active against insect larvae. After ingestion by the larvae, viruses are dissolved in the midgut and are released. Because the recombinant baculovirus produces this insect-selective neurotoxin, it acts more rapidly than the parent virus, and leaf damage by insects is markedly decreased. Characteristics of insect viruses (p. 415)

Fungi

Fungi also can be used to control insect pests. Fungal bioinsecticides, as listed in table 42.14, are finding increasing use in agriculture. The development of biopesticides is progressing rapidly.

Available bioinsecticides which are derived from fungi include kasugamycin and the polyoxins; in addition, special microbiological metabolites such as nikkomycin and the spinosyns are active against insects.

1. What two important bacteria have been used as bioinsecticides?
2. Briefly describe how the *Bacillus thuringiensis* toxin kills insects.
3. What types of viruses are being used to attempt to control insects? What is a trade name for one of these products?
4. Which fungi presently are being used as biopesticides?

42.6 Impacts of Microbial Biotechnology

The use of microorganisms in industrial microbiology and biotechnology, as discussed in this chapter, does not take place in an ethical and ecological vacuum. Decisions to make a particular product, and also the methods used, can have long-term and often unexpected effects, as with the appearance of antibiotic-resistant pathogens around the world.

Microbiology is a critical part of the area of **industrial ecology,** concerned with tracking the flow of elements and compounds though the natural and social worlds, or the **biosphere** and the **anthrosphere.** Microbiology, especially as an applied discipline, should be considered within its supporting social world.

Microorganisms have been of immense benefit to humanity through their role in food production and processing, the use of their products to improve human and animal health, in agriculture, and for the maintenance and improvement of environmental quality. Other microorganisms, however, are important pathogens and agents of spoilage, and microbiologists have helped control or limit the activities of these harmful microorganisms. The discovery and use of beneficial microbial products, such as antibiotics, have contributed to a doubling of the human life span in the last century.

A microbiologist who works in any of these areas of biotechnology should consider the longer-term impacts of possible technical decisions. An excellent introduction to the relationship between technology and possible societal impacts is given by Samuel Florman (see Additional Reading). Our first challenge, as microbiologists, is to understand, as much as is possible, the potential impacts of new products and processes on the broader society as well as on microbiology. An essential part of this responsibility is to be able to communicate effectively with the various “societal stakeholders” about the immediate and longer-term potential impacts of microbial-based (and other) technologies.

1. Discuss possible ethical and ecological impacts of a particular product or process discussed in this chapter. Think in terms of the broadest possible impacts in your discussion of this problem.
2. Define industrial ecology.
3. What are the biosphere and anthrosphere? Why might you think the term anthrosphere was coined?

Summary

1. Industrial microbiology has been used to manufacture such products as antibiotics, amino acids, and organic acids and has had many important positive effects on animal and human health. Most work in this area has been carried out using microorganisms isolated from nature or modified by the use of classic mutation techniques. Biotechnology involves the use of molecular techniques to modify and improve microorganisms.
2. Finding new microorganisms in nature for use in biotechnology is a continuing challenge. For most environments, only a very small part of the observable microbial community has been examined (**tables 42.1** and **42.2**).
3. Selection and mutation continue to be important approaches for identifying new microorganisms. These well-established procedures are now being complemented by molecular techniques, including metabolic engineering and combinatorial biology. With combinatorial biology (**table 42.3**), it is possible to transfer genes from one organism to another organism, and to form new products (**figure 42.5**).
4. Site-directed mutagenesis and protein engineering are used to modify gene expression. These approaches are leading to new and often different products with new properties (**figure 42.4**).
5. Natural genetic engineering is of increasing interest. This involves exploiting microbial responses to stress in adaptive mutation and forced evolution, with the hope of identifying microorganisms with new properties.
6. Microorganisms can be grown in controlled environments of various types using fermenters and other culture systems. If defined constituents are used, growth parameters can be chosen and varied in the course of growing a microorganism. This approach is used particularly for the production of amino acids, organic acids, and antibiotics (**figures 42.10** and **42.11**).

7. Growth in controlled environments is expensive and is used primarily for products employed in maintaining and improving animal and human health.
8. Specialty nonantibiotic compounds are an important part of industrial microbiology and biotechnology. These include widely used antitumor agents (**table 42.11**).
9. A wide variety of compounds are produced in industrial microbiology that impact our lives in many ways (**table 42.9**). These include biopolymers, such as the cyclodextrins (**figure 42.13**), and biosurfactants. Microorganisms also can be used as biocatalysts to carry out specific chemical reactions (**figure 42.14**).
10. Microorganism growth in complex environments such as soils and waters is not used to create microbial products but to carry out environmental management processes, including bioremediation, plant inoculation, and other related activities. In these cases, the microbes themselves are not final products.
11. Biodegradation is a critical part of natural systems mediated largely by microorganisms. This can involve minor changes in a molecule, fragmentation, or mineralization (**figure 42.15**).
12. Biodegradation can be influenced by many factors, including oxygen presence or absence, humic acids, and the presence of readily usable organic matter. Reductive dehalogenation proceeds best under anaerobic conditions, and the presence of organic matter can facilitate modification of recalcitrant compounds in the process of cometabolism.
13. The structure of organic compounds influences degradation. If constituents are in specific locations on a molecule, as in the *meta* position (**figure 42.16**), or if varied structural isomers are present (**figure 42.17**), degradation can be affected.
14. Degradation management can be carried out in place, whether this be large marine oil spills, soils, or the subsurface (**figure 42.20**). Such large-scale efforts usually involve the use of natural microbial communities.
15. Degradation can lead to increased toxicity in many cases. If not managed carefully, widespread pollution can occur. This is particularly critical with land farming, or the spreading of industrial and agricultural wastes on soils to facilitate degradation.
16. Plants can be used to stimulate biodegradation processes during phytoremediation. This can involve extraction, filtering, stabilization, and volatilization of pollutants (**figure 42.21** and **table 42.12**).
17. Microorganisms can be added to environments that contain complex microbial communities with greater success if living or inert microhabitats are used. These can include living plant surfaces (seeds, roots, leaves) or inert materials such as microporous glass. *Rhizobium* is an important example of a microorganism added to a complex environment using a living microhabitat (the plant root).
18. Microorganisms are being used in a wide range of biotechnological applications such as biosensors (**figure 42.24**). Microarrays are used to monitor gene expression in complex systems (**figure 42.26**).
19. Bacteria, viruses, and fungi can be used as bioinsecticides and biopesticides (**table 42.14**). *Bacillus thuringiensis* is an important biopesticide, and the BT gene has been incorporated into corn.
20. Industrial microbiology and biotechnology can have long-term and possibly unexpected positive and negative effects on the environment, and on animals and humans impacted by these technologies. Advances in biotechnology should be considered in a broad ecological and societal context, which is the focus of industrial ecology.

Questions for Thought and Review

1. What information or technical approaches will be required to be able to characterize the vast majority of microorganisms in nature that have not been grown? Consider that most of these microorganisms are in a resting vegetative state.
2. What makes the area of natural genetic engineering unique? Isn't this simply what has been going on in nature since the time microorganisms were first able to function?
3. What are the advantages of microarrays for the study of gene expression in complex organisms?
4. How is it possible to create a niche or microhabitat for a microorganism? What are the special points of concern in trying to make sure the microbe can find its best place to survive and function?
5. How might the "postgenomic" era differ from the "genomic era"?
6. Most commercial antibiotics are produced by actinomycetes, and only a few are synthesized by fungi and other bacteria. From physiological and environmental viewpoints, how might you attempt to explain this observation?
7. We hear much about the beneficial uses of recombinant DNA technology. What are some of the problems and disadvantages that should be considered when using microorganisms for these applications?

8. Why might *Bacillus thuringiensis* bioinsecticides be of interest in other areas of biotechnology? Consider the molecular aspects of their mode of action.
9. Do you think intrinsic bioremediation can solve all of our environmental pollutant degradation problems? Why or why not?
10. What are some of the possible advantages of biosensors as opposed to more traditional physical and chemical measurement procedures?
11. What are the major types of materials used as nutrients in fermentation media?
12. In what different ways can the term fermentation be used?
13. What parameters can be controlled in a modern industrial fermenter?
14. How do primary and secondary metabolites differ in terms of their synthesis and functions?

Critical Thinking Questions

1. The search for novel plants/microbes and their products can be in direct conflict with the exposure of humans to novel pathogens. Discuss the relative risks and benefits—are there strategies that are more likely to be "win-win"?
2. *Deinococcus radiodurans* is a species of bacteria that is highly resistant to radiation. Can you think of a biotechnological application? How would you test its utility?
3. Discuss the risks of releasing genetically modified microbes or ones that are not natural to the particular environment. What precautions, if any, would you take? What would be your concerns?
4. Why, when a microorganism is removed from a natural environment and grown in the laboratory, will it usually not be able to effectively colonize its original environment if it is grown and added back? Consider the nature of growth media used in the laboratory in comparison to growth conditions in a soil or water when attempting to understand this fundamental problem in microbial ecology.
5. The postgenomic era has been discussed in this and previous chapters of the book. Can you envision the job of a "postgenomicist"?
6. Why is phytoremediation of such current interest for environmental management? Why is it of interest to combine this approach with the use of transgenic plants?
7. The terms biosphere and anthrosphere have been used, together with the term industrial ecology. How does microbial biotechnology relate to these concerns?

Appendix I

A Review of the Chemistry of Biological Molecules

Appendix I provides a brief summary of the chemistry of organic molecules with particular emphasis on the molecules present in microbial cells. Only basic concepts and terminology are presented; introductory textbooks in biology and chemistry should be consulted for a more extensive treatment of these topics.

Atoms and Molecules

Matter is made of elements that are composed of atoms. An element contains only one kind of atom and cannot be broken down to simpler components by chemical reactions. An atom is the smallest unit characteristic of an element and can exist alone or in combination with other atoms. When atoms combine they form molecules. Molecules are the smallest particles of a substance. They have all the properties of the substance and are composed of two or more atoms.

Although atoms contain many subatomic particles, three directly influence their chemical behavior—protons, neutrons, and electrons. The atom's nucleus is located at its center and contains varying numbers of protons and neutrons (**figure AI.1**). Protons have a positive charge, and neutrons are uncharged. The mass of these particles and the atoms that they compose is given in terms of the atomic mass unit (AMU), which is 1/12 the mass of the most abundant carbon isotope. Often the term dalton (Da) is used to express the mass of molecules. It also is 1/12 the mass of an atom of ^{12}C or 1.661×10^{-24} grams. Both protons and neutrons have a mass of about one dalton. The atomic weight is the actual measured weight of an element and is almost identical to the mass number for the element, the total number of protons and neutrons in its nucleus. The mass number is indicated by a superscripted number preceding the element's symbol (e.g., ^{12}C, ^{16}O, and ^{14}N).

Negatively charged particles called electrons circle the atomic nucleus (figure AI.1). The number of electrons in a neutral atom equals the number of its protons and is given by the atomic number, the number of protons in an atomic nucleus. The atomic number is characteristic of a particular type of atom. For example, carbon has an atomic number of six, hydrogen's number is one, and oxygen's is eight (**table AI.1**).

The electrons move constantly within a volume of space surrounding the nucleus, even though their precise location in this volume cannot be determined accurately. This volume of space in which an electron is located is called its orbital. Each orbital can contain two electrons. Orbitals are grouped into shells of different energy that surround the nucleus. The first shell is closest to the nucleus and has the lowest energy; it contains only one orbital. The second shell contains four orbitals, one circular and three shaped like dumbbells (**figure AI.2*a***). It can contain up to eight electrons. The third shell has even higher energy and holds more than eight electrons. Shells are filled beginning with the innermost

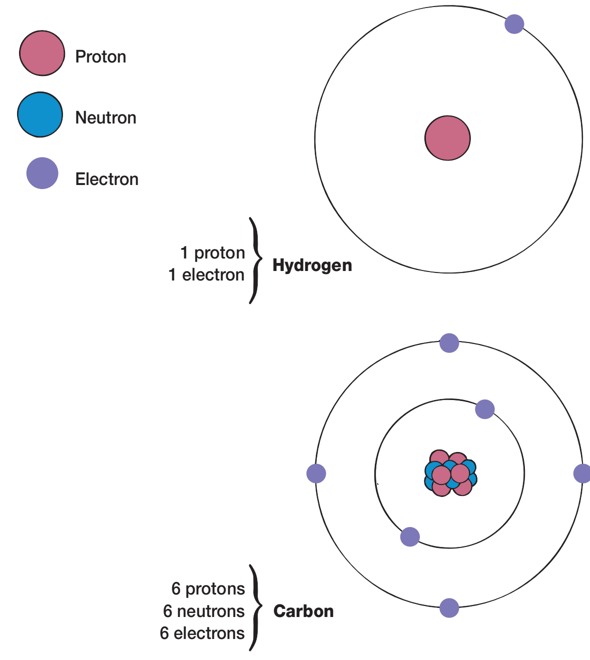

Figure AI.1 Diagrams of Hydrogen and Carbon Atoms. The electron orbitals are represented as concentric circles.

Table AI.1 Atoms Commonly Present in Organic Molecules

Atom	Symbol	Atomic Number	Atomic Weight	Number of Chemical Bonds
Hydrogen	H	1	1.01	1
Carbon	C	6	12.01	4
Nitrogen	N	7	14.01	3
Oxygen	O	8	16.00	2
Phosphorus	P	15	30.97	5
Sulfur	S	16	32.06	2

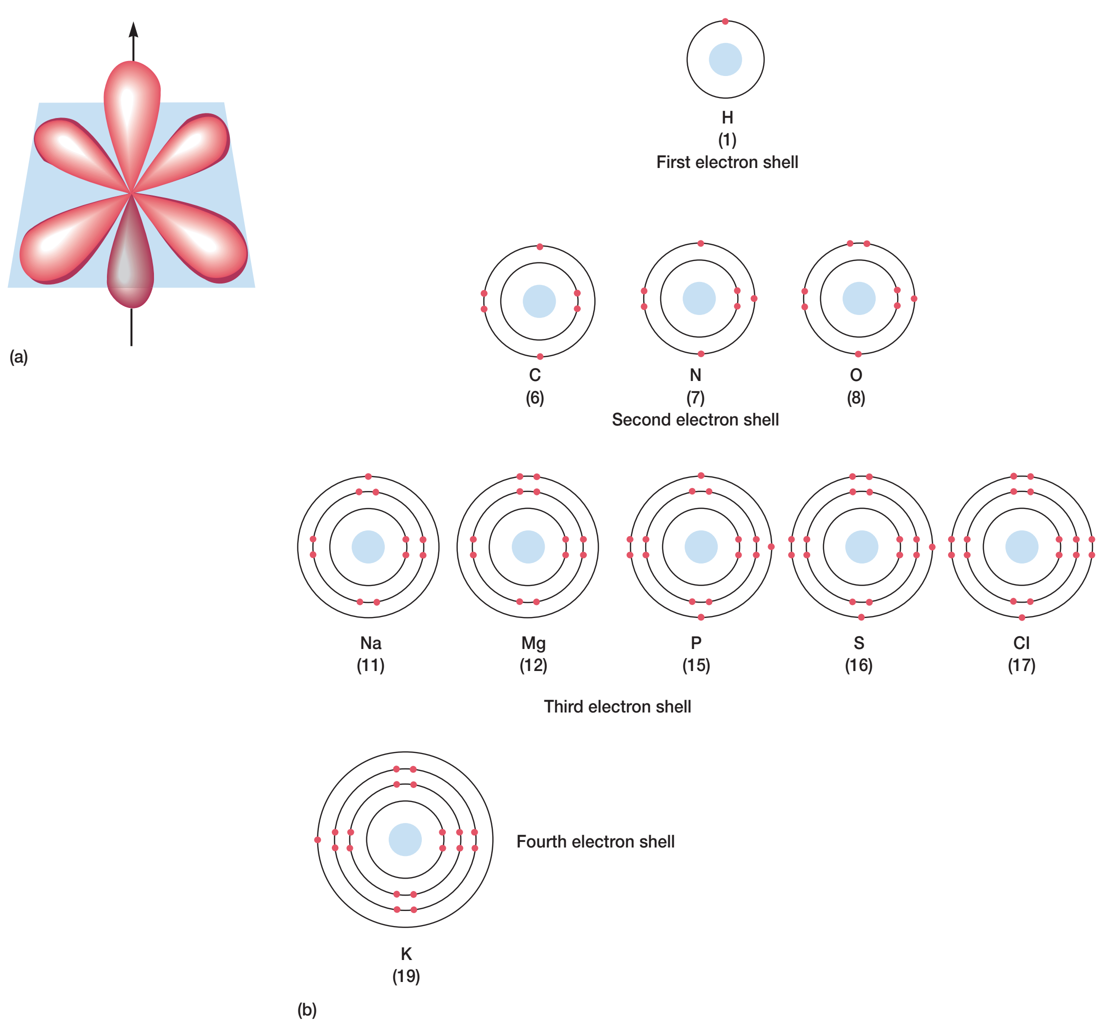

Figure AI.2 Electron Orbitals. (**a**) The three dumbbell-shaped orbitals of the second shell. The orbitals lie at right angles to each other. (**b**) The distribution of electrons in some common elements. Atomic numbers are given in parentheses.

and moving outward. For example, carbon has six electrons, two in its first shell and four in the second (figures AI.1 and AI.2*b*). The electrons in the outermost shell are the ones that participate in chemical reactions. The most stable condition is achieved when the outer shell is filled with electrons. Thus the number of bonds an element can form depends on the number of electrons required to fill the outer shell. Since carbon has four electrons in its outer shell and the shell is filled when it contains eight electrons, it can form four covalent bonds (table AI.1).

Chemical Bonds

Molecules are formed when two or more atoms associate through chemical bonding. Chemical bonds are attractive forces that hold together atoms, ions, or groups of atoms in a molecule or other substance. Many types of chemical bonds are present in organic molecules; three of the most important are covalent bonds, ionic bonds, and hydrogen bonds.

In covalent bonds, atoms are joined together by sharing pairs of electrons (**figure AI.3**). If the electrons are equally shared between identical atoms (e.g., in a carbon-carbon bond), the covalent bond is strong and nonpolar. When two different atoms such as carbon and oxygen share electrons, the covalent bond formed is polar since the electrons are pulled toward the more electronegative atom, the atom that more strongly attracts electrons. A single pair of electrons is shared in a single bond; a double bond is formed when two pairs of electrons are shared.

Atoms often contain either more or fewer electrons than the number of protons in their nuclei. When this is the case, they carry a net negative or positive charge and are called ions. Cations carry positive

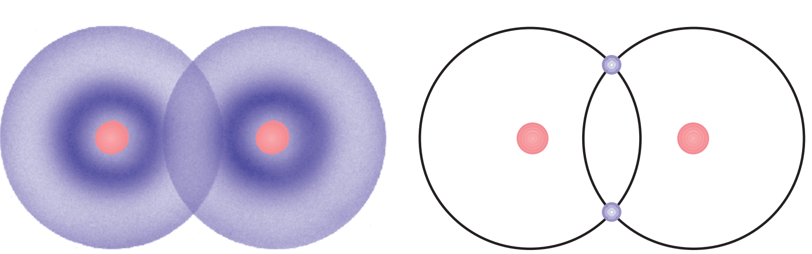

Figure AI.3 The Covalent Bond. A hydrogen molecule is formed when two hydrogen atoms share electrons.

Figure AI.4 Hydrogen Bonds. Representative examples of hydrogen bonds present in biological molecules.

(a) C_6H_{14} (Hexane)

(b) C_6H_{12} (Cyclohexane)

(c) C_6H_6 (Benzene)

Figure AI.5 Hydrocarbons. Examples of hydrocarbons that are (**a**) linear, (**b**) cyclic, and (**c**) aromatic.

charges and anions have a net negative charge. When a cation and an anion approach each other, they are attracted by their opposite charges. This ionic attraction that holds two groups together is called an ionic bond. Ionic bonds are much weaker than covalent bonds and are easily disrupted by a polar solvent such as water. For example, the Na^+ cation is strongly attracted to the Cl^- anion in a sodium chloride crystal, but sodium chloride dissociates into separate ions (ionizes) when dissolved in water. Ionic bonds are important in the structure and function of proteins and other biological molecules.

When a hydrogen atom is covalently bonded to a more electronegative atom such as oxygen or nitrogen, the electrons are unequally shared and the hydrogen atom carries a partial positive charge. It will be attracted to an electronegative atom such as oxygen or nitrogen, which carries an unshared pair of electrons; this attraction is called a hydrogen bond (**figure AI.4**). Although an individual hydrogen bond is weak, there are so many hydrogen bonds in proteins and nucleic acids that they play a major role in determining protein and nucleic acid structure.

Organic Molecules

Most molecules in cells are organic molecules, molecules that contain carbon. Since carbon has four electrons in its outer shell, it tends to form four covalent bonds in order to fill its outer shell with eight electrons. This property makes it possible to form chains and rings of carbon atoms that also can bond with hydrogen and other atoms (**figure AI.5**). Although adjacent carbons usually are connected by single bonds, they may be joined by double or triple bonds. Rings that have alternating single and double bonds, like the benzene ring, are called aromatic rings. The hydrocarbon chain or ring provides a chemically inactive skeleton to which more reactive groups of atoms may be attached. These reactive groups with specific properties are known as functional groups. They usually contain atoms of oxygen, nitrogen, phosphorus, or sulfur (**figure AI.6**) and are largely responsible for most characteristic chemical properties of organic molecules.

Organic molecules are often divided into classes based on the nature of their functional groups. Ketones have a carbonyl group within the carbon chain, whereas alcohols have a hydroxyl on the chain. Organic acids have a carboxyl group, and amines have an amino group (**figure AI.7**).

Organic molecules may have the same chemical composition and yet differ in their molecular structure and properties. Such molecules are called isomers. One important class of isomers is the stereoisomers. Stereoisomers have the same atoms arranged in the same nucleus-to-nucleus sequence but differ in the spatial arrangement of their atoms. For example, an amino acid such as alanine can form stereoisomers

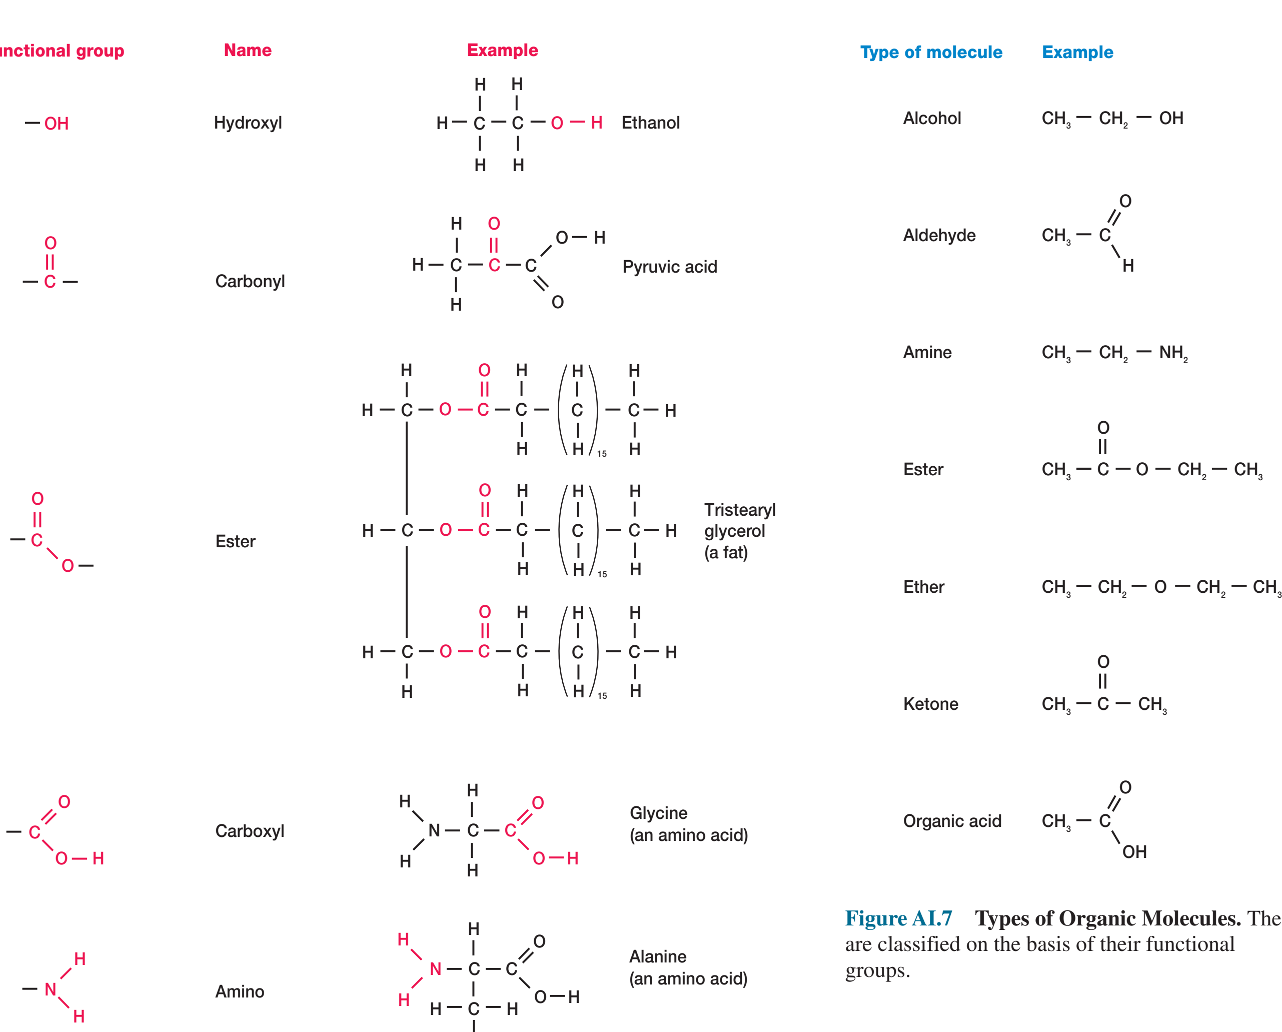

Figure AI.6 Functional Groups. Some common functional groups in organic molecules. The groups are shown in color.

Figure AI.7 Types of Organic Molecules. These are classified on the basis of their functional groups.

(**figure AI.8**). L-Alanine and other L-amino acids are the stereoisomer forms normally present in proteins.

Carbohydrates

Carbohydrates are aldehyde or ketone derivatives of polyhydroxy alcohols. The smallest and least complex carbohydrates are the simple sugars or monosaccharides. The most common sugars have five or six carbons (**figure AI.9**). A sugar in its ring form has two isomeric structures, the α and β forms, that differ in the orientation of the hydroxyl on the aldehyde or ketone carbon, which is called the anomeric or glycosidic carbon (**figure AI.10**). Microorganisms have many sugar derivatives in which a hydroxyl is replaced by an amino group or some other functional group (e.g., glucosamine).

Two monosaccharides can be joined by a bond between the anomeric carbon of one sugar and a hydroxyl or the anomeric carbon of the second (**figure AI.11**). The bond joining sugars is a glycosidic bond and may be either α or β depending on the orientation of the anomeric carbon. Two sugars linked in this way constitute a disaccharide. Some

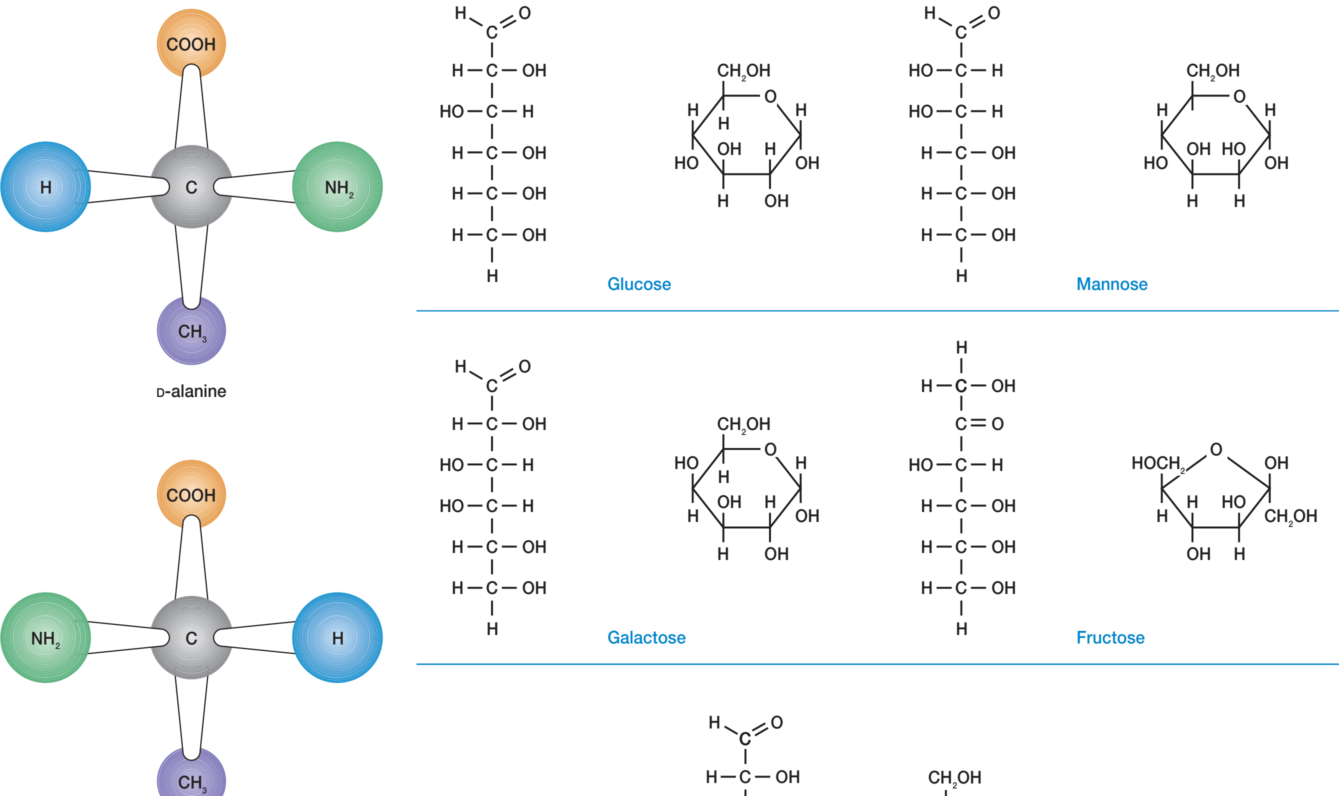

Figure AI.8 The Stereoisomers of Alanine. The α-carbon is in gray, L-alanine is the form usually present in proteins.

Figure AI.9 Common Monosaccharides. Structural formulas for both the open chains and the ring forms are provided.

β-D-glucose

α-D-glucose

Figure AI.10 The Interconversion of Monosaccharide Structures. The open chain form of glucose and other sugars is in equilibrium with closed ring structures (depicted here with Haworth projections). Aldehyde sugars form cyclic hemiacetals, and keto sugars produce cyclic hemiketals. When the hydroxyl on carbon one of cyclic hemiacetals projects above the ring, the form is known as a β form. The α form has a hydroxyl that lies below the plane of the ring. The same convention is used in showing the α and β forms of hemiketals such as those formed by fructose.

(a) Glucose + Glucose → Maltose $+H_2O$

(b) Sucrose

(c) Lactose (α form)

Figure AI.11 Common Disaccharides. (**a**) The formation of maltose from two molecules of an α-glucose. The bond connecting the glucose extends between carbons one and four, and involves the α form of the anomeric carbon. Therefore, it is called an α (1 → 4) glycosidic bond. (**b**) Sucrose is composed of a glucose and a fructose joined to each other through their anomeric carbons, and αβ (1 → 2) bond. (**c**) The milk sugar lactose contains galactose and glucose joined by a β (1 → 4) glycosidic bond.

common disaccharides are maltose (two glucose molecules), lactose (glucose and galactose), and sucrose (glucose and fructose). If 10 or more sugars are linked together by glycosidic bonds, a polysaccharide is formed. For example, starch and glycogen are common polymers of glucose that are used as sources of carbon and energy (**figure AI.12**).

Lipids

All cells contain a heterogeneous mixture of organic molecules that are relatively insoluble in water but very soluble in nonpolar solvents such as chloroform, ether, and benzene. These molecules are called lipids. Lipids vary greatly in structure and include triacylglycerols, phospholipids, steroids, carotenoids, and many other types. Among other functions, they serve as membrane components, storage forms for carbon and energy, precursors of other cell constituents, and protective barriers against water loss.

Most lipids contain fatty acids, monocarboxylic acids that often are straight chained but may be branched. Saturated fatty acids lack double bonds in their carbon chains, whereas unsaturated fatty acids have double bonds. The most common fatty acids are 16 or 18 carbons long.

Two good examples of common lipids are triacylglycerols and phospholipids. Triacylglycerols are composed of glycerol esterified to three fatty acids (**figure AI.13*a***). They are used to store carbon and energy. Phospholipids are lipids that contain at least one phosphate group and often have a nitrogenous constituent as well. Phosphatidyl ethanolamine is an important phospholipid frequently present in bacterial membranes (figure AI.13*b*). It is composed of two fatty acids esterified to glycerol. The third glycerol hydroxyl is joined with a phosphate group, and ethanolamine is attached to the phosphate. The resulting lipid is very asymmetric with a hydrophobic nonpolar end contributed by the fatty acids and a polar, hydrophilic end. In cell membranes the hydrophobic end is buried in the interior of the membrane, while the polar-charged end is at the membrane surface and exposed to water.

Proteins

The basic building blocks of proteins are amino acids. An amino acid contains a carboxyl group and an amino group on its alpha carbon (**figure AI.14**). About 20 amino acids are normally found in proteins; they differ from each other with respect to their side chains (**figure AI.15**). In proteins, amino acids are linked together by peptide bonds between their carboxyls and α-amino groups to form linear polymers called peptides (**figure AI.16**). If a peptide contains more than 10 amino acids, it usually is called a polypeptide. Each protein is composed of one or more polypeptide chains and has a molecular weight greater than about 6,000 to 7,000.

Proteins have three or four levels of structural organization and complexity. The primary structure of a protein is the sequence of the amino acids in its polypeptide chain or chains. The structure of the polypeptide chain backbone is also considered part of the primary structure. Each different polypeptide has its own amino acid sequence that is a reflection of the nucleotide sequence in the gene that codes for its synthesis. The polypeptide chain can coil along one axis in space into various shapes like the α-helix

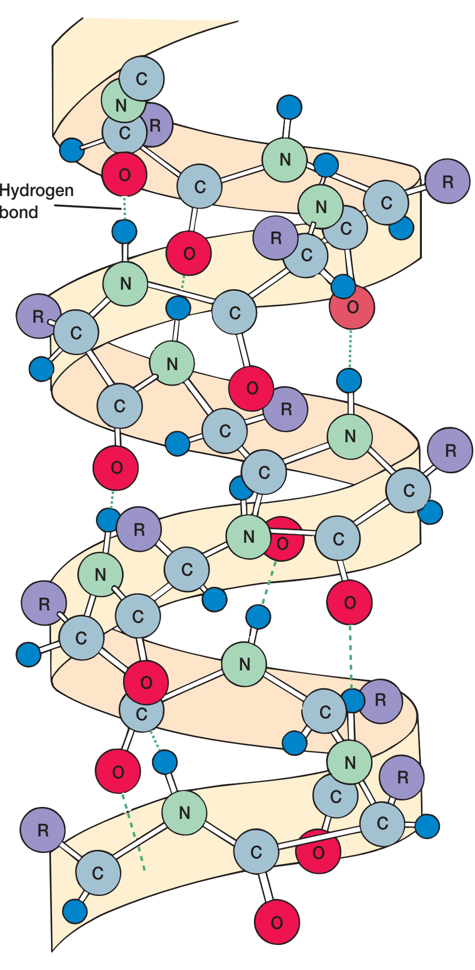

Figure AI.17 The α-Helix. A polypeptide twisted into one type of secondary structure, the α-helix. The helix is stabilized by hydrogen bonds joining peptide bonds that are separated by three amino acids.

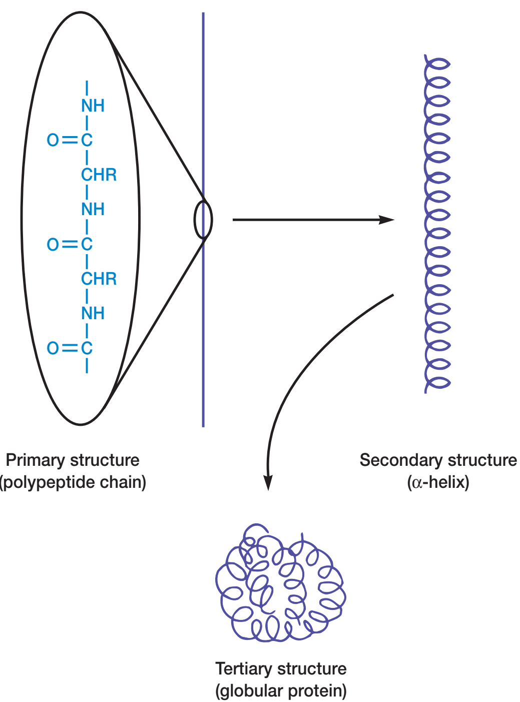

Figure AI.18 Secondary and Tertiary Protein Structures. The formation of secondary and tertiary protein structures by folding a polypeptide chain with its primary structure.

(**figure AI.17**). This arrangement of the polypeptide in space around a single axis is called the secondary structure. Secondary structure is formed and stabilized by the interactions of amino acids that are fairly close to one another on the polypeptide chain. The polypeptide with its primary and secondary structure can be coiled or organized in space along three axes to form a more complex, three-dimensional shape (**figure AI.18**). This level of organization is the tertiary structure (**figure AI.19**). Amino acids more distant from one another on the polypeptide chain contribute to tertiary structure. Secondary and tertiary structures are examples of conformation, molecular shape that can be changed by bond rotation and without breaking covalent bonds. When a protein contains more than one polypeptide chain, each chain with its own primary, secondary, and tertiary structure associates with the other chains to form the final molecule. The way in which polypeptides associate with each other in space to form the final protein is called the protein's quaternary structure (**figure AI.20**).

The final conformation of a protein is ultimately determined by the amino acid sequence of its polypeptide chains. Under proper conditions a completely unfolded polypeptide will fold into its normal final shape without assistance.

Protein secondary, tertiary, and quaternary structure is largely determined and stabilized by many weak noncovalent forces such as hydrogen bonds and ionic bonds. Because of this, protein shape often is very flexible and easily changed. This flexibility is very important in protein function and in the regulation of enzyme activity. Because of their flexibility, however, proteins readily lose their proper shape and activity when exposed to harsh conditions. The only covalent bond commonly involved in the secondary and tertiary structure of proteins is the disulfide bond. The disulfide bond is formed when two cysteines are linked through their sulfhydryl groups. Disulfide bonds generally strengthen or stabilize protein structure but are not especially important in directly determining protein conformation.

Nucleic Acids

The nucleic acids, deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), are polymers of deoxyribonucleosides and ribonucleosides joined by phosphate groups. The nucleosides in DNA contain the purines adenine and guanine, and the pyrimidine bases thymine and cytosine. In RNA the pyrimidine uracil is substituted for thymine. Because of their importance for genetics and molecular biology, the chemistry of nucleic acids is introduced earlier in the text. The structure and synthesis of purines and pyrimidines are discussed in chapter 10 (*pp. 217–18*). The structures of DNA and RNA are described in chapter 11 (*pp. 230–35*).

APPENDIX III

Classification of Procaryotes According to the First Edition of *Bergey's Manual of Systematic Bacteriology*

Great progress has occurred in bacterial taxonomy since the first edition of *Bergey's Manual of Systematic Bacteriology* was published between 1984 and 1989. Many completely new taxa have been added, and large, complex genera such as *Pseudomonas, Streptococcus,* and *Bacillus* have been subdivided to form new genera. Thus the classification presented here differs from that given in the 1994 edition of *Bergey's Manual of Determinative Bacteriology,* and even this more recent work is already out-of-date. Appendix III summarizes the system presented in the first edition of *Bergey's Manual of Systematic Bacteriology.*

Genus IX *Thiopedia*
Family II *Ectothiorhodospiraceae*
Genus *Ectothiorhodospira*
Purple Nonsulfur Bacteria
Genus *Rhodospirillum*
Genus *Rhodopila*
Genus *Rhodobacter*
Genus *Rhodopseudomonas*
Genus *Rhodomicrobium*
Genus *Rhodocyclus*

II. Green Bacteria

Green Sulfur Bacteria
Genus *Chlorobium*
Genus *Prosthecochloris*
Genus *Pelodictyon*
Genus *Ancalochloris*
Genus *Chloroherpeton*
Multicellular, Filamentous, Green Bacteria
Genus *Chloroflexus*
Genus *Heliothrix*
Genus "*Oscillochloris*"
Genus *Chloronema*

III. Genera Incertae Sedis

Genus *Heliobacterium*
Genus *Erythrobacter*

Section 19

Oxygenic Photosynthetic Bacteria

Group I Cyanobacteria

Subsection I Order *Chroococcales*
1. Genus I *Chamaesiphon*
2. Genus II *Gloeobacter*
3. *Synechococcus*-group
4. Genus III *Gloeothece*
5. *Cyanothece*-group
6. *Gloeocapsa*-group
7. *Synechocystis*-group

Subsection II Order *Pleurocapsales*
1. Genus I *Dermocarpa*
2. Genus II *Xenococcus*
3. Genus III *Dermocarpella*
4. Genus IV *Mxyosarcina*
5. Genus V *Chroococcidiopsis*
6. *Pleurocapsa*-group

Subsection III Order *Oscillatoriales*
Genus I *Spirulina*
Genus II *Arthrospira*
Genus III *Oscillatoria*
Genus IV *Lyngbya*
Genus V *Pseudanabaena*
Genus VI *Starria*
Genus VII *Crinalium*
Genus VIII *Microcoleus*
Subsection IV Order *Nostocales*
Family I *Nostocaceae*
Genus I *Anabaena*
Genus II *Aphanizomenon*
Genus III *Nodularia*
Genus IV *Cylindrospermum*
Genus V *Nostoc*
Family II *Scytonemataceae*
Genus I *Scytonema*
Family III *Rivulariaceae*
Genus I *Calothrix*
Subsection V Order *Stigonematales*
Genus I *Chlorogloeopsis*
Genus II *Fischerella*
Genus III *Stigonema*
Genus IV *Geitleria*

Group II Order Prochlorales

Family I *Prochloraceae*
Genus *Prochloron*
Other taxa
Genus "*Prochlorothrix*"

Section 20

Aerobic Chemolithotrophic Bacteria and Associated Organisms

A. Nitrifying Bacteria
Family *Nitrobacteraceae*
Nitrite-oxidizing bacteria
Genus I *Nitrobacter*
Genus II *Nitrospina*
Genus III *Nitrococcus*
Genus IV *Nitrospira*
Ammonia-oxidizing bacteria
Genus V *Nitrosomonas*
Genus VI *Nitrosococcus*
Genus VII *Nitrosospira*
Genus VIII *Nitrosolobus*
Genus IX "*Nitrosovibrio*"

B. Colorless Sulfur Bacteria
Genus *Thiobacterium*
Genus *Macromonas*
Genus *Thiospira*
Genus *Thiovulum*
Genus *Thiobacillus*
Genus *Thiomicrospira*
Genus *Thiosphaera*
Genus *Acidiphilium*
Genus *Thermothrix*

C. Obligately Chemolithotrophic Hydrogen Bacteria
Genus *Hydrogenobacter*

D. Iron- and Manganese-Oxidizing and/or Depositing Bacteria
Family "*Siderocapsaceae*"
Genus I "*Siderocapsa*"
Genus II "*Naumanniella*"
Genus III "*Siderococcus*"
Genus IV "*Ochrobium*"

E. Magnetotactic Bacteria
Genus *Aquaspirillum (A. magnetotacticum)*
Genus "*Bilophococcus*"

Section 21

Budding and/or Appendaged Bacteria

I. Prosthecate Bacteria

A. Budding bacteria
1. Buds produced at tip of prostheca
Genus *Hyphomicrobium*
Genus *Hyphomonas*
Genus *Pedomicrobium*
2. Buds produced on cell surface
Genus *Ancalomicrobium*
Genus *Prosthecomicrobium*
Genus *Labrys*
Genus *Stella*

B. Bacteria that divide by binary transverse fission
Genus *Caulobacter*
Genus *Asticcacaulis*
Genus *Prosthecobacter*

© The McGraw–Hill Companies, 2002

II. Nonprosthecate Bacteria

A. Budding bacteria
1. Lack peptidoglycan
Genus *Planctomyces*
Genus "*Isosphaera*"
2. Contain peptidoglycan
Genus *Ensifer*
Genus *Blastobacter*
Genus *Angulomicrobium*
Genus *Gemmiger*

B. Nonbudding, stalked bacteria
Genus *Gallionella*
Genus *Nevskia*

C. Other bacteria
1. Nonspinate bacteria
Genus *Seliberia*
Genus "*Metallogenium*"
Genus "*Thiodendron*"
2. Spinate bacteria

Section 22

Sheathed Bacteria

Genus *Sphaerotilus*
Genus *Leptothrix*
Genus *Haliscomenobacter*
Genus "*Lieskeella*"
Genus "*Phragmidiothrix*"
Genus *Crenothrix*
Genus "*Clonothrix*"

Section 23

Nonphotosynthetic, Nonfruiting Gliding Bacteria

Order I *Cytophagales*
Family I *Cytophagaceae*
Genus I *Cytophaga*
Genus II *Capnocytophaga*
Genus III *Flexithrix*
Genus IV *Sporocytophaga*
Other genera
Genus *Flexibacter*
Genus *Microscilla*
Genus *Chitinophaga*
Genus *Saprospira*
Order II *Lysobacterales*
Family I *Lysobacteraceae*
Genus I *Lysobacter*
Order III *Beggiatoales*
Family I *Beggiatoaceae*
Genus I *Beggiatoa*
Genus II *Thiothrix*
Genus III *Thioploca*
Genus IV "*Thiospirillopsis*"
Other families and genera
Family *Simonsiellaceae*
Genus I *Simonsiella*
Genus II *Alysiella*
Family "*Pelonemataceae*"
Genus I "*Pelonema*"
Genus II "*Achroonema*"
Genus III "*Peloploca*"
Genus IV "*Desmanthos*"
Other genera
Genus *Toxothrix*
Genus *Leucothrix*
Genus *Vitreoscilla*
Genus *Desulfonema*
Genus *Achromatium*
Genus *Agitococcus*
Genus *Herpetosiphon*

Section 24

Fruiting Gliding Bacteria: The Myxobacteria

Order *Myxococcales*
Family I *Myxococcaceae*
Genus *Myxococcus*
Family II *Archangiaceae*
Genus *Archangium*
Family III *Cystobacteraceae*
Genus I *Cystobacter*
Genus II *Melittangium*
Genus III *Stigmatella*
Family IV *Polyangiaceae*
Genus I *Polyangium*
Genus II *Nannocystis*
Genus III *Chondromyces*

Section 25

Archaeobacteria

Group I Methanogenic Archaeobacteria

Order I *Methanobacteriales*
Family I *Methanobacteriaceae*
Genus I *Methanobacterium*
Genus II *Methanobrevibacter*
Family II *Methanothermaceae*
Genus *Methanothermus*
Order II *Methanococcales*
Family *Methanococcaceae*
Genus *Methanococcus*
Order III *Methanomicrobiales*
Family I *Methanomicrobiaceae*
Genus I *Methanomicrobium*
Genus II *Methanospirillum*
Genus III *Methanogenium*
Family II *Methanosarcinaceae*
Genus I *Methanosarcina*
Genus II *Methanolobus*
Genus III *Methanothrix*
Genus IV *Methanococcoides*
Other Taxa
Family *Methanoplanaceae*
Genus *Methanoplanus*
Other Genus *Methanosphaera*

Group II Archaeobacterial Sulfate Reducers

Order "*Archaeoglobales*"
Family "*Archaeoglobaceae*"
Genus *Archaeoglobus*

Group III Extremely Halophilic Archaeobacteria

Order *Halobacteriales*
Family *Halobacteriaceae*
Genus I *Halobacterium*
Genus II *Haloarcula*
Genus III *Haloferax*
Genus IV *Halococcus*
Genus V *Natronobacterium*
Genus VI *Natronococcus*

Group IV Cell Wall-less Archaeobacteria

Genus *Thermoplasma*

Group V Extremely Thermophilic S^0-Metabolizers

Order I *Thermococcales*
Family *Thermococcaceae*
Genus I *Thermococcus*
Genus II *Pyrococcus*
Order II *Thermoproteales*
Family I *Thermoproteaceae*
Genus I *Thermoproteus*
Genus II *Thermofilum*
Family II *Desulfurococcaceae*
Genus *Desulfurococcus*
Other bacteria
Genus *Staphylothermus*
Genus *Pyrodictium*
Order III *Sulfolobales*
Family *Sulfolobaceae*
Genus I *Sulfolobus*
Genus II *Acidianus*

Volume IV

Section 26

Nocardioform Actinomycetes

Genus *Nocardia*
Genus *Rhodococcus*
Genus *Nocardioides*
Genus *Pseudonocardia*
Genus *Oerskovia*
Genus *Saccharopolyspora*
Genus *Faenia*
Genus *Promicromonospora*
Genus *Intrasporangium*
Genus *Actinopolyspora*
Genus *Saccharomonospora*

Section 27

Actinomycetes with Multilocular Sporangia

Genus *Geodermatophilus*
Genus *Dermatophilus*
Genus *Frankia*

Section 28

Actinoplanetes

Genus *Actinoplanes*
Genus *Ampullariella*
Genus *Pilimelia*

APPENDIX IV

Classification of Procaryotes According to the Second Edition of *Bergey's Manual of Systematic Bacteriology*

This appendix summarizes the classification of procaryotes that is being employed by the second edition of *Bergey's Manual.* The second edition will be published in five volumes over a period of several years beginning in 2001. Because of advances in taxonomy over the next few years, some of the details in this classification may well change. The overall organization and major taxa should remain constant. The quotation marks around some names indicate that they are not formally approved taxonomic names.

Domain *Archaea*

Phylum AI. *Crenarchaeota*

Class I. *Thermoprotei*

Order I. *Thermoproteales*
  Family I. *Thermoproteaceae*
    Genus I. *Thermoproteus*
    Genus II. *Caldivirga*
    Genus III. *Pyrobaculum*
    Genus IV. *Thermocladium*
  Family II. *Thermofilaceae*
    Genus I. *Thermofilum*
Order II. *Desulfurococcales*
  Family I. *Desulfurococcaceae*
    Genus I. *Desulfurococcus*
    Genus II. *Aeropyrum*
    Genus III. *Ignicoccus*
    Genus IV. *Staphylothermus*
    Genus V. *Stetteria*
    Genus VI. *Sulfophobococcus*
    Genus VII. *Thermodiscus*
    Genus VIII. *Thermosphaera*
  Family II. *Pyrodictiaceae*
    Genus I. *Pyrodictium*
    Genus II. *Hyperthermus*
    Genus III. *Pyrolobus*
Order III. *Sulfolobales*
  Family I. *Sulfolobaceae*
    Genus I. *Sulfolobus*
    Genus II. *Acidianus*
    Genus III. *Metallosphaera*
    Genus IV. *Stygiolobus*
    Genus V. *Sulfurisphaera*
    Genus VI. *Sulfurococcus*

Phylum AII. *Euryarchaeota*

Class I. *Methanobacteria*

Order I. *Methanobacteriales*
  Family I. *Methanobacteriaceae*
    Genus I. *Methanobacterium*
    Genus II. *Methanobrevibacter*
    Genus III. *Methanosphaera*
    Genus IV. *Methanothermobacter*
  Family II. *Methanothermaceae*
    Genus I. *Methanothermus*

Class II. *Methanococci*

Order I. *Methanococcales*
  Family I. *Methanococcaceae*
    Genus I. *Methanococcus*
    Genus II. *Methanothermococcus*
  Family II. *Methanocaldococcaceae*
    Genus I. *Methanocaldococcus*
    Genus II. *Methanotorris*
Order II. *Methanomicrobiales*
  Family I. *Methanomicrobiaceae*
    Genus I. *Methanomicrobium*
    Genus II. *Methanoculleus*
    Genus III. *Methanofollis*
    Genus IV. *Methanogenium*
    Genus V. *Methanolacinia*
    Genus VI. *Methanoplanus*
  Family II. *Methanocorpusculaceae*
    Genus I. *Methanocorpusculum*
  Family III. *Methanospirillaceae*
    Genus I. *Methanospirillum*
  Genera incertae sedis
    Genus I. *Methanocalculus*
Order III. *Methanosarcinales*
  Family I. *Methanosarcinaceae*
    Genus I. *Methanosarcina*
    Genus II. *Methanococcoides*
    Genus III. *Methanohalobium*
    Genus IV. *Methanohalophilus*
    Genus V. *Methanolobus*
    Genus VI. *Methanosalsum*
  Family II. *Methanosaetaceae*
    Genus I. *Methanosaeta*

Class III. *Halobacteria*

Order I. *Halobacteriales*
  Family I. *Halobacteriaceae*
    Genus I. *Halobacterium*
    Genus II. *Haloarcula*
    Genus III. *Halobaculum*
    Genus IV. *Halococcus*
    Genus V. *Haloferax*
    Genus VI. *Halogeometricum*
    Genus VII. *Halorhabdus*
    Genus VIII. *Halorubrum*
    Genus IX. *Haloterrigena*
    Genus X. *Natrialba*
    Genus XI. *Natrinema*
    Genus XII. *Natronobacterium*
    Genus XIII. *Natronococcus*
    Genus XIV. *Natronomonas*
    Genus XV. *Natronorubrum*

Class IV. *Thermoplasmata*

Order I. *Thermoplasmatales*
  Family I. *Thermoplasmataceae*
    Genus I. *Thermoplasma*
  Family II. *Picrophilaceae*
    Genus I. *Picrophilus*

Class V. *Thermococci*

Order I. *Thermococcales*
  Family I. *Thermococcaceae*
    Genus I. *Thermococcus*
    Genus II. *Pyrococcus*

Class VI. *Archaeoglobi*

Order I. *Archaeoglobales*
  Family I. *Archaeoglobaceae*
    Genus I. *Archaeoglobus*
    Genus II. *Ferroglobus*

Class VII. *Methanopyri*

Order I. *Methanopyrales*
  Family I. *Methanopyraceae*
    Genus I. *Methanopyrus*

Domain *Bacteria*

Phylum BI. *Aquificae*

Class I. *Aquificae*

Order I. *Aquificales*
  Family I. *Aquificaceae*
    Genus I. *Aquifex*
    Genus II. *Calderobacterium*
    Genus III. *Hydrogenobacter*
    Genus IV. *Thermocrinis*
  Genera incertae sedis
    Genus I. *Desulfurobacterium*

Phylum BII. *Thermotogae*

Class I. *Thermotogae*

Order I. *Thermotogales*

Family I. *Thermotogaceae*
Genus I. *Thermotoga*
Genus II. *Fervidobacterium*
Genus III. *Geotoga*
Genus IV. *Petrotoga*
Genus V. *Thermosipho*

Phylum BIII. *Thermodesulfobacteria*

Class I. *Thermodesulfobacteria*

Order I. *Thermodesulfobacteriales*
Family I. *Thermodesulfobacteriaceae*
Genus I. *Thermodesulfobacterium*

Phylum BIV. "Deinococcus-Thermus"

Class I. *Deinococci*

Order I. *Deinococcales*
Family I. *Deinococcaceae*
Genus I. *Deinococcus*
Order II. *Thermales*
Family I. *Thermaceae*
Genus I. *Thermus*
Genus II. *Meiothermus*

Phylum BV. *Chrysiogenetes*

Class I. *Chrysiogenetes*

Order I. *Chrysiogenales*
Family I. *Chrysiogenaceae*
Genus I. *Chrysiogenes*

Phylum BVI. *Chloroflexi*

Class I. "Chloroflexi"

Order I. "Chloroflexales"
Family I. "Chloroflexaceae"
Genus I. *Chloroflexus*
Genus II. *Chloronema*
Genus III. *Heliothrix*
Genus IV. *Oscillochloris*
Order II. "Herpetosiphonales"
Family I. "Herpetosiphonaceae"
Genus I. *Herpetosiphon*

Phylum BVII. *Thermomicrobia*

Class I. *Thermomicrobia*

Order I. *Thermomicrobiales*
Family I. *Thermomicrobiaceae*
Genus I. *Thermomicrobium*

Phylum BVIII. *Nitrospira*

Class I. "Nitrospira"

Order I. "Nitrospirales"
Family I. "Nitrospiraceae"
Genus I. *Nitrospira*
Genus II. *Leptospirillum*
Genus III. *Magnetobacterium*
Genus IV. *Thermodesulfovibrio*

Phylum BIX. *Deferribacteres*

Class I. *Deferribacteres*

Order I. *Deferribacterales*
Family I. *Deferribacteraceae*
Genus I. *Deferribacter*
Genus II. "Flexistipes"
Genus III. *Geovibrio*
Genera incertae sedis
Genus I. *Synergistes*

Phylum BX. *Cyanobacteria*

Class I. "Cyanobacteria"

Subsection I.
Genus I. *Chamaesiphon*
Genus II. *Chroococcus*
Genus III. *Cyanobacterium*
Form genus IV. *Cyanobium*
Genus V. *Cyanothece*
Genus VI. *Dactylococcopsis*
Genus VII. *Gloeobacter*
Genus VIII. *Gloeocapsa*
Genus IX. *Gloeothece*
Genus X. *Microcystis*
Genus XI. *Prochlorococcus*
Genus XII. *Prochloron*
Form genus XIII. *Synechococcus*
Form genus XIV. *Synechocystis*
Subsection II.
Subgroup I.
Genus I. *Cyanocystis*
Genus II. *Dermocarpella*
Genus III. *Stanieria*
Genus IV. *Xenococcus*
Subgroup II.
Genus I. *Chroococcidiopsis*
Genus II. *Myxosarcina*
Genus III. *Pleurocapsa*
Subsection III.
Genus I. *Arthrospira*
Genus II. *Borzia*
Genus III. *Crinalium*
Genus IV. *Geitlerinema*
Genus V. *Leptolyngbya*
Genus VI. *Limnothrix*
Genus VII. *Lyngbya*
Genus VIII. *Microcoleus*
Genus IX. *Oscillatoria*
Genus X. *Planktothrix*
Genus XI. *Prochlorothrix*
Genus XII. *Pseudanabaena*
Genus XIII. *Spirulina*
Genus XIV. *Starria*
Genus XV. *Symploca*
Genus XVI. *Trichodesmium*
Genus XVII. *Tychonema*
Subsection IV.
Subgroup I.
Genus I. *Anabaena*
Genus II. *Anabaenopsis*
Genus III. *Aphanizomenon*
Genus IV. *Cyanospira*
Genus V. *Cylindrospermopsis*
Genus VI. *Cylindrospermum*
Genus VII. *Nodularia*
Genus VIII. *Nostoc*
Genus IX. *Scytonema*
Subgroup II.
Genus I. *Calothrix*
Genus II. *Rivularia*
Genus III. *Tolypothrix*
Subsection V.
Family I.
Genus I. *Chlorogloeopsis*
Genus II. *Fischerella*
Genus III. *Geitleria*
Genus IV. *Iyengariella*
Genus V. *Nostochopsis*
Genus VI. *Stigonema*

Phylum BXI. *Chlorobi*

Class I. "Chlorobia"

Order I. *Chlorobiales*
Family I. *Chlorobiaceae*
Genus I. *Chlorobium*
Genus II. *Ancalochloris*
Genus III. *Chloroherpeton*
Genus IV. *Pelodictyon*
Genus V. *Prosthecochloris*

Phylum BXII. *Proteobacteria*

Class I. "Alphaproteobacteria"

Order I. *Rhodospirillales*
Family I. *Rhodospirillaceae*
Genus I. *Rhodospirillum*
Genus II. *Azospirillum*
Genus III. *Magnetospirillum*
Genus IV. *Phaeospirillum*
Genus V. *Rhodocista*
Genus VI. *Rhodospira*

Family I. *Neisseriaceae*
Genus I. *Neisseria*
Genus II. *Alysiella*
Genus III. *Aquaspirillum*
Genus IV. *Catenococcus*
Genus V. *Chromobacterium*
Genus VI. *Eikenella*
Genus VII. *Formivibrio*
Genus VIII. *Iodobacter*
Genus IX. *Kingella*
Genus X. *Microvirgula*
Genus XI. *Prolinoborus*
Genus XII. *Simonsiella*
Genus XIII. *Vitreoscilla*
Genus XIV. *Vogesella*
Order V. "Nitrosomonadales"
Family I. "Nitrosomonadaceae"
Genus I. *Nitrosomonas*
Genus II. *Nitrosospira*
Family II. *Spirillaceae*
Genus I. *Spirillum*

Family III. *Gallionellaceae*
Genus I. *Gallionella*
Order VI. "Rhodocyclales"
Family I. *Rhodocyclaceae*
Genus I. *Rhodocyclus*
Genus II. *Azoarcus*
Genus III. *Propionibacter*
Genus IV. *Propionivibrio*
Genus V. *Thauera*
Genus VI. *Zoogloea*

Class III. "Gammaproteobacteria"

Order I. "Chromatiales"
Family I. *Chromatiaceae*
Genus I. *Chromatium*
Genus II. *Allochromatium*
Genus III. *Amoebobacter*
Genus IV. *Halochromatium*
Genus V. *Isochromatium*
Genus VI. *Lamprobacter*
Genus VII. *Lamprocystis*
Genus VIII. *Marichromatium*
Genus IX. *Nitrosococcus*
Genus X. *Pfennigia*
Genus XI. *Rhabdochromatium*
Genus XII. *Thermochromatium*
Genus XIII. *Thiocapsa*
Genus XIV. *Thiococcus*
Genus XV. *Thiocystis*
Genus XVI. *Thiodictyon*
Genus XVII. *Thiohalocapsa*
Genus XVIII. *Thiolamprovum*
Genus XIX. *Thiopedia*
Genus XX. *Thiorhodococcus*
Genus XXI. *Thiorhodovibrio*
Genus XXII. *Thiospirillum*
Family II. *Ectothiorhodospiraceae*
Genus I. *Ectothiorhodospira*
Genus II. *Arhodomonas*
Genus III. *Halorhodospira*
Genus IV. *Nitrococcus*
Genus V. *Thiorhodospira*
Order II. "Xanthomonadales"
Family I. "Xanthomonadaceae"
Genus I. *Xanthomonas*
Genus II. *Frateuria*
Genus III. *Lysobacter*
Genus IV. *Nevskia*
Genus V. *Pseudoxanthomonas*
Genus VI. *Rhodanobacter*
Genus VII. *Stenotrophomonas*
Genus VIII. *Xylella*
Order III. "Cardiobacteriales"
Family I. *Cardiobacteriaceae*
Genus I. *Cardiobacterium*
Genus II. *Dichelobacter*
Genus III. *Suttonella*
Order IV. "Thiotrichales"
Family I. "Thiotrichaceae"
Genus I. *Thiothrix*
Genus II. *Achromatium*
Genus III. *Beggiatoa*
Genus IV. *Leucothrix*
Genus V. *Macromonas*
Genus VI. *Thiobacterium*
Genus VII. *Thiomargarita*
Genus VIII. *Thioploca*
Genus IX. *Thiospira*
Family II. "Piscirickettsiaceae"
Genus I. *Piscirickettsia*
Genus II. *Cycloclasticus*
Genus III. *Hydrogenovibrio*
Genus IV. *Methylophaga*
Genus V. *Thiomicrospira*
Family III. "Francisellaceae"
Genus I. *Francisella*
Order V. "Legionellales"
Family I. *Legionellaceae*
Genus I. *Legionella*
Family II. "Coxiellaceae"
Genus I. *Coxiella*
Genus II. *Rickettsiella*
Order VI. "Methylococcales"
Family I. *Methylococcaceae*
Genus I. *Methylococcus*
Genus II. *Methylobacter*
Genus III. *Methylocaldum*
Genus IV. *Methylomicrobium*
Genus V. *Methylomonas*
Genus VI. *Methylosphaera*
Order VII. "Oceanospirillales"
Family I. "Oceanospirillaceae"
Genus I. *Oceanospirillum*
Genus II. *Balneatrix*
Genus III. *Fundibacter*
Genus IV. *Marinomonas*
Genus V. *Marinospirillum*
Genus VI. *Neptunomonas*
Family II. *Halomonadaceae*
Genus I. *Halomonas*
Genus II. *Alcanivorax*
Genus III. *Carnimonas*
Genus IV. *Chromohalobacter*
Genus V. *Deleya*
Genus VI. *Zymobacter*
Order VIII. *Pseudomonadales*
Family I. *Pseudomonadaceae*
Genus I. *Pseudomonas*
Genus II. *Azomonas*
Genus III. *Azotobacter*
Genus IV. *Cellvibrio*
Genus V. *Chryseomonas*
Genus VI. *Flavimonas*
Genus VII. *Lampropedia*
Genus VIII. *Mesophilobacter*
Genus IX. *Morococcus*
Genus X. *Oligella*
Genus XI. *Rhizobacter*
Genus XII. *Rugamonas*
Genus XIII. *Serpens*
Genus XIV. *Thermoleophilum*
Genus XV. *Xylophilus*
Family II. *Moraxellaceae*
Genus I. *Moraxella*
Genus II. *Acinetobacter*
Genus III. *Psychrobacter*
Order IX. "Alteromonadales"
Family I. "Alteromonadaceae"
Genus I. *Alteromonas*
Genus II. *Colwellia*
Genus III. *Ferrimonas*
Genus IV. *Glaciecola*
Genus V. *Marinobacter*
Genus VI. *Marinobacterium*
Genus VII. *Microbulbifer*
Genus VIII. *Moritella*
Genus IX. *Pseudoalteromonas*
Genus X. *Shewanella*
Order X. "Vibrionales"
Family I. *Vibrionaceae*
Genus I. *Vibrio*
Genus II. *Allomonas*
Genus III. *Enhydrobacter*
Genus IV. *Listonella*
Genus V. *Photobacterium*
Genus VI. *Salinivibrio*
Order XI. "Aeromonadales"
Family I. *Aeromonadaceae*
Genus I. *Aeromonas*
Genus II. *Tolumonas*
Family II. *Succinivibrionaceae*
Genus I. *Succinivibrio*
Genus II. *Anaerobiospirillum*
Genus III. *Ruminobacter*
Genus IV. *Succinimonas*
Order XII. "Enterobacteriales"
Family I. *Enterobacteriaceae*
Genus I. *Enterobacter*
Genus II. *Alterococcus*
Genus III. *Arsenophonus*
Genus IV. *Brenneria*
Genus V. *Buchnera*
Genus VI. *Budvicia*
Genus VII. *Buttiauxella*
Genus VIII. *Calymmatobacterium*
Genus IX. *Cedecea*
Genus X. *Citrobacter*
Genus XI. *Edwardsiella*
Genus XII. *Erwinia*
Genus XIII. *Escherichia*
Genus XIV. *Ewingella*
Genus XV. *Hafnia*
Genus XVI. *Klebsiella*
Genus XVII. *Kluyvera*
Genus XVIII. *Leclercia*
Genus XIX. *Leminorella*
Genus XX. *Moellerella*
Genus XXI. *Morganella*
Genus XXII. *Obesumbacterium*
Genus XXIII. *Pantoea*
Genus XXIV. *Pectobacterium*
Genus XXV. *Photorhabdus*
Genus XXVI. *Plesiomonas*

Genus XXVII. *Pragia*
Genus XXVIII. *Proteus*
Genus XXIX. *Providencia*
Genus XXX. *Rahnella*
Genus XXXI. *Saccharobacter*
Genus XXXII. *Salmonella*
Genus XXXIII. *Serratia*
Genus XXXIV. *Shigella*
Genus XXXV. *Sodalis*
Genus XXXVI. *Tatumella*
Genus XXXVII. *Trabulsiella*
Genus XXXVIII. *Wigglesworthia*
Genus XXXIX. *Xenorhabdus*
Genus XL. *Yersinia*
Genus XLI. *Yokenella*
Order XIII. "Pasteurellales"
Family I. *Pasteurellaceae*
Genus I. *Pasteurella*
Genus II. *Actinobacillus*
Genus III. *Haemophilus*
Genus IV. *Lonepinella*
Genus V. *Mannheimia*
Genus VI. *Phocoenobacter*

Class IV. "Deltaproteobacteria"

Order I. "Desulfurellales"
Family I. "Desulfurellaceae"
Genus I. *Desulfurella*
Genus II. *Hippea*
Order II. "Desulfovibrionales"
Family I. "Desulfovibrionaceae"
Genus I. *Desulfovibrio*
Genus II. *Bilophila*
Genus III. *Lawsonia*
Family II. "Desulfomicrobiaceae"
Genus I. *Desulfomicrobium"*
Family III. "Desulfohalobiaceae"
Genus I. *Desulfohalobium*
Genus II. *Desulfomonas*
Genus III. *Desulfonatronovibrio*
Order III. "Desulfobacterales"
Family I. "Desulfobacteraceae"
Genus I. *Desulfobacter*
Genus II. *Desulfobacterium*
Genus III. "Desulfobacula"
Genus IV. "Desulfobotulus"
Genus V. *Desulfocella*
Genus VI. *Desulfococcus*
Genus VII. *Desulfofaba*
Genus VIII. *Desulfofrigus*
Genus IX. *Desulfonema*
Genus X. *Desulfosarcina*
Genus XI. *Desulfospira*
Genus XII. *Desulfotalea*
Family II. "Desulfobulbaceae"
Genus I. *Desulfobulbus*
Genus II. *Desulfocapsa*
Genus III. *Desulfofustis*
Genus IV. *Desulforhopalus*
Family III. "Desulfoarculaceae"
Genus I. "Desulfoarculus"
Genus II. *Nitrospina*
Genus III. *Desulfobacca*
Genus IV. *Desulfomonile*
Order IV. "Desulfuromonadales"
Family I. "Desulfuromonadaceae"
Genus I. *Desulfuromonas*
Genus II. *Desulfuromusa*
Family II. "Geobacteraceae"
Genus I. *Geobacter*
Family III. "Pelobacteraceae
Genus I. *Pelobacter*
Genus II. *Malonomonas*
Order V. "Syntrophobacterales"
Family I. "Syntrophobacteraceae"
Genus I. *Syntrophobacter*
Genus II. *Desulfacinum*
Genus III. *Desulforhabdus*
Genus IV. *Thermodesulforhabdus*
Family II. "Syntrophaceae"
Genus I. *Syntrophus*
Genus II. *Smithella*
Order VI. "Bdellovibrionales"
Family I. "Bdellovibrionaceae"
Genus I. *Bdellovibrio*
Genus II. *Micavibrio*
Genus III. *Vampirovibrio*
Order VII. *Myxococcales*
Family I. *Myxococcaceae*
Genus I. *Myxococcus*
Genus II. *Angiococcus*
Family II. *Archangiaceae*
Genus I. *Archangium*
Family III. *Cystobacteraceae*
Genus I. *Cystobacter*
Genus II. *Melittangium*
Genus III. *Stigmatella*
Family IV. *Polyangiaceae*
Genus I. *Polyangium*
Genus II. *Chondromyces*
Genus III. *Nannocystis*

Class V. "Epsilonproteobacteria"

Order I. "Campylobacterales"
Family I. *Campylobacteraceae*
Genus I. *Campylobacter*
Genus II. *Arcobacter*
Genus III. *Sulfurospirillum*
Genus IV. *Thiovulum*
Family II. "Helicobacteraceae"
Genus I. *Helicobacter*
Genus II. *Wolinella*

Phylum BXIII. *Firmicutes*

Class I. "Clostridia"

Order I. *Clostridiales*
Family I. *Clostridiaceae*
Genus I. *Clostridium*
Genus II. *Acetivibrio*
Genus III. *Acidaminobacter*
Genus IV. *Anaerobacter*
Genus V. *Caloramator*
Genus VI. *Natronincola*
Genus VII. *Oxobacter*
Genus VIII. *Sarcina*
Genus IX. *Sporobacter*
Genus X. *Thermobrachium*
Genus XI. *Tindallia*
Family II. "Lachnospiraceae"
Genus I. *Lachnospira*
Genus II. *Acetitomaculum*
Genus III. *Anaerofilum*
Genus IV. *Butyrivibrio*
Genus V. *Catonella*
Genus VI. *Coprococcus*
Genus VII. *Johnsonella*
Genus VIII. *Pseudobutyrivibrio*
Genus IX. *Roseburia*
Genus X. *Ruminococcus*
Genux XI. *Sporobacterium*
Family III. "Peptostreptococcaceae"
Genus I. *Peptostreptococcus*
Genus II. *Filifactor*
Genus III. *Fusibacter*
Genus IV. *Helococcus*
Genus V. *Tissierella*
Family IV. "Eubacteriaceae"
Genus I. *Eubacterium*
Genus II. *Acetobacterium*
Genus III. *Pseudoramibacter*
Family V. *Peptococcaceae*
Genus I. *Peptococcus*
Genus II. *Anaeroarcus*
Genus III. *Anaerosinus*
Genus IV. *Anaerovibrio*
Genus V. *Carboxydothermus*
Genus VI. *Centipeda*
Genus VII. *Dehalobacter*
Genus VIII. *Dendrosporobacter*
Genus IX. *Desulfitobacterium*
Genus X. *Desulfonispora*
Genus XI. *Desulfosporosinus*
Genus XII.*Desulfotomaculum*
Genus XIII. *Mitsuokella*
Genus XIV. *Propionispira*
Genus XV. *Succinispira*
Genus XVI. *Syntrophobotulus*
Genus XVII. *Thermoterrabacterium*
Family VI. "Heliobacteriaceae"
Genus I. *Heliobacterium*
Genus II. *Heliobacillus*
Genus III. *Heliophilum*
Family VII. "Acidaminococcaceae"
Genus I. *Acidaminococcus*
Genus II. *Acetonema*
Genus III. *Anaeromusa*
Genus IV. *Dialister*
Genus V. *Megasphaera*
Genus VI. *Pectinatus*
Genus VII. *Phascolarctobacterium*
Genus VIII. *Quinella*
Genus IX. *Schwartzia*
Genus X. *Selenomonas*

Genus XI. *Sporomusa*
Genus XII. *Succiniclasticum*
Genus XIII. *Veillonella*
Genus XIV. *Zymophilus*
Family VIII. *Syntrophomonadaceae*
Genus I. *Syntrophomonas*
Genus II. *Acetogenium*
Genus III. *Aminobacterium*
Genus IV. *Aminomonas*
Genus V. *Anaerobaculum*
Genus VI. *Anaerobranca*
Genus VII. *Caldicellulosiruptor*
Genus VIII. *Dethiosulfovibrio*
Genus IX. *Syntrophospora*
Genus X. *Thermaerobacter*
Genus XI. *Thermanaerovibrio*
Genus XII. *Thermohydrogenium*
Genus XIII. *Thermosyntropha*
Order II. "Thermoanaerobacteriales"
Family I. "Thermoanaerobacteriaceae"
Genus I. *Thermoanaerobacterium*
Genus II. *Ammonifex*
Genus III. *Coprothermobacter*
Genus IV. *Moorella*
Genus V. *Sporotomaculum*
Genus VI. *Thermoanaerobacter*
Genus VII. *Thermoanaerobium*
Order III. *Haloanaerobiales*
Family I. *Haloanaerobiaceae*
Genus I. *Haloanaerobium*
Genus II. *Halocella*
Genus III. *Halothermothrix*
Genus IV. *Natroniella*
Family II. *Halobacteroidaceae*
Genus I. *Halobacteroides*
Genus II. *Acetohalobium*
Genus III. *Haloanaerobacter*
Genus IV. *Orenia*
Genus V. *Sporohalobacter*

Class II. *Mollicutes*

Order I. *Mycoplasmatales*
Family I. *Mycoplasmataceae*
Genus I. *Mycoplasma*
Genus II. *Eperythrozoon*
Genus III. *Haemobartonella*
Genus IV. *Ureaplasma*
Order II. *Entomoplasmatales*
Family I. *Entomoplasmataceae*
Genus I. *Entomoplasma*
Genus II. *Mesoplasma*
Family II. *Spiroplasmataceae*
Genus I. *Spiroplasma*
Order III. *Acholeplasmatales*
Family I. *Acholeplasmataceae*
Genus I. *Acholeplasma*
Order IV. *Anaeroplasmatales*
Family I. *Anaeroplasmataceae*
Genus I. *Anaeroplasma*
Genus II. *Asteroleplasma*
Order V. Incertae sedis
Family I. "Erysipelotrichaceae"
Genus I. *Erysipelothrix*
Genus II. *Holdemania*

Class III. "Bacilli"

Order I. *Bacillales*
Family I. *Bacillaceae*
Genus I. *Bacillus*
Genus II. *Amphibacillus*
Genus III. *Exiguobacterium*
Genus IV. *Gracilibacillus*
Genus V. *Halobacillus*
Genus VI. *Saccharococcus*
Genus VII. *Salibacillus*
Genus VIII. *Virgibacillus*
Family II. *Planococcaceae*
Genus I. *Planococcus*
Genus II. *Filibacter*
Genus III. *Kurthia*
Genus IV. *Sporosarcina*
Family III. *Caryophanaceae*
Genus I. *Caryophanon*
Family IV. "Listeriaceae"
Genus I. *Listeria*
Genus II. *Brochothrix*
Family V. "Staphylococcaceae"
Genus I. *Staphylococcus*
Genus II. *Gemella*
Genus III. *Macrococcus*
Genus IV. *Salinicoccus*
Family VI. "Sporolactobacillaceae"
Genus I. *Sporolactobacillus*
Genus II. *Marinococcus*
Family VII. "Paenibacillaceae"
Genus I. *Paenibacillus*
Genus II. *Ammoniphilus*
Genus III. *Aneurinibacillus*
Genus IV. *Brevibacillus*
Genus V. *Oxalophagus*
Genus VI. *Thermobacillus*
Family VIII. "Alicyclobacillaceae"
Genus I. *Alicyclobacillus*
Genus II. *Pasteuria*
Genus III. *Sulfobacillus*
Family IX. "Thermoactinomycetaceae"
Genus I. *Thermoactinomyces*
Order II. "Lactobacillales"
Family I. *Lactobacillaceae*
Genus I. *Lactobacillus*
Genus II. *Pediococcus*
Family II. "Aerococcaceae"
Genus I. *Aerococcus*
Genus II. *Abiotrophia*
Genus III. *Dolosicoccus*
Genus IV. *Eremococcus*
Genus V. *Facklamia*
Genus VI. *Globicatella*
Genus VII. *Ignavigranum*
Family III. "Carnobacteriaceae"
Genus I. *Carnobacterium*
Genus II. *Agitococcus*
Genus III. *Alloiococcus*
Genus IV. *Desemzia*
Genus V. *Dolosigranulum*
Genus VI. *Lactosphaera*
Genus VII. *Trichococcus*
Family IV. "Enterococcaceae"
Genus I. *Enterococcus*
Genus II. *Melissococcus*
Genus III. *Tetragenococcus*
Genus IV. *Vagococcus*
Family V. "Leuconostocaceae"
Genus I. *Leuconostoc*
Genus II. *Oenococcus*
Genus III. *Weissella*
Family VI. *Streptococcaceae*
Genus I. *Streptococcus*
Genus II. *Lactococcus*
Family VII. Incertae sedis
Genus I. *Acetoanaerobium*
Genus II. *Oscillospira*
Genus III. *Syntrophococcus*

Phylum BXIV. *Actinobacteria*

Class I. *Actinobacteria*

Subclass I. *Acidimicrobidae*
Order I. *Acidimicrobiales*
Suborder I. "Acidimicrobineae"
Family I. *Acidimicrobiaceae*
Genus I. *Acidimicrobium*
Subclass II. *Rubrobacteridae*
Order I. *Rubrobacterales*
Suborder I. "Rubrobacterineae"
Family I. *Rubrobacteraceae*
Genus I. *Rubrobacter*
Subclass III. *Coriobacteridae*
Order I. *Coriobacteriales*
Suborder I. "Coriobacterineae"
Family I. *Coriobacteriaceae*
Genus I. *Coriobacterium*
Genus II. *Atopobium*
Genus III. *Collinsella*
Genus IV. *Crytobacterium*
Genus V. *Eggerthella*
Genus VI. *Slackia*
Subclass IV. *Sphaerobacteridae*
Order I. *Sphaerobacterales*
Suborder I. "Sphaerobacterineae"
Family I. *Sphaerobacteraceae*
Genus I. *Sphaerobacter*
Subclass V. *Actinobacteridae*
Order I. *Actinomycetales*
Suborder I. *Actinomycineae*
Family I. *Actinomycetaceae*
Genus I. *Actinomyces*
Genus II. *Actinobaculum*
Genus III. *Arcanobacterium*
Genus IV. *Mobiluncus*
Suborder VI. *Micrococcineae*
Family I. *Micrococcaceae*
Genus I. *Micrococcus*

Genus II. *Arthrobacter*
Genus III. *Bogoriella*
Genus IV. *Demetria*
Genus V. *Kocuria*
Genus VI. *Leucobacter*
Genus VII. *Nesterenkonia*
Genus VIII. *Renibacterium*
Genus IX. *Rothia*
Genus X. *Stomatococcus*
Genus XI. *Terracoccus*
Family II. *Brevibacteriaceae*
Genus I. *Brevibacterium*
Family III. *Cellulomonadaceae*
Genus I. *Cellulomonas*
Genus II. *Oerskovia*
Genus III. *Rarobacter*
Family IV. *Dermabacteraceae*
Genus I. *Dermabacter*
Genus II. *Brachybacterium*
Family V. *Dermatophilaceae*
Genus I. *Dermatophilus*
Genus II. *Dermacoccus*
Genus III. *Kytococcus*
Family VI. *Intrasporangiaceae*
Genus I. *Intrasporangium*
Genus II. *Janibacter*
Genus III. *Ornithinicoccus*
Genus IV. *Sanguibacter*
Genus V. *Terrabacter*
Family VII. *Jonesiaceae*
Genus I. *Jonesia*
Family VIII. *Microbacteriaceae*
Genus I. *Microbacterium*
Genus II. *Agrococcus*
Genus III. *Agromyces*
Genus IV. *Aureobacterium*
Genus V. *Clavibacter*
Genus VI. *Cryobacterium*
Genus VII. *Curtobacterium*
Genus VIII. *Frigoribacterium*
Genus IX. *Leifsonia*
Genus X. *Rathayibacter*
Family IX. "Beutenbergiaceae"
Genus I. *Beutenbergia*
Family X. *Promicromonosporaceae*
Genus I. *Promicromonospora*
Suborder VII. *Corynebacterineae*
Family I. *Corynebacteriaceae*
Genus I. *Corynebacterium*
Family II. *Dietziaceae*
Genus I. *Dietzia*
Family III. *Gordoniaceae*
Genus I. *Gordonia*
Genus II. *Skermania*
Family IV. *Mycobacteriaceae*
Genus I. *Mycobacterium*
Family V. *Nocardiaceae*
Genus I. *Nocardia*
Genus II. *Rhodococcus*
Family VI. *Tsukamurellaceae*
Genus I. *Tsukamurella*
Family VII. "Williamsiaceae"
Genus I. *Williamsia*
Suborder VIII. *Micromonosporineae*
Family I. *Micromonosporaceae*
Genus I. *Micromonospora*
Genus II. *Actinoplanes*
Genus III. *Catellatospora*
Genus IV. *Catenuloplanes*
Genus V. *Couchioplanes*
Genus VI. *Dactylosporangium*
Genus VII. *Pilimelia*
Genus VIII. *Spirilliplanes*
Genus IX. *Verrucosispora*
Suborder IX. *Propionibacterineae*
Family I. *Propionibacteriaceae*
Genus I. *Propionibacterium*
Genus II. *Luteococcus*
Genus III. *Microlunatus*
Genus IV. *Propioniferax*
Genus V. *Tessaracoccus*
Family II. *Nocardioidaceae*
Genus I. *Nocardioides*
Genus II. *Aeromicrobium*
Genus III. *Friedmanniella*
Genus IV. *Kribbella*
Genus V. *Micropruina*
Suborder X. *Pseudonocardineae*
Family I. *Pseudonocardiaceae*
Genus I. *Pseudonocardia*
Genus II. *Actinopolyspora*
Genus III. *Amycolatopsis*
Genus IV. *Kibdelosporangium*
Genus V. *Kutzneria*
Genus VI. *Prauserella*
Genus VII. *Saccharomonospora*
Genus VIII. *Saccharopolyspora*
Genus IX. *Streptoalloteichus*
Genus X. *Thermobispora*
Genus XI. *Thermocrispum*
Family II. *Actinosynnemataceae*
Genus I. *Actinosynnema*
Genus II. *Actinokineospora*
Genus III. *Lentzea*
Genus IV. *Saccharothrix*
Suborder XI. *Streptomycineae*
Family I. *Streptomycetaceae*
Genus I. *Streptomyces*
Genus II. *Kitasatospora*
Genus III. *Streptoverticillium*
Suborder XII. *Streptosporangineae*
Family I. *Streptosporangiaceae*
Genus I. *Streptosporangium*
Genus II. *Herbidospora*
Genus III. *Microbispora*
Genus IV. *Microtetraspora*
Genus V. *Nonomuraea*
Genus VI. *Planobispora*
Genus VII. *Planomonospora*
Genus VIII. *Planopolyspora*
Genus IX. *Planotetraspora*
Family II. *Nocardiopsaceae*
Genus I. *Nocardiopsis*
Genus II. *Thermobifida*
Family III. *Thermomonosporaceae*
Genus I. *Thermomonospora*
Genus II. *Actinomadura*
Genus III. *Spirillospora*
Suborder XIII. *Frankineae*
Family I. *Frankiaceae*
Genus I. *Frankia*
Family II. *Geodermatophilaceae*
Genus I. *Geodermatophilus*
Genus II. *Blastococcus*
Genus III. *Modestobacter*
Family III. *Microsphaeraceae*
Genus I. *Microsphaera*
Family IV. *Sporichthyaceae*
Genus I. *Sporichthya*
Family V. *Acidothermaceae*
Genus I. *Acidothermus*
Family VI. "Kineosporiaceae"
Genus I. *Kineosporia*
Genus II. *Cryptosporangium*
Genus III. *Kineococcus*
Suborder XIV. *Glycomycineae*
Family I. *Glycomycetaceae*
Genus I. *Glycomyces*
Order II. *Bifidobacteriales*
Family I. *Bifidobacteriaceae*
Genus I. *Bifidobacterium*
Genus II. *Falcivibrio*
Genus III. *Gardnerella*
Family II. Unknown Affiliation
Genus I. *Actinobispora*
Genus II. *Actinocorallia*
Genus III. *Excellospora*
Genus IV. *Pelczaria*
Genus V. *Turicella*

Phylum BXV. *Planctomycetes*

Class I. "Planctomycetacia"

Order I. *Planctomycetales*
Family I. *Planctomycetaceae*
Genus I. *Planctomyces*
Genus II. *Gemmata*
Genus III. *Isosphaera*
Genus IV. *Pirellula*

Phylum BXVI. *Chlamydiae*

Class I. "Chlamydiae"

Order I. *Chlamydiales*
Family I. *Chlamydiaceae*
Genus I. *Chlamydia*
Genus II. *Chlamydophila*
Family II. *Parachlamydiaceae*
Genus I. *Parachlamydia*
Family III. *Simkaniaceae*
Genus I. *Simkania*
Family IV. *Waddliaceae*
Genus I. *Waddlia*

Phylum BXVII. *Spirochaetes*

Class I. "Spirochaetes"

Order I. *Spirochaetales*
  Family I. *Spirochaetaceae*
    Genus I. *Spirochaeta*
    Genus II. *Borrelia*
    Genus III. *Brevinema*
    Genus IV. *Clevelandina*
    Genus V. *Cristispira*
    Genus VI. *Diplocalyx*
    Genus VII. *Hollandina*
    Genus VIII. *Pillotina*
    Genus IX. *Treponema*
  Family II. "Serpulinaceae"
    Genus I. *Brachyspira*
    Genus II. *Serpulina*
  Family III. *Leptospiraceae*
    Genus I. *Leptonema*
    Genus II. *Leptospira*

  Family I. *Verrucomicrobiaceae*
    Genus I. *Verrucomicrobium*
    Genus II. *Prosthecobacter*

Phylum BXXIII. *Dictyoglomi*

Class I. "Dictyoglomi"

Order I. "Dictyoglomales"
  Family I. "Dictyoglomaceae"
    Genus I. *Dictyoglomus*

APPENDIX V

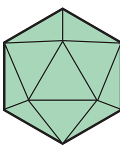
Classification of Viruses

In this appendix selected groups of viruses are briefly described and a sketch of each is included. The illustrations are not to scale but should provide a general idea of the morphology of each group. The viruses are separated into six sections based on their host preferences. The following material has been adapted with permission from chapter 21 of *Introduction to Modern Virology,* 4th ed. by N. J. Dimmock and S. B. Primrose, copyright © 1994 by Blackwell Scientific Publications, Ltd.

Viruses Multiplying in Vertebrates and Other Hosts

Note that some or all of the *Reoviridae, Bunyaviridae, Rhabdoviridae,* and *Togaviridae* multiply in both vertebrates and other hosts. Other families include genera that multiply solely in vertebrates.

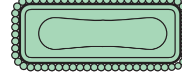
1. Family: *Iridoviridae*



Icosahedral particle (125 to 300 nm) consisting of a spherical nucleocapsid surrounded by lipid modified by protein subunits. Envelope may be present but is not required for infectivity. Double-stranded DNA of mol wt 100 to 250 × 10^6, which is circularly permuted with direct terminal repeats. Contain several enzymes. Transcription and DNA synthesis are nuclear. mRNAs have no polyA tails. Cytoplasmic.

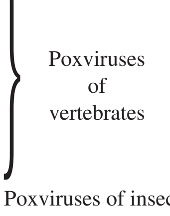
Selected genera:
- *Iridovirus* (small 120 nm blue iridescent viruses of insects)
- *Chloriridovirus* (large 180 nm iridescent viruses of insects)
- *Ranavirus* (frog virus group)
- *Lymphocystivirus* (viruses of fish)

2. Family: *Poxviridae*



Double-stranded DNA of mol wt 85 to 240 × 10^6 with inverted terminal repeats. Largest viruses 170 to 260 × 300 to 450 nm. Complex structure composed of several layers and includes lipid. Core contains all enzymes required for mRNA synthesis. Cytoplasmic multiplication.

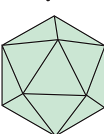
Selected genera:
- *Orthopoxvirus* (vaccinia and related viruses)
- *Molluscipoxvirus* (*Molluscum contagiosum* virus of humans)
- *Avipoxvirus* (fowlpox and related viruses)
- *Parapoxvirus* (milker's node and related viruses)
- *Entomopoxvirus*



Poxviruses of vertebrates

Poxviruses of insects

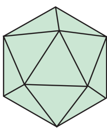
3. Family: *Parvoviridae*



Single-stranded DNA of mol wt 1.5 to 2.0 × 10^6. Particle is an 18 to 22 nm icosahedron. Contains no enzymes. Multiplication has a nuclear stage.

Genera:
- *Parvovirus*—viruses of vertebrates including humans. Virions mostly –DNA.
- *Dependovirus*—adeno-associated virus. Infects vertebrates. Particles contain either +DNA or –DNA, which forms a double strand upon extraction. Require helper adenovirus or herpesvirus for efficient replication.
- *Densovirus*—viruses of insects. Virions –DNA or +DNA. Helper not required.

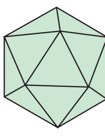
4. Family: *Reoviridae*



Ten to twelve segments of double-stranded RNA of total mol wt 12 to 20 × 10^6. Particle is a 60 to 80 nm icosahedron. Has an isometric nucleocapsid with transcriptase activity. Cytoplasmic multiplication.

Selected genera:
- *Orthoreovirus*—of vertebrates
- *Orbivirus*—of vertebrates, but also multiply in insects
- *Coltivirus*—of vertebrates and ticks
- *Rotavirus*—of vertebrates
- *Cypovirus*—cytoplasmic polyhedrosis viruses of insects
- *Phytoreovirus*—wound tumor virus

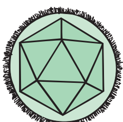
5. Family: *Picornaviridae*



Single-stranded, positive-sense RNA of mol wt 2.5 × 10^6. Particle is 30 nm and icosahedral. Multiplication is cytoplasmic.

Genera:
- *Enterovirus* (acid-resistant, primarily viruses of gastrointestinal tract)
- *Hepatovirus* (hepatitis A virus group)
- *Rhinovirus* (acid-labile, mainly viruses of upper respiratory tract)
- *Aphthovirus* (foot-and-mouth disease virus)
- *Cardiovirus* (EMC virus of mice)
- Also various viruses of insects

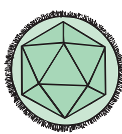
6. Family: *Togaviridae*



Single-stranded, positive-sense RNA of mol wt 4×10^6. Enveloped particles 60 to 70 nm diameter contain an icosahedral nucleocapsid. Hemagglutinate. Cytoplasmic, budding from plasma membrane. Have a subgenomic mRNA.

Genera:
Alphavirus (arboviruses, e.g., Semliki Forest and Sindbis viruses)
Rubivirus (rubella virus)

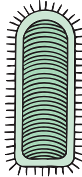
7. Family: *Flaviviridae*



Single-stranded RNA of mol wt $\sim 4 \times 10^6$. Enveloped particles 40 to 60 nm diameter. Differ from *Alphaviridae* by presence of a matrix protein, the lack of intracellular subgenomic mRNAs, and budding from the endoplasmic reticulum. Hemagglutinate. Cytoplasmic.

Genera:
Flavivirus (arboviruses, e.g., yellow fever virus)
Pestivirus (e.g., hog cholera)
Hepatitis C virus group

8. Family: *Rhabdoviridae*



Single-stranded, negative-sense RNA of mol wt 3.5 to 4.6×10^6 complementary to mRNA. The bullet-shaped or bacilliform (100 to 430×70 nm) particle is enveloped with 5 to 10 nm spikes. Inside is a helical nucleocapsid with transcriptase activity. Cytoplasmic, budding from plasma membrane. Some are arboviruses.

Genera:
Vesiculovirus (vesicular stomatitis virus group) viruses of vertebrates and insects
Lyssavirus (viruses of vertebrates, e.g., rabies, and of insects, e.g., sigma)
Plant viruses (e.g., lettuce necrotic yellows, potato yellow dwarf, and many others)

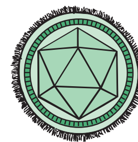
9. Family: *Bunyaviridae*

Three segments (large, medium, and small) of single-stranded RNA of total mol wt 6×10^6. Enveloped 100 nm particles with spikes and three internal ribonucleoprotein filaments 2 nm wide. Cytoplasmic, budding from the Golgi apparatus. Arthropod-transmitted except *Hantavirus* genus.

Selected genera:
Bunyavirus (Bunyamwera and 150 or so related viruses)
Hantavirus (Korean hemorrhagic fever or Hantaan virus) not arboviruses
Tospovirus (tomato spotted wilt group)

Viruses Multiplying Only in Vertebrates

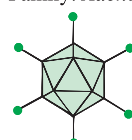
1. Family: *Herpesviridae*



Double-stranded DNA of mol wt 80 to 150×10^6. Particle is a 100 to 110 nm icosahedron enclosed in a lipid envelope (120 to 200 nm virion diameter). Buds from nuclear membrane. Latency for the lifetime of the host is common.

Subfamily: *Alphaherpesvirinae*
Genera:
Simplexvirus—human (alpha) herpesvirus 1 and 2 (herpes simplex virus types 1 and 2)
Varicellovirus—human (alpha) herpesvirus 3 (varicella-zoster virus)
Subfamily: *Betaherpesvirinae* (cytomegaloviruses)
Genera:
Cytomegalovirus—human cytomegalovirus group, e.g., human (beta) herpesvirus 5 (human cytomegalovirus)
Muromegalovirus—mouse cytomegalovirus group
Subfamily: *Gammaherpesvirinae* (lymphoproliferative virus group)
Genera:
Lymphocryptovirus—e.g., human (gamma) herpesvirus 4 (Epstein-Barr virus)

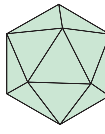
2. Family: *Adenoviridae*



Double-stranded DNA of mol wt 20 to 30×10^6. Particle is a 70 to 90 nm icosahedron, which replicates and is assembled in the nucleus.

Genera:
Mastadenovirus (adenoviruses of mammals)
Aviadenovirus (adenoviruses of birds)

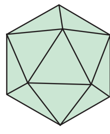
3. Family: *Polyomaviridae*



Double-stranded circular DNA. Nonenveloped, icosahedral particles are 40 nm in diameter, have 72 capsomers in a skewed arrangement, and are assembled in the nucleus. Oncogenic.

Genus:
Polyomavirus is found in rodents, humans, and other primates; DNA 3×10^6 mol wt; includes simian virus 40 (SV-40) and polyomavirus itself.

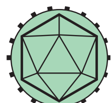
4. Family: *Papillomaviridae*



Double-stranded circular DNA. Nonenveloped, icosahedral particles are 55 nm in diameter, have 72 capsomers in a skewed arrangement, and are assembled in the nucleus. Oncogenic.

Genus:
Papillomavirus produces warts and papillomas in several mammalian species; DNA 5×10^6 mol wt; includes human papillomavirus (HPV).

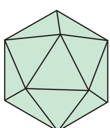
5. Family: *Hepadnaviridae*



One complete DNA minus strand of mol wt 1×10^6 with a 5′ terminal protein. DNA is circularized by an incomplete plus strand of variable length (50 to 100%), which overlaps the 3′ and 5′ termini of DNA minus. There is a 40–48 nm enveloped particle containing a core with DNA polymerase and protein kinase activities. Reverse transcriptase is involved in virus reproduction. Includes hepatitis B of humans, Pekin duck hepatitis, beechy ground squirrel hepatitis, and woodchuck hepatitis viruses. HBV is strongly associated with liver cancer.

Genus:
Orthohepadnavirus—hepatitis B virus

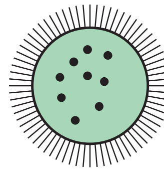
6. Family: *Caliciviridae*



Single-stranded, positive-sense RNA of mol wt 2.7×10^6. Icosahedral 37 nm particle with calixlike (cup-shaped) surface depressions.

Genus:
Calicivirus (vesicular exanthema of swine virus, Norwalk virus, possibly hepatitis E virus)

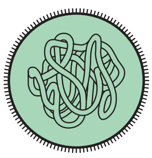
7. Family: *Arenaviridae*



Two (a large and a small) segments of single-stranded RNA of mol wt 3×10^6 and 1.3×10^6. Latter RNA is ambisense. Enveloped 50 to 300 nm particles with spikes. Contain ribosomes which have no known function. Cytoplasmic multiplication; buds from plasma membrane.

Genus:
Arenavirus (lymphocytic choriomeningitis virus and related viruses—e.g., Lassa, Junin, and Macupo viruses)

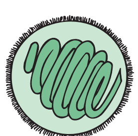
8. Family: *Paramyxoviridae*



Single-stranded RNA of mol wt 5 to 7×10^6. Enveloped 150 nm particles have spikes and contain a helical nucleocapsid 12 to 17 nm in diameter with transcriptase activity. Filamentous forms common. Cytoplasmic, budding from plasma membrane. Airborne transmission.

Subfamily: *Paramyxovirinae*
Genera:
Rubulavirus (mumps, Newcastle disease virus, parainfluenza virus) Only this genus has a neuraminidase activity which is on the same protein (HN) as the hemagglutination activity.
Morbillivirus (measles virus, canine distemper) Hemagglutinate
Subfamily: *Pneumovirinae*
Pneumovirus (respiratory syncytial virus group)

9. Family: *Orthomyxoviridae*



Eight segments of single-stranded RNA of total mol wt 4×10^6. Enveloped 100 nm particles have spikes and contain a helical nucleocapsid 9 nm in diameter with transcriptase activity. Only A and B virions have separate hemagglutinin and neuraminidase proteins. Multiplication requires the nucleus. RNA segments in a mixed infection readily assort to form genetically stable hybrids within a virus. Buds from plasma membrane.

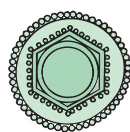
Genera:
Influenza virus A and B
Influenza C virus. Has seven RNA segments and a receptor-destroying activity (a sialic acid-O-acetyl esterase), which is on the hemagglutinin protein.

10. Family: *Filoviridae*

Long filamentous particles 800 to 900 (sometimes 14,000) $\times$ 80 nm with helical nucleocapsid of 50 nm diameter. Linear, single-stranded, negative-sense RNA of mol wt 4.2×10^6. Buds from plasma membrane. Contains Marburg and Ebola viruses, which are highly pathogenic for humans. Transmitted by contact.

Genus:
Filovirus—Marburg and Ebola viruses

11. Family: *Retroviridae*



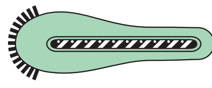
Single-stranded "diploid" RNA with unique sequence having a mol wt 1 to 3×10^6. Enveloped 80–100 nm particles with a core containing a helical nucleoprotein. Contains RNA-dependent DNA polymerase (reverse transcriptase). The DNA provirus is nuclear.

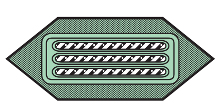
Selected genera:
MLV-related viruses (mammalian type C retrovirus group)—murine leukemia virus
Spumavirus—human foamy virus
HTLV-BLV group—human T-cell lymphotrophic viruses types 1 and 2
Lentivirus—human immunodeficiency viruses types 1 and 2; simian immunodeficiency virus, visna virus

Viruses Multiplying Only in Invertebrates

Viruses occur not only in insects, crustacea, and mollusks but probably in all groups of invertebrates. The *Poxviridae, Reoviridae, Parvoviridae, Rhabdoviridae,* and *Togaviridae* (see earlier) have representatives that multiply in invertebrates. Some plant viruses are transmitted by, but do not multiply in, these vectors.

1. Family: *Baculoviridae*

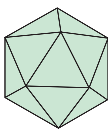




Double-stranded circular DNA of mol wt 60 to 110 × 10^6. Bacilliform particles 30 to 60 nm × 250 to 300 nm with an outer membrane. May be occluded in a protein inclusion body containing usually one particle (granulosis viruses, upper illustration) or in a polyhedra containing many particles (polyhedrosis viruses, lower illustration).

Selected genera:
- Nuclear polyhedrosis virus
- Granulosis viruses
- Nonoccluded baculoviruses

2. Family: *Tetraviridae*

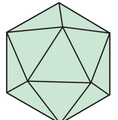


Single-stranded RNA of mol wt 1.8 × 10^6 in a 35 nm particle. T = 4 (whereas in *Picornaviridae* T = 1). All isolated from Lepidoptera. No infection of cultured cells. *Nudaurelia* β virus.

Viruses Multiplying Only in Plants

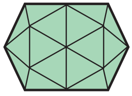
Knowledge of virus multiplication in plants is relatively rudimentary since the cell culture systems are less manageable than animal cell cultures. Work has concentrated on physical properties and disease characteristics. The *Reoviridae* and *Rhabdoviridae* have members that multiply in both plants and invertebrates. The plant viruses listed on the following page are not known to multiply in their invertebrate vector. Differences in virus proteins and translation strategy are important classification criteria.

1. *Caulimoviridae*



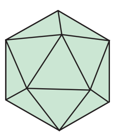
Open circular dsDNA with single-strand discontinuities like the hepadnavirus. Mol wt 4 to 5 × 10^6. Isometric 50 nm particles; some are bacilliform. Contains reverse transcriptase. Aphid vectors. Includes cauliflower mosaic virus.

2. *Geminiviridae*



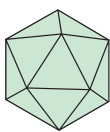
Circular single-stranded DNA of mol wt 0.7 to 0.8 × 10^6. Two incomplete icosahedral particles joined as a pair, ~18 × 30 nm, and usually found in the nucleus. One or two molecules of DNA per pair of particles. Persistent in whitefly or leafhopper vectors.

3. *Luteoviridae*



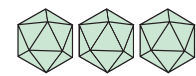
Single-stranded, positive-sense RNA of mol wt 2 × 10^6. Isometric 25 to 30 nm particle. Persistent retention by aphid vectors. Includes barley yellow dwarf virus.

4. *Tombusviridae*



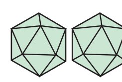
Single-stranded, linear, positive-sense RNA of mol wt 1.5 × 10^6. Not polyadenylated. Particle 32 to 35 nm in diameter. Cytoplasmic, nuclear, and sometimes mitochondrial location. Transmitted through the soil and by mechanical inoculation, contact, and seeds. Includes tobacco necrosis virus and tomato bushy stunt virus.

5. *Bromoviridae*



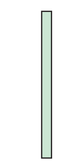
Three single-stranded, linear, positive-sense RNAs. Icosahedral particles 26 to 35 nm diameter and bacilliform particles (18 to 26 nm × 30 to 85 nm). Infectivity requires the three RNAs. Each is in a different particle. Assembly in cytoplasm. Some with a beetle vector. Includes brome mosaic virus, cucumber mosaic virus, and alfalfa mosaic virus.

6. *Comoviridae*



Two 28 to 30 nm nonenveloped particles containing single-stranded, linear, positive-sense RNA of mol wt 2.4 or 1.4 × 10^6. Two coat polypeptides encoded by the smaller RNA. Both RNAs needed for infectivity. Cytoplasmic. Transmitted by beetles or seed. Includes cowpea mosaic virus and tobacco ringspot virus.

7. *Tobamovirus*—tobacco mosaic virus group



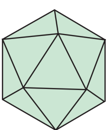
Single-stranded, linear, positive-sense RNA of mol wt 2 × 10^6. Rigid cylindrical particles 300 × 18 nm. Transmitted mechanically or by seed.

8. *Potyviridae*

Single-stranded, linear, positive-sense RNA of mol wt 3.0 to 3.5 × 10^6. Particle is a flexuous rod with helical symmetry, usually 650 to 900 × 11 to 15 nm. Cytoplasmic but some have nuclear inclusions. Nonpersistent in aphid vectors. Includes potato virus y.

Viruses Multiplying Only in Algae, Fungi, and Protozoa

1. Family: *Totiviridae*



Isometric 40 to 43 nm particles with a genome consisting of a single molecule of double-stranded RNA of mol wt 3.3 to 4.2×10^6. One major capsid protein. Single shell. Transcriptase present. Cytoplasmic.

Genus:
Totivirus (*Saccharomyces cerevisiae* virus LA)

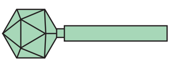
2. Family: *Phycodnaviridae*

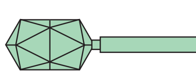
Large polyhedral 130 to 200 nm diameter particles containing linear, double-stranded DNA of mol wt 150 to 210 $\times 10^6$. Nonenveloped. Contain lipid in shell. Infect *Paramecium* and *Chlorella* sp.

Viruses Multiplying Only in Bacteria

Surprisingly little is known of the comparative biology of bacterial viruses as only a few representatives have been studied in detail.

1. Family: *Myoviridae* (Phages with contractile tails)





Linear double-stranded DNA of mol wt 120×10^6. Head isometric or elongated, 110×80 nm; complex contractile tail 113 $\times$ 16 nm. Tail has collar, base plate, spikes, and fibers. Includes T2, T4, T6, PBS1, SP8, SP50, P2, Mu.

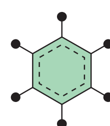
2. Family: *Siphoviridae* (Phages with long, noncontractile tails)

Linear double-stranded DNA of mol wt 33×10^6. Head 60 nm diameter; long noncontractile tail up to 570 nm. No breakdown of host DNA. Includes λ, χ (chi), and ϕ80.

3. Family: *Podoviridae* (Phages with short tails)

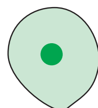
Linear double-stranded DNA of mol wt 25×10^6. Head 60 nm diameter. Short (17×8 nm) tail with 6 short fibers. Includes T7 and P22.

4. Family: *Tectiviridae* (Phages with double capsids)



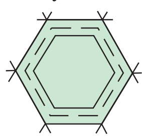
Linear double-stranded DNA of mol wt 10×10^6 in 63 nm particles. Contains internal lipid. Double capsid with a rigid outer shell and flexible inner coat. After injection of DNA a tail structure of about 60 nm appears. PRD1, Bam35.

5. Family: *Plasmaviridae* (Pleomorphic phages)



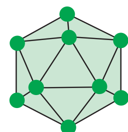
Circular double-stranded DNA of 8×10^6 mol wt in lipid-containing envelope. 50 to 125 nm particle with small dense core. Slightly pleomorphic. Formed by budding. Infects mycoplasmas.

6. Family: *Corticoviridae* (PM2 phage group)



Circular double-stranded DNA of mol wt 6×10^6, isometric 60 nm particle, lipid between protein shells, no envelope, no tail. Spikes at vertices. Infects *Pseudomonas.*

7. Family: *Microviridae* (Isometric phages with ssDNA)



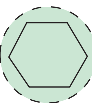
Circular single-stranded DNA of mol wt 1.6 to 1.7×10^6. Icosahedron (25 to 27 nm) with knobs on 12 vertices. No envelope. Includes ϕX174 and G4.

8. Family: *Inoviridae* (Rod-shaped phages)

Helical, filamentous or rod-shaped phages with a circular, single-stranded, positive-sense DNA. No host lysis.

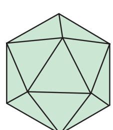
Genera:
Inovirus
DNA of 1.9 to 2.7×10^6, long flexible filamentous particle 760 to $1{,}950 \times 6$ to 8 nm. Host bacteria not lysed. Includes M13 and fd phages.
Plectovirus
Mycoplasma virus type 1 phages. DNA 2.5 to 5.2×10^6 mol wt. Short rods of 85 to 280×14 nm.

9. Family: *Cystoviridae* (ϕ6 phage group)



Three molecules of linear, double-stranded RNA of mol wt 2.3, 3.1, and 5.0×10^6. Isometric 75 nm particle with lipid envelope. Infects *Pseudomonas.*

10. Family: *Leviviridae* (single-stranded RNA phages)



Linear, single-stranded, positive-sense RNA of mol wt 1.2×10^6. Icosahedral capsid is 24 nm.

Genera:
Levivirus—coliphage MS2 group
Allolevivirus—coliphage Qβ group

Nobel Prizes Awarded for Research in Microbiology

Date	Scientist[a]	Research
1901	E. von Behring (GR)	Diphtheria antitoxin
1902	R. Ross (GB)	Cause and transmission of malaria
1905	R. Koch (GR)	Tuberculosis research
1907	C. Laveran (F)	Role of protozoa in disease
1908	P. Ehrlich (GR) E. Metchnikoff (R)	Work on immunity
1913	C. Richet (F)	Work on anaphylaxis
1919	J. Bordet (B)	Discoveries about immunity
1928	C. Nicolle (F)	Work on typhus fever
1930	K. Landsteiner (US)	Discovery of human blood groups
1939	G. Domagk (GR)	Antibacterial effect of prontosil
1945	A. Fleming (GB) E. B. Chain (GB) H. W. Florey (AU)	Discovery of penicillin and its therapeutic value
1951	M. Theiler (SA)	Development of yellow fever vaccine
1952	S. A. Waksman (US)	Discovery of streptomycin
1954	J. F. Enders (US) T. H. Weller (US) F. Robbins (US)	Cultivation of poliovirus in tissue culture
1957	D. Bovet (I)	Discovery of the first antihistamine
1958	G. W. Beadle (US) E. L. Tatum (US) J. Lederberg (US)	Microbial genetics
1959	S. Ochoa (US) A. Kornberg (US)	Discovery of enzymes catalyzing nucleic acid synthesis
1960	F. M. Burnet (AU) P. B. Medawar (GB)	Discovery of acquired immune tolerance to tissue transplants
1962	F. H. C. Crick (GB) J. D. Watson (US) M. Wilkins (GB)	Discoveries concerning the structure of DNA
1965	F. Jacob (F) A. Lwoff (F) J. Monod (F)	Discoveries about the regulation of genes
1966	F. P. Rous (US)	Discovery of cancer viruses
1968	R. W. Holley (US) H. G. Khorana (US) M. W. Nirenberg (US)	Deciphering of the genetic code
1969	M. Delbrück (US) A. D. Hershey (US) S. E. Luria (US)	Discoveries concerning viruses and viral infection of cells
1972	G. Edelman (US) R. Porter (GB)	Research on the structure of antibodies
1975	H. Temin (US) D. Baltimore (US) R. Dulbecco (US)	Discovery of RNA-dependent DNA synthesis by RNA tumor viruses; reproduction of DNA tumor viruses
1976	B. Blumberg (US) D. C. Gajdusek (US)	Mechanism for the origin and dissemination of hepatitis B virus; research on slow virus infections
1977	R. Yalow (US)	Development of the radioimmunoassay technique
1978	H. O. Smith (US) D. Nathans (US) W. Arber (SW)	Discovery of restriction enzymes and their application to the problems of molecular genetics
1980	B. Benacerraf (US) G. Snell (US) J. Dausset (F)	Discovery of the histocompatibility antigens
	P. Berg (US) W. Gilbert (US) & F. Sanger (GB)	Development of recombinant DNA technology (Berg); development of DNA sequencing techniques (Chemistry Prize)
1982	A. Klug (GB)	Development of crystallographic electron microscopy and the elucidation of the structure of viruses and other nucleic-acid–protein complexes (Chemistry Prize)
1984	C. Milstein (GB) G. J. F. Kohler (GR) N. K. Jerne (D)	Development of the technique for formation of monoclonal antibodies (Milstein & Kohler); theoretical work in immunology (Jerne)
1986	E. Ruska (GR)	Development of the transmission electron microscope (Physics Prize)
1987	S. Tonegawa (J)	The genetic principle for generation of antibody diversity
1988	J. Deisenhofer, R. Huber, and H. Michel (GR)	Crystallization and study of the photosynthetic reaction center from a bacterial membrane
	G. Elion (US) G. Hitchings (US)	Development of drugs for the treatment of cancer, malaria, and viral infections
1989	J. M. Bishop (US) H. E. Varmus (US)	Discovery of oncogenes
	S. Altman (US) T. R. Cech (US)	Discovery of catalytic RNA
1993	K. B. Mullis (US)	Invention of the polymerase chain reaction
	M. Smith (US)	Development of site-directed mutagenesis
	R. J. Roberts (US) P. A. Sharp (US)	Discovery of split genes
1996	P. C. Doherty (AU) R. M. Zinkernagel (SW)	Discovery of the mechanism by which T lymphocytes recognize virus-infected cells
1997	S. Prusiner (US)	Discovery of prions

[a]The Nobel laureates were citizens of the following countries: Australia (AU), Belgium (B), Denmark (D), France (F), Germany (GR), Great Britain (GB), Italy (I), Japan (J), Russia (R), South Africa (SA), Switzerland (SW), and the United States (US).

Comparison of *Bacteria, Archaea,* and *Eucarya*

Property	*Bacteria*	*Archaea*	*Eucarya*
Membrane-Enclosed Nucleus with Nucleolus	Absent	Absent	Present
Complex Internal Membranous Organelles	Absent	Absent	Present
Cell Wall	Almost always have peptidoglycan containing muramic acid	Variety of types, no muramic acid	No muramic acid
Membrane Lipid	Have ester-linked, straight-chained fatty acids	Have ether-linked, branched aliphatic chains	Have ester-linked, straight-chained fatty acids
Gas Vesicles	Present	Present	Absent
Transfer RNA	Thymine present in most tRNAs	No thymine in T or TψC arm of tRNA	Thymine present
	N-formylmethionine carried by initiator tRNA	Methionine carried by initiator tRNA	Methionine carried by initiator tRNA
Polycistronic mRNA	Present	Present	Absent
mRNA Introns	Absent	Absent	Present
mRNA Splicing, Capping, and Poly A Tailing	Absent	Absent	Present
Ribosomes			
Size	70S	70S	80S (cytoplasmic ribosomes)
Elongation factor 2	Does not react with diphtheria toxin	Reacts	Reacts
Sensitivity to chloramphenicol and kanamycin	Sensitive	Insensitive	Insensitive
Sensitivity to anisomycin	Insensitive	Sensitive	Sensitive
DNA-Dependent RNA Polymerase			
Number of enzymes	One	Several	Three
Structure	Simple subunit pattern (4 subunits)	Complex subunit pattern similar to eucaryotic enzymes (8–12 subunits)	Complex subunit pattern (12–14 subunits)
Rifampicin sensitivity	Sensitive	Insensitive	Insensitive
Polymerase II Type Promoters	Absent	Present	Present
Metabolism			
Similar ATPase	No	Yes	Yes
Methanogenesis	Absent	Present	Absent
Nitrogen fixation	Present	Present	Absent
Chlorophyll-based photosynthesis	Present	Absent	Present[a]
Chemolithotrophy	Present	Present	Absent

[a]Present in chloroplasts (of bacterial origin).

(repeated as Table 19.8)

Microorganism Pronunciation Guide

The pronunciation of each name is given in parentheses. The phonetic spelling system is explained at the beginning of the glossary (p. G1)

Bacteria

Acetobacter (ah-se″to-bak′ter)
Acinetobacter (as″ĭ-net″o-bak′ter)
Actinomyces (ak″ti-no-mi′sēz)
Agrobacterium (ag″ro-bak-te′re-um)
Alcaligenes (al″kah-lij′ĕ-nēz)
Anabaena (ah-nab′ē-nah)
Arthrobacter (ar″thro-bak′ter)
Bacillus (bah-sil′lus)
Bacteroides (bak″tĕ-roi′dēz)
Bdellovibrio (del″o-vib′re-o)
Beggiatoa (bej″je-ah-to′ah)
Beijerinckia (bi″jer-ink′e-ah)
Bifidobacterium (bi″fid-o-bak-te′re-um)
Bordetella (bor″dĕ-tel′lah)
Borrelia (bŏ-rel′e ah)
Brucella (broo-sel′lah)
Campylobacter (kam″pĭ-lo-bak′ter)
Caulobacter (kaw″lo-bak′ter)
Chlamydia (klah-mid′e-ah)
Chlorobium (klo-ro′be-um)
Chromatium (kro-ma′te-um)
Citrobacter (sit″ro-bak′ter)
Clostridium (klo-strid′e-um)
Corynebacterium (ko-ri″ne-bak-te′re-um)
Coxiella (kok″se-el′lah)
Cytophaga (si-tof′ah-gah)
Desulfovibrio (de-sul″fo-vib′re-o)
Enterobacter (en″ter-o-bak′ter)
Erwinia (er-win′e-ah)
Escherichia (esh″er-i′ke-ah)
Flexibacter (flek″sĭ-bak′ter)
Francisella (fran-si-sel′ah)
Frankia (frank′e-ah)
Gallionella (gal″le-o-nel′ah)
Haemophilus (he-mof′ĭ-lus)
Halobacterium (hal″o-bak-te′re-um)
Hydrogenomonas (hi-dro″jĕ-no-mo′nas)
Hyphomicrobium (hi″fo-mi-kro′be-um)
Klebsiella (kleb″se-el′lah)
Lactobacillus (lak″to-bah-sil′lus)
Legionella (le″jun-el′ah)
Leptospira (lep″to-spi′rah)
Leptothrix (lep′to-thriks)
Leuconostoc (loo″ko-nos′tok)
Listeria (lis-te′re-ah)
Methanobacterium (meth″ah-no-bak-te′re-um)
Methylococcus (meth″il-o-kok′-us)
Methylomonas (meth″il-o-mo′nas)
Micrococcus (mi″kro-kok′us)
Mycobacterium (mi″ko-bak-te′re-um)
Mycoplasma (mi″ko-plaz′mah)
Neisseria (nīs-se′re-ah)
Nitrobacter (ni″tro-bak′ter)
Nitrosomonas (ni-tro″so-mo′nas)
Nocardia (no-kar′de-ah)
Pasteurella (pas″tĕ-rel′ah)
Photobacterium (fo″to-bak-te′re-um)
Propionibacterium (pro″pe-on″e-bak-te′re-um)
Proteus (pro′te-us)
Pseudomonas (soo″do-mo′nas)
Rhizobium (ri-zo′be-um)
Rhodopseudomonas (ro″do-soo″do-mo′nas)
Rhodospirillum (ro″do-spi-ril′um)
Rickettsia (rĭ-ket′se-ah)
Salmonella (sal″mo-nel′ah)
Sarcina (sar′sĭ-nah)
Serratia (sĕ-ra′she-ah)
Shigella (shi-gel′ah)
Sphaerotilus (sfe-ro′ti-lus)
Spirillum (spi-ril′um)
Spirochaeta (spi″ro-ke′tah)
Spiroplasma (spi″ro-plaz′mah)
Staphylococcus (staf″ĭ-lo-kok′us)
Streptococcus (strep″to-kok′us)
Streptomyces (strep″to-mi′sēz)
Sulfolobus (sul″fo-lo′bus)
Thermoactinomyces (ther″mo-ak″ti-no-mi′sēz)
Thermoplasma (ther″mo-plaz′mah)
Thiobacillus (thi″o-bah-sil′us)
Thiothrix (thi′o-thriks)
Treponema (trep″o-ne′mah)
Ureaplasma (u-re′ah-plaz″ma)
Veillonella (va″yon-el′ah)
Vibrio (vib′re-o)
Xanthomonas (zan″tho-mo′nas)
Yersinia (yer-sin′e-ah)
Zoogloea (zo″o-gle′ah)

Viruses

Vernacular, nonscientific virus names are not written in italics, and thus the following names are not italicized.

adenovirus (ad″ĕ-no-vi′rus)
arbovirus (ar″bo-vi′rus)
baculovirus (bak″u-lo-vi′rus)
coronavirus (kor″o-nah-vi′rus)
cytomegalovirus (si″to-meg″ah-lo-vi′rus)
Epstein-Barr virus (ep′stīn-bar′)
hepadnavirus (hep-ad″nə-vi′rus)
hepatitis virus (hep″ah-ti′tis)
herpesvirus (her″pēz-vi′rus)
influenza virus (in″flu-en′zah)
measles virus (me′zelz)
mumps virus (mumps)
orthomyxovirus (or″tho-mik″so-vi′rus)
papillomavirus (pap″ĭ-lo″mah-vi′rus)
paramyxovirus (par″ah-mik″so-vi′rus)
parvovirus (par″vo-vi′rus)
picornavirus (pi-kor″nah-vi′rus)
poliovirus (po″le-o-vi′rus)
polyomavirus (pol″e-o-mah-vi′rus)
poxvirus (poks-vi′rus)
rabies virus (ra′bēz)
reovirus (re″o-vi′rus)
retrovirus (re″tro-vi′rus)
rhabdovirus (rab″do-vi′rus)
rhinovirus (ri″no-vi′rus)
rotavirus (ro′tah-vi″rus)
rubella virus (roo-bel′ah)
togavirus (to″gah-vi′rus)
varicella-zoster virus (var″ĭ-sel′ah zos′ter)
variola virus (vah-ri′o-lah)

Fungi

Agaricus (ah-gar′ĭ-kus)
Amanita (am″ah-ni′tah)
Arthrobotrys (ar″thro-bo′tris)
Aspergillus (as″per-jil′us)
Blastomyces (blas″to-mi′sēz)
Candida (kan′dĭ-dah)
Cephalosporium (sef″ah-lo-spo′re-um)
Claviceps (klav′ĭ-seps)
Coccidioides (kok-sid″e-oi′dēz)
Cryptococcus (krip″to-kok′us)
Epidermophyton (ep″ĭ-der-mof′ĭ-ton)
Fusarium (fu-sa′re-um)
Histoplasma (his″to-plaz′mah)
Microsporum (mi-kros′po-rum)
Mucor (mu′kor)
Neurospora (nu-ros′po-rah)
Penicillium (pen″ĭ-sil′e-um)
Phytophthora (fi-tof′tho-rah)
Rhizopus (ri-zo′pus)
Saccharomyces (sak″ah-ro-mi′sēz)
Saprolegnia (sap″ro-leg′ne-ah)
Sporothrix (spo′ro-thriks)
Trichoderma (trik-o-der′mah)
Trichophyton (tri-kof′ĭ-ton)

Protozoa

Acanthamoeba (ah-kan″thah-me′bah)
Amoeba (ah-me′bah)
Balantidium (bal″an-tid′e-um)
Cryptosporidium (krip″to-spo-rid′e-um)
Entamoeba (en″tah-me′bah)
Giardia (je-ar′de-ah)
Leishmania (lēsh-ma′ne-ah)
Naegleria (na-gle′re-ah)
Paramecium (par″ah-me′she-um)
Plasmodium (plaz-mo′de-um)
Pneumocystis (noo″mo-sis′tis)
Tetrahymena (tet″rah-hi′mĕ-nah)
Toxoplasma (toks″o-plaz′mah)
Trichomonas (trik″o-mo′nas)
Trypanosoma (tri″pan-o-so′mah)

Algae

Acetabularia (as″ĕ-tab″u-la′re-ah)
Chlamydomonas (klah-mid″do-mo′nas)
Chlorella (klo-rel′ah)
Euglena (u-gle′nah)
Gonyaulax (gon″e-aw′laks)
Laminaria (lam″ĭ-na′re-ah)
Prototheca (pro″to-the′kah)
Spirogyra (spi″ro-ji′rah)
Volvox (vol′voks)

GLOSSARY

Pronunciation Guide

Many of the boldface terms in this glossary are followed by a phonetic spelling in parentheses. These pronunciation aids usually come from *Dorland's Illustrated Medical Dictionary.* The following rules are taken from this dictionary and will help in using its phonetic spelling system.

1. An unmarked vowel ending a syllable (an open syllable) is long; thus *ma* represents the pronunciation of *may; ne,* that of *knee; ri,* of *wry; so,* of *sew; too,* of *two;* and *vu,* of *view.*
2. An unmarked vowel in a syllable ending with a consonant (a closed syllable) is short; thus *kat* represents *cat; bed, bed; hit, hit; not, knot; foot, foot;* and *kusp, cusp.*
3. A long vowel in a closed syllable is indicated by a macron; thus *māt* stands for *mate; sēd,* for *seed; bīl,* for *bile; mōl,* for *mole; fūm,* for *fume;* and *fo͞ol,* for *fool.*
4. A short vowel that ends or itself constitutes a syllable is indicated by a breve; thus *ĕ-fekt´* for *effect, ĭ-mūn´* for *immune,* and *ŏ-klo͞od´* for *occlude.*

Primary (´) and secondary (″) accents are shown in polysyllabic words. Unstressed syllables are followed by hyphens.

Some common vowels are pronounced as indicated here.

ə	sofa	ĕ	met	ŏ	got
ā	mate	ī	bite	ū	fuel
ă	bat	ĭ	bit	ŭ	but
ē	beam	ō	home		

From Dorland's Illustrated Medical Dictionary. *Copyright © 1988 W. B. Saunders, Philadelphia, Pa. Reprinted by permission.*

A

AB toxins The structure and activity of many exotoxins are based on the AB model. In this model, the B portion of the toxin is responsible for toxin binding to a cell but does not directly harm it. The A portion enters the cell and disrupts its function. *797*

accessory pigments Photosynthetic pigments such as carotenoids and phycobiliproteins that aid chlorophyll in trapping light energy. *196*

acetyl coenzyme A (acetyl-CoA) A combination of acetic acid and coenzyme A that is energy rich; it is produced by many catabolic pathways and is the substrate for the tricarboxylic acid cycle, fatty acid biosynthesis, and other pathways. *183*

acid dyes Dyes that are anionic or have negatively charged groups such as carboxyls. *27*

acid fast Refers to bacteria like the mycobacteria that cannot be easily decolorized with acid alcohol after being stained with dyes such as basic fuchsin. *543*

acid-fast staining A staining procedure that differentiates between bacteria based on their ability to retain a dye when washed with an acid alcohol solution. *28*

acidophile (as′id-o-fīl″) A microorganism that has its growth optimum between about pH 0 and 5.5. *123*

acquired enamel pellicle A membranous layer on the tooth enamel surface formed by selectively adsorbing glycoproteins (mucins) from saliva. This pellicle confers a net negative charge to the tooth surface. *934*

acquired immune deficiency syndrome (AIDS) An infectious disease syndrome caused by the human immunodeficiency virus and is characterized by the loss of a normal immune response, followed by increased susceptibility to opportunistic infections and an increased risk of some cancers. *878*

acquired immune tolerance The ability to produce antibodies against nonself antigens while "tolerating" (not producing antibodies against) self-antigens. *758*

acquired immunity Refers to the type of specific immunity that develops after exposure to a suitable antigen or is produced after antibodies are transferred from one individual to another. *729*

actinobacteria (ak″tĭ-no-bak-tēr-e-ah) A group of gram-positive bacteria containing the actinomycetes and their high G + C relatives. *541*

actinomycete (ak″tĭ-no-mi′sēt) An aerobic, gram-positive bacterium that forms branching filaments (hyphae) and asexual spores. *537*

actinorhizae Associations between actinomycetes and plant roots. *682*

activated sludge (sluj) Solid matter or sediment composed of actively growing microorganisms that participate in the aerobic portion of a biological sewage treatment process. The microbes readily use dissolved organic substrates and transform them into additional microbial cells and carbon dioxide. *659*

activation energy The energy required to bring reacting molecules together to reach the transition state in a chemical reaction. *162*

active carrier An individual who has an overt clinical case of a disease and who can transmit the infection to others. *854*

active immunization The induction of active immunity by natural exposure to a pathogen or by vaccination. *764*

active site The part of an enzyme that binds the substrate to form an enzyme-substrate complex and catalyze the reaction. Also called the catalytic site. *162*

active transport The transport of solute molecules across a membrane against an electrochemical gradient; it requires a carrier protein and the input of energy. *101*

acute carrier *See* casual carrier. *854*

acute infections Virus infections with a fairly rapid onset that last for a relatively short time. *410*

acute viral gastroenteritis An inflammation of the stomach and intestines, normally caused by Norwalk and Norwalklike viruses, other caliciviruses, rotaviruses, and astroviruses. *891*

acyclovir (a-si′klo-vir) A synthetic purine nucleoside derivative with antiviral activity against herpes simplex virus. *821*

adenine (ad′e-nēn) A purine derivative, 6-aminopurine, found in nucleosides, nucleotides, coenzymes, and nucleic acids. *217*

adenosine diphosphate (ADP; ah-den′o-sēn) The nucleoside diphosphate usually formed upon the breakdown of ATP when it provides energy for work. *155*

adenosine 5′-triphosphate (ATP) The triphosphate of the nucleoside adenosine, which is a high energy molecule or has high phosphate group transfer potential and serves as the cell's major form of energy currency. *155*

adhesin (ad-he′zin) A molecular component on the surface of a microorganism that is involved in adhesion to a substratum or cell. Adhesion to a specific host tissue usually is a preliminary stage in pathogenesis, and adhesins are important virulence factors. *792*

adjuvant (aj′ə-vənt) Material added to an antigen to increase its immunogenicity. Common examples are alum, killed *Bordetella pertussis,* and an oil emulsion of the antigen, either alone (Freund's incomplete adjuvant) or with killed mycobacteria (Freund's complete adjuvant). *741*

adult T-cell leukemia A type of white blood cell cancer caused by the HTLV-1 virus. *887*

aerobe (a′er-ōb) An organism that grows in the presence of atmospheric oxygen. *127*

aerobic anoxygenic photosynthesis Photosynthetic process in which electron donors such as organic matter or sulfide, which do not result in oxygen evolution, are used under aerobic conditions. *614*

aerobic respiration (res″pĭ-ra′shun) A metabolic process in which molecules, often organic, are oxidized with oxygen as the final electron acceptor. *154, 173*

aerotolerant anaerobes Microorganisms that grow equally well whether or not oxygen is present. *127*

aflatoxin (af″lah-tok′sin) A polyketide secondary fungal metabolite that can cause cancer. *967*

agar (ahg′ar) A complex sulfated polysaccharide, usually extracted from red algae, that is used as a solidifying agent in the preparation of culture media. *105*

agglutinates The visible aggregates or clumps formed by an agglutination reaction. *775*

agglutination reaction (ah-gloo″tĭ-na′shun) The formation of an insoluble immune complex by the cross-linking of cells or particles. *756*

agglutinin (ah-gloo″tĭ-nin) The antibody responsible for an agglutination reaction. *756*

AIDS *See* acquired immune deficiency syndrome. *878*

AIDS-related complex (ARC) A collection of symptoms such as lymphadenopathy (swollen lymph glands), fever, malaise, fatigue, loss of appetite, and weight loss. It results from an HIV infection and may progress to frank AIDS. *879*

airborne transmission The type of infectious organism transmission in which the pathogen is truly suspended in the air and travels over a meter or more from the source to the host. *854*

akinetes Specialized, nonmotile, dormant, thick-walled resting cells formed by some cyanobacteria. *473*

alcoholic fermentation A fermentation process that produces ethanol and CO_2 from sugars. *179*

alga (al′gah) A common term for a series of unrelated groups of photosynthetic eucaryotic microorganisms lacking multicellular sex organs (except for the charophytes) and conducting vessels. *571*

algicide (al′jĭ-sīd) An agent that kills algae. *138*

algology (al-gol′o-je) The scientific study of algae. *571*

alkalophile A microorganism that grows best at pHs from about 8.5 to 11.5. *123*

allergen (al′er-jen) A substance capable of inducing allergy or specific susceptibility. *768*

allergic contact dermatitis An allergic reaction caused by haptens that combine with proteins in the skin to form the allergen that produces the immune response. *771*

allergy (al′er-je) *See* hypersensitivity. *768*

allograft (al′o-graft) A transplant between genetically different individuals of the same species. *773*

allosteric enzyme (al″o-ster′ik) An enzyme whose activity is altered by the binding of a small effector or modulator molecule at a regulatory site separate from the catalytic site; effector binding causes a conformational change in the enzyme and its catalytic site, which leads to enzyme activation or inhibition. *165*

allotype Allelic variants of antigenic determinant(s) found on antibody chains of some, but not all, members of a species, which are inherited as simple Mendelian traits. *734*

alpha hemolysis A greenish zone of partial clearing around a bacterial colony growing on blood agar. *531, 797*

alpha-proteobacteria One of the five subgroups of proteobacteria, each with distinctive 16S rRNA sequences. This group contains most of the oligotrophic proteobacteria; some have unusual metabolic modes such as methylotrophy, chemolithotrophy, and nitrogen fixing ability. Many have distinctive morphological features. *487*

alternative complement pathway An antibody-independent pathway of complement activation that includes the C3–C9 components of the classical pathway and several other serum protein factors (e.g., factor B and properdin). *716*

alveolar macrophage A vigorously phagocytic macrophage located on the epithelial surface of the lung alveoli where it ingests inhaled particulate matter and microorganisms. *711*

amantadine (ah-man′tah-den) An antiviral compound used to prevent type A influenza infections. *821*

amebiasis (amebic dysentery) (am″e-bi′ah-sis) An infection with amoebae, often resulting in dysentery; usually it refers to an infection by *Entamoeba histolytica.* *950*

amensalism (a-men′səl-iz-əm) A relationship in which the product of one organism has a negative effect on another organism. *609*

American trypanosomiasis (Chagas' disease) *See* trypanosomiasis. *957*

Ames test A test that uses a special *Salmonella* strain to test chemicals for mutagenicity and potential carcinogenicity. *253*

amino acid activation The initial stage of protein synthesis in which amino acids are attached to transfer RNA molecules. *266*

aminoacyl or acceptor site (A site) The site on the ribosome that contains an aminoacyl-tRNA at the beginning of the elongation cycle during protein synthesis; the growing peptide chain is transferred to the aminoacyl-tRNA and lengthens by an amino acid. *270*

aminoglycoside antibiotics (am″ĭ-no-gli′ko-sīd) A group of antibiotics synthesized by *Streptomyces* and *Micromonospora,* which contain a cyclohexane ring and amino sugars; all aminoglycoside antibiotics bind to the small ribosomal subunit and inhibit protein synthesis. *816*

amnesic shellfish poisoning (am-ne′sik) The disease arising in humans and animals that eat seafood such as mussels contaminated with domoic acid from diatoms. The disease produces short-term memory loss in its victims. *580*

amoeboid movement Moving by means of cytoplasmic flow and the formation of pseudopodia (temporary cytoplasmic protrusions of the cytoplasm). *590*

amphibolic pathways (am″fe-bol′ik) Metabolic pathways that function both catabolically and anabolically. *176*

amphitrichous (am-fit′rĕ-kus) A cell with a single flagellum at each end. *63*

amphotericin B (am″fo-ter′i-sin) An antibiotic from a strain of *Streptomyces nodosus* that is used to treat systemic fungal infections; it also is used topically to treat candidiasis. *820*

anabolism (ah-nab′o-lizm″) The synthesis of complex molecules from simpler molecules with the input of energy. *173*

anaerobe (an-a′er-ōb) An organism that grows in the absence of free oxygen. *127*

anaerobic digestion (an″a-er-o′bik) The microbiological treatment of sewage wastes under anaerobic conditions to produce methane. *659*

anaerobic respiration (an″a-er-o′bik) An energy-yielding process in which the electron transport chain acceptor is an inorganic molecule other than oxygen. *173*

anammox process The coupled use of nitrite as an oxidant and ammonium ion as a reductant under anaerobic conditions to yield nitrogen gas. *616*

anamnestic response (an″am-nes′tik) The recall, or the remembering, by the immune system of a prior response to a given antigen. *729, 743*

anaphylaxis (an″ah-fĭ-lak′sis) An immediate (type I) hypersensitivity reaction following exposure of a sensitized individual to the appropriate antigen. Mediated by reagin antibodies, chiefly IgE. *768*

anaplerotic reactions (an″ah-plĕ-rot′ik) Reactions that replenish depleted tricarboxylic acid cycle intermediates. *216*

anergy (an′ər-je) A state of unresponsiveness to antigens. Absence of the ability to generate a sensitivity reaction to substances that are expected to be antigenic. *758*

annotation The process of determining the location of specific genes in a genome map after it has been produced by nucleic acid sequencing. *347*

anogenital condylomata (venereal warts) (kon″dĭ-lo″ mah-tah) Warts that are sexually transmitted and caused by types 6, 11, and 42 human papillomavirus. Usually occur around the cervix, vulva, perineum, anus, anal canal, urethra, or glans penis. *894*

anoxic (ə-nok′ sik) Without oxygen present. *635*

anoxygenic photosynthesis Photosynthesis that does not oxidize water to produce oxygen; the form of photosynthesis characteristic of purple and green photosynthetic bacteria. *199, 468*

antheridium (an″ther-id′e-um; pl., **antheridia**) A male gamete-producing organ, which may be unicellular or multicellular. *561, 574*

anthrax (an′thraks) An infectious disease of animals caused by ingesting *Bacillus anthracis* spores. Can also occur in humans and is sometimes called woolsorter's disease. *913*

antibiotic (an″tĭ-bi-ot′ik) A microbial product or its derivative that kills susceptible microorganisms or inhibits their growth. *806*

antibody (immunoglobulin) (an′tĭ-bod″e) A glycoprotein produced in response to the introduction of an antigen; it has the ability to combine with the antigen that stimulated its production. Also known as an immunoglobulin (Ig). *734*

antibody-dependent cell-mediated cytotoxicity (ADCC) The killing of antibody-coated target cells by cells with Fc receptors that recognize the Fc region of the bound antibody. Most ADCC is mediated by NK cells that have the Fc receptor or CD16 on their surface. *723*

antibody-mediated immunity *See* humoral immunity. *729*

anticodon triplet The base triplet on a tRNA that is complementary to the triplet codon on mRNA. *266*

antigen (an′tĭ-jen) A foreign (nonself) substance (such as a protein, nucleoprotein, polysaccharide, or sometimes a glycolipid) to which lymphocytes respond; also known as an immunogen because it induces the immune response. *731*

antigen-binding fragment (Fab) "Fragment antigen binding." A monovalent antigen-binding fragment of an immunoglobulin molecule that consists of one light chain and part of one heavy chain, linked by interchain disulfide bonds. *734*

antigenic determinant site (epitope) *See* epitope. *731*

antigenic drift A small change in the antigenic character of an organism that allows it to avoid attack by the immune system. *852*

antigenic shift A major change in the antigenic character of an organism that alters it to an antigenic strain unrecognized by host immune mechanisms. *852*

antigen-presenting cells Antigen-presenting cells (APCs) are cells that take in protein antigens, process them, and present antigen fragments to B cells and T cells in conjunction with class II MHC molecules so that the cells are activated. Macrophages, B cells, dendritic cells, and Langerhans cells may act as APCs. *745*

antimetabolite (an″tĭ-mĕ-tab′o-līt) A compound that blocks metabolic pathway function by competitively inhibiting a key enzyme's use of a metabolite because it closely resembles the normal enzyme substrate. *812*

antimicrobial agent An agent that kills microorganisms or inhibits their growth. *139*

antisense RNA A single-stranded RNA with a base sequence complementary to a segment of another RNA molecule that can specifically bind to the target RNA and inhibit its activity. *283*

antisepsis (an″tĭ-sep′sis) The prevention of infection or sepsis. *138*

antiseptic (an″tĭ-sep′tik) Chemical agents applied to tissue to prevent infection by killing or inhibiting pathogens. *138*

antiserum (an″tĭ-se′rum) Serum containing induced antibodies. *742*

antitoxin (an″tĭ-tok′sin) An antibody to a microbial toxin, usually a bacterial exotoxin, that combines specifically with the toxin, in vivo and in vitro, neutralizing the toxin. *756, 796*

apical complex (ap′ĭ-kal) A set of organelles characteristic of members of the phylum *Apicomplexa:* polar rings, subpellicular microtubules, conoid, rhoptries, and micronemes. *591*

apicomplexan (a′pĭ-kom-plek′san) A sporozoan protist that lacks special locomotor organelles but has an apical complex and a spore-forming stage. It is either an intra- or extracellular parasite of animals; a member of the phylum *Apicomplexa.* *591*

aplanospore (a′plan-o-spor) A nonflagellated, nonmotile spore that is involved in asexual reproduction. *573*

apoenzyme (ap″o-en′zīm) The protein part of an enzyme that also has a nonprotein component. *161*

apoptosis (ap″o-to′sis) Programmed cell death. The fragmentation of a cell into membrane-bound particles that are eliminated by phagocytosis. Apoptosis is a physiological suicide mechanism that preserves homeostasis and occurs during normal tissue turnover. It is responsible for cell death in pathological circumstances, such as exposure to low concentrations of xenobiotics and infections by HIV and various other viruses. Apoptotic cells display profound structural changes such as plasma membrane blebbing and nuclear collapse. DNA is cleaved into short oligonucleosomal length DNA fragments. Apoptosis usually occurs after the activation of a calcium-dependent endogenous endonuclease. *750, 881*

aporepressor An inactive form of the repressor protein, which becomes the active repressor when the corepressor binds to it. *276*

arbuscular mycorrhizal (AM) fungi The mycorrhizal fungi in a symbiotic fungus-root association that penetrate the outer layer of the root, grow intracellularly, and form characteristic much-branched hyphal structures called arbuscules. *681*

arbuscules Branched, treelike structures formed in cells of plant roots colonized by endotrophic mycorrhizal fungi. *681*

Archaea The domain that contains procaryotes with isoprenoid glycerol diether or diglycerol tetraether lipids in their membranes and archaeal rRNA (among many differences). *424, 451*

arthroconidium (ar′thro-ko-nid′e-um; pl., **arthroconidia**) A thallic conidium released by the fragmentation or lysis of hypha. It is not notably larger than the parental hypha, and separation occurs at a septum. *557*

arthrospore (ar′thro-spōr) A spore resulting from the fragmentation of a hypha. *557*

artificially acquired active immunity The type of immunity that results from immunizing an animal with a vaccine. The immunized animal now produces its own antibodies and activated lymphocytes. *730*

artificially acquired passive immunity The type of immunity that results from introducing into an animal antibodies that have been produced either in another animal or by in vitro methods. Immunity is only temporary. *731*

ascocarp (as′ko-karp) A multicellular structure in ascomycetes lined with specialized cells called asci in which nuclear fusion and meiosis produce ascospores. An ascocarp can be open or closed and may be referred to as a fruiting body. *561*

ascogenous hypha A specialized hypha that gives rise to one or more asci. *561*

ascogonium (as″ko-go′ne-um; pl., **ascogonia**) The receiving (female) organ in ascomycetous fungi which, after fertilization, gives rise to ascogenous hyphae and later to asci and ascospores. *561*

ascomycetes (as″ko-mi-se′tēz) A division of fungi that form ascospores. *560*

ascospore (as′ko-spor) A spore contained or produced in an ascus. *558*

ascus (as′kus) A specialized cell, characteristic of the ascomycetes, in which two haploid nuclei fuse to produce a zygote, which immediately divides by meiosis; at maturity an ascus will contain ascospores. *561*

aseptic meningitis syndrome *See* meningitis. *902*

aspergillosis (as″per-jil-o′sis) A fungal disease caused by species of *Aspergillus.* *948*

assimilatory reduction The reduction of an inorganic molecule to incorporate it into organic material. No energy is made available during this process. *210, 211, 614*

associative nitrogen fixation Nitrogen fixation by bacteria in the plant root zone (rhizosphere). *675*

athlete's foot *See* tinea pedis. *944*

atomic force microscope A type of scanning probe microscope that images a surface by moving a sharp probe over the surface at a constant distance; a very small amount of force is exerted on the tip and probe movement is followed with a laser. *38*

ATP-binding cassette transporters (ABC transporters) Membrane protein complexes that use ATP energy to move substances across membranes without modifying the compound being transported. They require an extracytoplasmic substrate-binding protein for proper function. *101*

attenuation (ah-ten″u-a′shun) 1. A mechanism for the regulation of transcription of some bacterial operons by aminoacyl-tRNAs. 2. A procedure that reduces or abolishes the virulence of a pathogen without altering its immunogenicity. *281, 766*

attenuator A rho-independent termination site in the leader sequence that is involved in attenuation. *279*

autoclave (aw′to-klāv) An apparatus for sterilizing objects by the use of steam under pressure. Its development tremendously stimulated the growth of microbiology. *140*

autogenous infection (aw-toj′e-nus) An infection that results from a patient's own microbiota, regardless of whether the infecting organism became part of the patient's microbiota subsequent to admission to a clinical care facility. *866*

autoimmune disease (aw″to-ĭ-mūn′) A disease produced by the immune system attacking self-antigens. Autoimmune disease results from the activation of self-reactive T and B cells that damage tissues after stimulation by genetic or environmental triggers. *772*

autoimmunity (aw″to-ĭ-mun′ĭ-te) Autoimmunity is a condition characterized by the presence of serum autoantibodies and self-reactive lymphocytes. It may be benign or pathogenic. Autoimmunity is a normal consequence of aging; is readily inducible by infectious agents, organisms, or drugs; and is potentially reversible in that it disappears when the offending "agent" is removed or eradicated. *772*

autolysins (aw-tol′ĭ-sins) Enzymes that partially digest peptidoglycan in growing bacteria so that the peptidoglycan can be enlarged. *223*

autotroph (aw′to-trōf) An organism that uses CO_2 as its sole or principal source of carbon. *96*

auxotroph (awk′so-trōf) A mutated prototroph that lacks the ability to synthesize an essential nutrient and therefore must obtain it or a precursor from its surroundings. *245*

axial filament The organ of motility in spirochetes. It is made of axial fibrils or periplasmic flagella that extend from each end of the protoplasmic cylinder and overlap in the middle of the cell. The outer sheath lies outside the axial filament. *66, 479*

B

bacillus (bah-sil′lus) A rod-shaped bacterium. *43*

bacteremia (bak″ter-e′me-ah) The presence of viable bacteria in the blood. *793*

Bacteria (bak-te′re-ə) The domain that contains procaryotic cells with primarily diacyl glycerol diesters in their membranes and with bacterial rRNA. Bacteria also is a general term for organisms that are composed of procaryotic cells and are not multicellular. *424*

bacterial artificial chromosome (BAC) A cloning vector constructed from the *E. coli* F-factor plasmid that is used to clone foreign DNA fragments in *E. coli*. *335*

bacterial (septic) meningitis *See* meningitis. *902*

bacterial vaginosis (bak-te′re-əl vaj″ĭ-no′sis) Bacterial vaginosis is a sexually transmitted disease caused by *Gardnerella vaginalis, Mobiluncus* spp., *Mycoplasma hominis,* and various anaerobic bacteria. Although a mild disease it is a risk factor for obstetric infections and pelvic inflammatory disease. *914*

bactericide (bak-tēr′ĭ-sid) An agent that kills bacteria. *138*

bacteriochlorophyll (bak-te″re-o-klo′ro-fil) A modified chlorophyll that serves as the primary light-trapping pigment in purple and green photosynthetic bacteria. *199*

bacteriocin (bak-te′re-o-sin) A protein produced by a bacterial strain that kills other closely related strains. *297, 712, 972*

bacteriophage (bak-te′re-o-fāj″) A virus that uses bacteria as its host; often called a phage. *364, 382*

bacteriophage (phage) typing A technique in which strains of bacteria are identified based on their susceptibility to a variety of bacteriophages. *842*

bacteriostatic (bak-te″re-o-stat′ik) Inhibiting the growth and reproduction of bacteria. *138*

bacteroid (bak′tĕ-roid) A modified, often pleomorphic, bacterial cell within the root nodule cells of legumes; after transformation into a symbiosome it carries out nitrogen fixation. *676*

baeocytes Small, spherical, reproductive cells produced by pleurocapsalean cyanobacteria through multiple fission. *475*

balanced growth Microbial growth in which all cellular constituents are synthesized at constant rates relative to each other. *114*

balanitis (bal″ah-ni′tis) Inflammation of the glans penis usually associated with *Candida* fungi; a sexually transmitted disease. *950*

barophilic (bar″o-fil′ik) or **barophile** Organisms that prefer or require high pressures for growth and reproduction. *129, 644*

barotolerant Organisms that can grow and reproduce at high pressures but do not require them. *129, 624*

basal body The cylindrical structure at the base of procaryotic and eucaryotic flagella that attaches them to the cell. *64, 90*

base analogs Molecules that resemble normal DNA nucleotides and can substitute for them during DNA replication, leading to mutations. *246*

basic dyes Dyes that are cationic, or have positively charged groups, and bind to negatively charged cell structures. Usually sold as chloride salts. *27*

basidiocarp (bah-sid′e-o-karp″) The fruiting body of a basidiomycete that contains the basidia. *561*

basidiomycetes (bah-sid″e-o-mi-se′tēz) A division of fungi in which the spores are born on club-shaped organs called basidia. *561*

basidiospore (bah-sid′e-o-spōr) A spore born on the outside of a basidium following karyogamy and meiosis. *558*

basidium (bah-sid′e-um; pl., **basidia**) A structure that bears on its surface a definite number of basidiospores (typically four) that are formed following karyogamy and meiosis. Basidia are found in the basidiomycetes and are usually club-shaped. *561*

basophil (ba′so-fil) A phagocytic leukocyte whose granules stain bluish-black with a basic dye. It has a segmented nucleus. The granules contain histamine and heparin. *707*

batch culture A culture of microorganisms produced by inoculating a closed culture vessel containing a single batch of medium. *113*

B cell, also known as a **B lymphocyte** A type of lymphocyte derived from bone marrow stem cells that matures into an immunologically competent cell under the influence of the bursa of Fabricius in the chicken and bone marrow in nonavian species. Following interaction with antigen, it becomes a plasma cell, which synthesizes and secretes antibody molecules involved in humoral immunity. *705, 751*

B-cell antigen receptor (BCR) A transmembrane immunoglobulin complex on the surface of a B cell that binds an antigen and stimulates the B cell. It is composed of a membrane-bound immunoglobulin, usually IgD or a modified IgM, complexed with another membrane protein (the Ig-α/Ig-β heterodimer). *751*

benthic (ben′thic) Pertaining to the bottom of the sea or another body of water. *571*

beta hemolysis A zone of complete clearing around a bacterial colony growing on blood agar. The zone does not change significantly in color. *532, 797*

β-oxidation pathway The major pathway of fatty acid oxidation to produce NADH, $FADH_2$, and acetyl coenzyme A. *192*

beta-proteobacteria One of the five subgroups of proteobacteria, each with distinctive 16S rRNA sequences. Members of this subgroup are similar to the alpha-proteobacteria metabolically, but tend to use substances that diffuse from organic matter decomposition in anaerobic zones. *495*

binal symmetry The symmetry of some virus capsids (e.g., those of complex phages) that is a combination of icosahedral and helical symmetry. *376*

binary fission Asexual reproduction in which a cell or an organism separates into two cells. *490, 573, 586*

binomial system The nomenclature system in which an organism is given two names; the first is the capitalized generic name, and the second is the uncapitalized specific epithet. *426*

biochemical oxygen demand (BOD) The amount of oxygen used by organisms in water under certain standard conditions; it provides an index of the amount of microbially oxidizable organic matter present. *657*

biodegradation (bi″o-deg″rah-da′shun) The breakdown of a complex chemical through biological processes that can result in minor loss of functional groups, fragmentation into larger constitutents, or complete breakdown to carbon dioxide and minerals. Often the term refers to the undesired microbial-mediated destruction of materials such as paper, paint, and textiles. *1010*

biofilms Organized microbial systems consisting of layers of microbial cells associated with surfaces, often with complex structural and functional characteristics. Biofilms have physical/chemical gradients that influence microbial metabolic processes. They can form on inanimate devices (catheters, medical prosthetic devices) and also cause fouling (e.g., of ships' hulls, water pipes, cooling towers). *620, 920*

biogeochemical cycling The oxidation and reduction of substances carried out by living organisms and/or abiotic processes that results in the cycling of elements within and between different parts of the ecosystem (the soil, aquatic environment, and atmosphere). *611*

bioinsecticide A pathogen that is used to kill or disable unwanted insect pests. Bacteria, fungi, or viruses are used, either directly or after manipulation, to control insect populations. *1018*

biologic transmission A type of vector-borne transmission in which a pathogen goes through some morphological or physiological change within the vector. *858*

bioluminescence (bi″o-loo″mĭ-nes′əns) The production of light by living cells, often through the oxidation of molecules by the enzyme luciferase. *505*

biomagnification The increase in concentration of a substance in higher-level consumer organisms. *618*

biopesticide The use of a microorganism or another biological agent to control a specific pest. *1018*

bioremediation The use of biologically mediated processes to remove or degrade pollutants from specific environments. Bioremediation can be carried out by modification of the environment to accelerate biological processes, either with or without the addition of specific microorganisms. *1012*

biosensor The coupling of a biological process with production of an electrical signal or light to detect the presence of particular substances. *1017*

biosynthesis *See* anabolism. *173*

bioterrorism The intentional or threatened use of viruses, bacteria, fungi, or toxins from living organisms to produce death or disease in humans, animals, and plants. *863*

biotransformation or **microbial transformation** The use of living organisms to modify substances that are not normally used for growth. *1009*

black peidra (pe-a′drah) A fungal infection caused by *Piedraia hortae* that forms hard black nodules on the hairs of the scalp. *943*

blastomycosis (blas″to-mi-ko′sis) A systemic fungal infection caused by *Blastomyces dermatitidis* and marked by suppurating tumors in the skin or by lesions in the lungs. *946*

blastospore (blas′to-spōr) A spore formed by budding from a hypha. *557*

B lymphocyte *See* B cell. *705, 751*

botulism (boch′oo-lizm) A form of food poisoning caused by a neurotoxin (botulin) produced by *Clostridium botulinum* serotypes A–G; sometimes found in improperly canned or preserved food. *929*

bright-field microscope A microscope that illuminates the specimen directly with bright light and forms a dark image on a brighter background. *19*

Bright's disease *See* glomerulonephritis. *905*

broad-spectrum drugs Chemotherapeutic agents that are effective against many different kinds of pathogens. *808*

bronchial-associated lymphoid tissue (BALT) The type of defensive tissue found in the lungs. Part of the nonspecific immune system. *710*

bronchial asthma An example of an atopic allergy involving the lower respiratory tract. *769*

bubo (bu′bo) A tender, inflamed, enlarged lymph node that results from a variety of infections. *911*

bubonic plague *See* plague. *911*

budding A vegetative outgrowth of yeast and some bacteria as a means of asexual reproduction; the daughter cell is smaller than the parent. *490*

bulking sludge Sludges produced in sewage treatment that do not settle properly, usually due to the development of filamentous microorganisms. *659*

bursa of Fabricius (bər′sə fə-bris′e-əs) Found in birds; the blind saclike structure located on the posterior wall of the cloaca; it performs a thymuslike function. A primary lymphoid organ where B-cell maturation occurs. Bone marrow is the equivalent in mammals. *708*

burst *See* rise period. *383*

burst size The number of phages released by a host cell during the lytic life cycle. *383*

butanediol fermentation A type of fermentation most often found in the family *Enterobacteriaceae* in which 2,3-butanediol is a major product; acetoin is an intermediate in the pathway and may be detected by the Voges-Proskauer test. *181, A–18*

C

Calvin cycle The main pathway for the fixation (or reduction and incorporation) of CO_2 into organic material by photoautotrophs during photosynthesis; it also is found in chemolithoautotrophs. *207, A–20*

cancer (kan′ser) A malignant tumor that expands locally by invasion of surrounding tissues, and systemically by metastasis. *411*

candidal vaginitis Vaginitis caused by *Candida* species. *950*

candidiasis (kan″dĭ-di′ah-sis) An infection caused by *Candida* species of dimorphic fungi, commonly involving the skin. *949*

capsid (kap′sid) The protein coat or shell that surrounds a virion's nucleic acid. *369*

capsomer (kap′so-mer) The ring-shaped morphological unit of which icosahedral capsids are constructed. *390*

capsule A layer of well-organized material, not easily washed off, lying outside the bacterial cell wall. *61*

carboxysomes Polyhedral inclusion bodies that contain the CO_2 fixation enzyme ribulose 1,5-bisphosphate carboxylase; found in cyanobacteria, nitrifying bacteria, and thiobacilli. *51, 207*

caries (kar′e-ēz) Tooth decay. *936*

carotenoids (kah-rot′e-noids) Pigment molecules, usually yellowish in color, that are often used to aid chlorophyll in trapping light energy during photosynthesis. *196*

carrier An infected individual who is a potential source of infection for others and plays an important role in the epidemiology of a disease. *854*

caseous lesion (ka′se-us) A lesion resembling cheese or curd; cheesy. Most caseous lesions are caused by *M. tuberculosis.* *908*

casual carrier An individual who harbors an infectious organism for only a short period. *854*

catabolism (kah-tab′o-lizm) That part of metabolism in which larger, more complex molecules are broken down into smaller, simpler molecules with the release of energy. *173*

catabolite repression (kah-tab′o-līt) Inhibition of the synthesis of several catabolic enzymes by a metabolite such as glucose. *281*

catalyst (kat′ah-list) A substance that accelerates a reaction without being permanently changed itself. *161*

catalytic site *See* active site. *162*

catheter (kath′ ĕ-ter) A tubular surgical instrument for withdrawing fluids from a cavity of the body, especially one for introduction into the bladder through the urethra for the withdrawal of urine. *827*

cat-scratch disease (CSD) A loosely defined syndrome caused by either of the following gram-negative bacilli: *Bartonella (Rochalimaea) henselae* or *Afipia felis.* The typical case of CSD is self-limiting, with abatement of symptoms over a period of days to weeks. *914*

CD95 pathway The CD95 receptor is found on many nucleated eucaryotic cells. When the receptor is bound to a specific ligand (CD95L), the CD95-CD95L complex activates several cytoplasmic proteins that initiate a cellular suicide cascade leading to apoptosis. *750*

cell cycle The sequence of events in a cell's growth-division cycle between the end of one division and the end of the next. In eucaryotic cells, it is composed of the G_1 period, the S period in which DNA and histones are synthesized, the G_2 period, and the M period (mitosis). *87, 285*

cell-mediated immunity The type of immunity that results from T cells coming into close contact with foreign cells or infected cells to destroy them; it can be transferred to a nonimmune individual by the transfer of cells. *729*

cellular slime molds Slime molds with a vegetative phase consisting of amoeboid cells that aggregate to form a multicellular pseudoplasmodium; they belong to the division *Acrasiomycota.* *565*

cellulitis (sel″u-li′tis) A diffuse spreading infection of subcutaneous skin tissue caused by streptococci, staphylococci, or other organisms. The tissue is inflamed with edema, redness, pain, and interference with function. *903*

cell wall The strong layer or structure that lies outside the plasma membrane; it supports and protects the membrane and gives the cell shape. *88*

cephalosporin (sef″ah-lo-spōr′in) A group of β-lactam antibiotics derived from the fungus *Cephalosporium,* which share the 7-aminocephalosporanic acid nucleus. *814*

chancre (shang′ker) The primary lesion of syphilis, occurring at the site of entry of the infection. *923*

chancroid (shang′kroid) A sexually transmitted disease caused by the gram-negative bacterium *Haemophilus ducreyi.* Worldwide, chancroid is an important cofactor in the transmission of the AIDS virus. Also known as genital ulcer disease due to the painful circumscribed ulcers that form on the penis or entrance to the vagina. *914*

chemical oxygen demand (COD) The amount of chemical oxidation required to convert organic matter in water and wastewater to CO_2. *657*

chemiosmotic hypothesis (kem″e-o-os-mot′ik) The hypothesis that a proton gradient and an electrochemical gradient are generated by electron transport and then used to drive ATP synthesis by oxidative phosphorylation. *187*

chemoheterotroph (ke″mo-het′er-o-trōf″) *See* chemoorganotrophic heterotrophs. *98*

chemolithotroph (ke″mo-lith′o-trōf) *See* chemolithotrophic autotrophs. *98, 193*

chemolithotrophic autotrophs Microorganisms that oxidize reduced inorganic compounds to derive both energy and electrons; CO_2 is their carbon source. Also called chemolithoautotrophs. *98*

chemoorganotrophic heterotrophs Organisms that use organic compounds as sources of energy, hydrogen, electrons, and carbon for biosynthesis. *98*

chemoreceptors Special protein receptors in the plasma membrane or periplasmic space that bind chemicals and trigger the appropriate chemotaxic response. *67*

chemostat (ke′mo-stat) A continuous culture apparatus that feeds medium into the culture vessel at the same rate as medium containing microorganisms is removed; the medium in a chemostat contains one essential nutrient in a limiting quantity. *120*

chemotaxis (ke″mo-tak′sis) The pattern of microbial behavior in which the microorganism moves toward chemical attractants and/or away from repellents. *67*

chemotherapeutic agents (ke″mo-ther-ah-pu′tik) Compounds used in the treatment of disease that destroy pathogens or inhibit their growth at concentrations low enough to avoid doing undesirable damage to the host. *806*

chemotrophs (ke′mo-trōfs) Organisms that obtain energy from the oxidation of chemical compounds. *97*

chickenpox (**varicella;** chik′en-poks) A highly contagious skin disease, usually affecting 2- to 7-year-old children; it is caused by the varicella-zoster virus, which is acquired by droplet inhalation into the respiratory system. *871*

chimera (ki-me′rah) A recombinant plasmid containing foreign DNA, which is used as a cloning vector in genetic engineering. *334*

chiral (ki′ rəl) Having handedness: consisting of one or another stereochemical form. *1010*

chitin (ki′tin) A tough, resistant, nitrogen-containing polysaccharide forming the walls of certain fungi, the exoskeleton of arthropods, and the epidermal cuticle of other surface structures of certain protists and animals. *554*

chlamydiae (klə-mid′e-e) Members of the genus *Chlamydia:* gram-negative, coccoid cells that reproduce only within the cytoplasmic vesicles of host cells using a life cycle that alternates between elementary bodies and reticulate bodies. *477*

chlamydial pneumonia (klə-mid′e-əl noo-mo′ ne-ə) A pneumonia caused by *Chlamydia pneumoniae.* Clinically, infections are mild and 50% of adults have antibodies to the chlamydiae. *914*

chlamydospore (klam′ĭ-do-spōr″) An asexually produced, thick-walled resting spore formed by some fungi. *557*

chloramphenicol (klo″ram-fen′ĭ-kol) A broad-spectrum antibiotic that is produced by *Streptomyces venezuelae* or synthetically; it binds to the large ribosomal subunit and inhibits the peptidyl transferase reaction. *817*

chlorophyll (klor′o-fil) The green photosynthetic pigment that consists of a large tetrapyrrole ring with a magnesium atom in the center. *196*

chloroplast (klo′ra-plast) A eucaryotic plastid that contains chlorophyll and is the site of photosynthesis. *85*

cholera (kol′er-ah) An acute infectious enteritis, endemic and epidemic in Asia, which periodically spreading to the Middle East, Africa, Southern Europe, and South America; caused by *Vibrio cholerae.* *930*

choleragen (kol′er-ah-gen) The cholera toxin; an extremely potent protein molecule elaborated by strains of *Vibrio cholerae* in the small intestine after ingestion of feces-contaminated water or food. It acts on epithelial cells to cause hypersecretion of chloride and bicarbonate and an outpouring of large quantities of fluid from the mucosal surface. *930*

chromatin (kro′mah-tin) The DNA-containing portion of the eucaryotic nucleus; the DNA is almost always complexed with histones. It can be very condensed (heterochromatin) or more loosely organized and genetically active (euchromatin). *86*

chromoblastomycosis (kro″mo-blas″to-mi-ko′sis) A chronic fungal infection of the skin, producing wartlike nodules that may ulcerate. It is caused by the black molds *Phialophora verrucosa* or *Fonsecaea pedrosoi.* *945*

chromogen (kro′me-jen) A colorless substrate that is acted on by an enzyme to produce a colored end product. *779*

chromophore group (kro′mo-fōr) A chemical group with double bonds that absorbs visible light and gives a dye its color. *27*

chromosomes (kro′mo-somz) The bodies that have most or all of the cell’s DNA and contain most of its genetic information (mitochondria and chloroplasts also contain DNA and genes). *86*

chronic carrier An individual who harbors a pathogen for a long time. *854*

chrysolaminarin The polysaccharide storage product of the chrysophytes and diatoms. *577*

chytrids A group of chytridiomycetes, which are simple terrestrial and aquatic fungi that produce motile zoospores with single, posterior, whiplash flagella. Also considered protists. *564, 641*

cilia (sil′e-ah) Threadlike appendages extending from the surface of some protozoa that beat rhythmically to propel them; cilia are membrane-bound cylinders with a complex internal array of microtubules, usually in a 9 + 2 pattern. *89*

citric acid cycle *See* tricarboxylic acid (TCA) cycle. *183, A–16*

classical complement pathway The antibody-dependent pathway of complement activation; it leads to the lysis of pathogens and stimulates phagocytosis and other host defenses. *758*

classification The arrangement of organisms into groups based on mutual similarity or evolutionary relatedness. *422*

clone (klōn) A group of genetically identical cells or organisms derived by asexual reproduction from a single parent. *228, 741*

clostridial myonecrosis (klo-strid′e-al mi″o-ne-kro′sis) Death of individual muscle cells caused by clostridia. Also called gas gangrene. *915*

cluster of differentiation molecules (CDs) Functional cell surface proteins or receptors that can be measured in situ from peripheral blood, biopsy samples, or other body fluids. They can be used to identify leukocyte subpopulations. Some examples include interleukin-2 receptor (IL-2R), CD4, CD8, CD25, and intercellular adhesion molecule-1 (ICAM-1). *733*

coaggregation The collection of a variety of bacteria on a surface such as a tooth surface because of cell-to-cell recognition of genetically distinct bacterial types. Many of these interactions appear to be mediated by a lectin on one bacterium that interacts with a complementary carbohydrate receptor on another bacterium. *934*

coagulase (ko-ag′u-las) An enzyme that induces blood clotting; it is characteristically produced by pathogenic staphylococci. *529*

coccidioidomycosis (kok-sid″e-oi″do-mi-ko′sis) A fungal disease caused by *Coccidioides immitis* that exists in dry, highly alkaline soils. Also known as valley fever, San Joaquin fever, or desert rheumatism. *946*

coccus (kok′us, pl. **cocci,** kok′si) A roughly spherical bacterial cell. *42*

code degeneracy The genetic code is organized in such a way that often there is more than one codon for each amino acid. *240*

codon (ko′don) A sequence of three nucleotides in mRNA that directs the incorporation of an amino acid during protein synthesis or signals the start or stop of translation. *240*

coenocytic (se″no-sit′ik) Refers to a multinucleate cell or hypha formed by repeated nuclear divisions not accompanied by cell divisions. *113, 556*

coenzyme (ko-en′zīm) A loosely bound cofactor that often dissociates from the enzyme active site after product has been formed. *161*

cofactor The nonprotein component of an enzyme; it is required for catalytic activity. *161*

cold sore A lesion caused by the herpes simplex virus; usually occurs on the border of the lips or nares. Also known as a fever blister or herpes labialis. *884*

colicin (kol′ĭ-sin) A plasmid-encoded protein that is produced by enteric bacteria and binds to specific receptors on the cell envelope of sensitive target bacteria, where it may cause lysis or attack specific intracellular sites such as ribosomes. *712*

coliform (ko′lĭ-form) A gram-negative, nonsporing, facultative rod that ferments lactose with gas formation within 48 hours at 35°C. *654*

colonization (kol″ə-nĭ-za′shən) The establishment of a site of microbial reproduction on an inanimate surface or organism without necessarily resulting in tissue invasion or damage. *792*

colony A cluster or assemblage of microorganisms growing on a solid surface such as the surface of an agar culture medium; the assemblage often is directly visible, but also may be seen only microscopically. *106*

colony forming units (CFU) The number of microorganisms that can form colonies when cultured using spread plates or pour plates, an indication of the number of viable microorganisms in a sample. *118*

Colorado tick fever A disease that occurs in the mountainous regions of the western United States. It is caused by an RNA virus of the genus *Coltivirus* that is spread from ground squirrels, rabbits, and deer to humans by the tick, *Dermacentor andersoni.* Complications are rare. *878*

colorless sulfur bacteria A diverse group of nonphotosynthetic proteobacteria that can oxidize reduced sulfur compounds such as hydrogen sulfide. Many are lithotrophs and derive energy from sulfur oxidation. Some are unicellular, whereas others are filamentous gliding bacteria. *496*

combinatorial biology Introduction of genes from one microorganism into another microorganism to synthesize a new product or a modified product, especially in relation to antibiotic synthesis. *995*

comedo (kom′ĕ-do; pl., **comedones**) A plug of dried sebum in an excretory duct of the skin. *701*

cometabolism The modification of a compound not used for growth by a microorganism, which occurs in the presence of another organic material that serves as a carbon and energy source. *1013*

commensal (kŏ-men′sal) Living on or within another organism without injuring or benefiting the other organism. *606*

commensalism (kŏ-men′sal-izm″) A type of symbiosis in which one individual gains from the association and the other is neither harmed nor benefited. *606*

common cold An acute, self-limiting, and highly contagious virus infection of the upper respiratory tract that produces inflammation, profuse discharge, and other symptoms. *884*

common-source epidemic An epidemic that is characterized by a sharp rise to a peak and then a rapid, but not as pronounced, decline in the number of individuals infected; it usually involves a single contaminated source from which individuals are infected. *851*

common vehicle transmission The transmission of a pathogen to a host by means of an inanimate medium or vehicle. *857*

communicable disease A disease associated with a pathogen that can be transmitted from one host to another. *854*

community An assemblage of different types of organisms or a mixture of different microbial populations. *596*

competent A bacterial cell that can take up free DNA fragments and incorporate them into its genome during transformation. *305*

competition An interaction between two organisms attempting to use the same resource (nutrients, space, etc.). *609*

competitive exclusion principle Two competing organisms overlap in resource use, which leads to the exclusion of one of the organisms. *609, 987*

complementary DNA (cDNA) A DNA copy of an RNA molecule (e.g., a DNA copy of an mRNA). *321*

complement system A group of plasma proteins that plays a major role in an animal's defensive immune response. *714, 758*

complex medium Culture medium that contains some ingredients of unknown chemical composition. *105*

complex viruses Viruses with capsids having a complex symmetry that is neither icosahedral nor helical. *369*

composting The microbial processing of fresh organic matter under moist, aerobic conditions, resulting in the accumulation of a stable humified product, which is suitable for soil improvement and stimulation of plant growth. *686*

compromised host A host with lowered resistance to infection and disease for any of several reasons. The host may be seriously debilitated (due to malnutrition, cancer, diabetes, leukemia, or another infectious disease), traumatized (from surgery or injury), immunosuppressed, or have an altered microbiota due to prolonged use of antibiotics. *704, 948*

concatemer A long DNA molecule consisting of several genomes linked together in a row. *387*

conditional mutations Mutations that are expressed only under certain environmental conditions. *245*

confocal scanning laser microscope (CSLM) A light microscope in which monochromatic laser-derived light scans across the specimen at a specific level and illuminates one spot at a time to form an image. Stray light from other parts of the specimen is blocked out to give an image with excellent contrast and resolution. *36*

congenital (neonatal) herpes An infection of a newborn caused by transmission of the herpesvirus during vaginal delivery. *886*

congenital rubella syndrome A wide array of congenital defects affecting the heart, eyes, and ears of a fetus during the first trimester of pregnancy, and caused by the rubella virus. *876*

congenital syphilis Syphilis that is acquired in utero from the mother. *923*

conidiospore (ko-nid′e-o-spōr) An asexual, thin-walled spore borne on hyphae and not contained within a sporangium; it may be produced singly or in chains. *537, 557*

conidium (ko-nid′e-um; pl., **conidia**) *See* conidiospore. *537*

conjugants (kon′joo-gants) Complementary mating types that participate in a form of protozoan sexual reproduction called conjugation. *586*

conjugation (kon″ju-ga′shun) 1. The form of gene transfer and recombination in bacteria that requires direct cell-to-cell contact. 2. A complex form of sexual reproduction commonly employed by protozoa. *302, 586*

conjugative plasmid A plasmid that carries the genes for sex pili and can transfer copies of itself to other bacteria during conjugation. *294*

conjunctivitis of the newborn *See* ophthalmia neonatorum. *916*

conoid (ko′noid) A hollow cone of spirally coiled filaments in the anterior tip of certain apicomplexan protozoa. *591*

consortium A physical association of two different organisms, usually beneficial to both organisms. *596*

constant region (C_L and C_H) The part of an antibody molecule that does not vary greatly in amino acid sequence among molecules of the same class, subclass, or type. *734*

constitutive mutant A strain that produces an inducible enzyme continually, regardless of need, because of a mutation in either the operator or regulator gene. *276*

constructed wetlands Intentional creation of marshland plant communities and their associated microorganisms for environmental restoration or to purify water by the removal of bacteria, organic matter, and chemicals as the water passes through the aquatic plant communities. *662*

consumer An organism that feeds directly on living or dead animals, by ingestion or by phagocytosis. *622*

contact transmission Transmission of the pathogen by contact of the source or reservoir of the pathogen with the host. *856*

continuous culture system A culture system with constant environmental conditions maintained through continual provision of nutrients and removal of wastes. *120*

contractile vacuole (vak′u-ōl) In protists and some animals, a clear fluid-filled cell vacuole that takes up water from within the cell and then contracts, releasing it to the outside through a pore in a cyclical manner. Contractile vacuoles function primarily in osmoregulation and excretion. *585*

convalescent carrier (kon″vah-les′ent) An individual who has recovered from an infectious disease but continues to harbor large numbers of the pathogen. *854*

copiotrophic Having a high nutrient level. *638*

corepressor (ko″re-pre′sor) A small molecule that inhibits the synthesis of a repressible enzyme. *276*

cortex (kor′teks) The layer of a bacterial endospore that is thought to be particularly important in conferring heat resistance on the endospore. *69*

coryza (kŏ-ri′zah) *See* common cold. *884*

cosmid (koz′mid) A plasmid vector with lambda phage cos sites that can be packaged in a phage capsid; it is useful for cloning large DNA fragments. *335*

cristae (kris′te) Infoldings of the inner mitochondrial membrane. *83*

cross-feeding *See* syntropism. *604*

crossing-over A process in which segments of two adjacent DNA strands are exchanged; breaks occur in both strands, and the exposed ends of each strand join to those of the opposite segment on the other strand. *292*

cryptins Peptides produced by Paneth cells in the intestines. Cryptins are toxic for some bacteria, although their mode of action is not known. *711*

cryptococcosis (krip″to-kok-o′sis) An infection caused by the basidiomycete, *Cryptococcus neoformans,* which may involve the skin, lungs, brain, or meninges. *561, 947*

cryptosporidiosis (krip″to-spo-rid″e-o′sis) Infection with protozoa of the genus *Cryptosporidium.* The most common symptoms are prolonged diarrhea, weight loss, fever, and abdominal pain. *952*

crystallizable fragment (Fc) The stem of the Y portion of an antibody molecule. Cells such as macrophages bind to the Fc region, and it also is involved in complement activation. *734*

cutaneous anthrax (ku-ta′ne-us an′thraks) A form of anthrax involving the skin. *913*

cutaneous diphtheria (ku-ta′ne-us dif-the′re-ah) A skin disease caused by *Corynebacterium diphtheriae* that infects wound or skin lesions, causing a slow-healing ulceration. *901*

cyanobacteria (si″ah-no-bak-te′re-ah) A large group of bacteria that carry out oxygenic photosynthesis using a system like that present in photosynthetic eucaryotes. *471*

cyclic photophosphorylation (fo″to-fos″for-ĭ-la′shun) The formation of ATP when light energy is used to move electrons cyclically through an electron transport chain during photosynthesis; only photosystem I participates. *198*

cyst (sist) A general term used for a specialized microbial cell enclosed in a wall. Cysts are formed by protozoa and a few bacteria. They may be dormant, resistant structures formed in response to adverse conditions or reproductive cysts that are a normal stage in the life cycle. *586*

cytochromes (si′to-krōms) Heme proteins that carry electrons, usually as members of electron transport chains. *159*

cytokine (si′to-kīn) A general term for nonantibody proteins, released by a cell in response to inducing stimuli, which are mediators that influence other cells. Are produced by lymphocytes, monocytes, macrophages, and other cells. *720*

cytomegalovirus inclusion disease (si″to-meg″ah-lo-vi′rus) An infection caused by the cytomegalovirus and marked by nuclear inclusion bodies in enlarged infected cells. *885*

cytopathic effect (si″to-path′ik) The observable change that occurs in cells as a result of viral replication. Examples include ballooning, binding together, clustering, or even death of the cultured cells. *364, 832*

cytoplasmic matrix (si″to-plaz′mik) The protoplasm of a cell that lies within the plasma membrane and outside any other organelles. In bacteria it is the substance between the cell membrane and the nucleoid. *49, 76*

cytoproct (si′to-prokt) Site on a protozoan where undigestible matter is expelled. *592*

cytosine (si′to-sēn) A pyrimidine 2-oxy-4-aminopyrimidine found in nucleosides, nucleotides, and nucleic acids. *217*

cytoskeleton (si″to-skel′ĕ-ton) A network of microfilaments, microtubules, intermediate filaments, and other components in the cytoplasm of eucaryotic cells that helps give them shape. *79*

cytostome (si′to-stōm) A permanent site in the protozoan ciliate body through which food is ingested. *586*

cytotoxic T (T_C) cell (si″to-tok′sik) A cell that is capable of recognizing virus-infected cells through the major histocompatability molecules and developing into an activated cell that destroys the infected cells. *748*

cytotoxic T lymphocyte (CTL) The activated T cell that can attack and destroy virus-infected cells, tumor cells, and foreign cells. *748*

cytotoxin (si′to-tok′sin) A toxin or antibody that has a specific toxic action upon cells; cytotoxins are named according to the cell for which they are specific (e.g., nephrotoxin). *797*

D

Dane particle A 42 nm spherical particle that is one of three that are seen in hepatitis B virus infections. The Dane particle is the complete virion. *889*

dark-field microscopy Microscopy in which the specimen is brightly illuminated while the background is dark. *22*

dark reactivation The excision and replacement of thymine dimers in DNA that occurs in the absence of light. *130*

deamination (de-am″i-na′shun) The removal of amino groups from amino acids. *192*

death phase The decrease in viable microorganisms that occurs after the completion of growth in a batch culture. *115*

decimal reduction time (*D* or *D* value) The time required to kill 90% of the microorganisms or spores in a sample at a specified temperature. *140*

decomposer An organism that breaks down complex materials into simpler ones, including the release of simple inorganic products. Often a decomposer such as an insect or earthworm physically reduces the size of substrate particles. *622*

defensin (de-fens′sin) Specific peptides produced by neutrophils that permeabilize the outer and inner membranes of certain microorganisms, thus killing them. *720*

defined medium Culture medium made with components of known composition. *105*

Delta agent A defective RNA virus that is transmitted as an infectious agent, but cannot cause disease unless the individual is also infected with the hepatitis B virus. *See* hepatitis D. *891*

delta-proteobacteria One of the five subgroups of proteobacteria, each with distinctive 16S rRNA sequences. Chemoorganotrophic bacteria that usually are either predators on other bacteria or anaerobes that generate sulfide from sulfate and sulfite. *507*

denaturation (de-na″chur-a′shun) A change in the shape of an enzyme that destroys its activity; the term is also applied to changes in nucleic-acid shape. *163*

dendritic cell (den-drit′ ik) An antigen-presenting cell that has long membrane extensions resembling the dendrites of neurons. These cells are found in the lymph nodes, spleen, and thymus (interdigitating dendritic cells); skin (Langerhans cells); and other tissues (interstitial dendritic cells). Express MHC class II and B7 costimulatory molecules and thus are efficient presenters of antigens to T-helper cells. *708*

dendrogram A treelike diagram that is used to graphically summarize mutual similarities and relationships between organisms. *427*

denitrification (de-ni″trĭ-fĭ-ka′shən) The reduction of nitrate to gas products, primarily nitrogen gas, during anaerobic respiration. *190*, *616*

dental plaque (plak) A thin film on the surface of teeth consisting of bacteria embedded in a matrix of bacterial polysaccharides, salivary glycoproteins, and other substances. *934*

deoxyribonucleic acid (DNA; de-ok″se-ri″bo-nu-kle′ik) The nucleic acid that constitutes the genetic material of all cellular organisms. It is a polynucleotide composed of deoxyribonucleotides connected by phosphodiester bonds. *54*, *230*

dermatophyte (der′mah-to-fīt″) A fungus parasitic on the skin. *943*

dermatomycosis (der′ma-to-mi-ko′sis) A fungal infection of the skin; the term is a general term that comprises the various forms of tinea, and it is sometimes used to specifically refer to athlete's foot (tinea pedis). *943*

desensitization (de-sen″si-ti-za′shun) To make a sensitized or hypersensitive individual insensitive or nonreactive to a sensitizing agent. *769*

desert crust A crust formed by microbial binding of sand grains in the surface zone of desert soil; crust formation primarily involves cyanobacteria. *673*

detergent (de-ter′jent) An organic molecule, other than a soap, that serves as a wetting agent and emulsifier; it is normally used as cleanser, but some may be used as antimicrobial agents. *148*

deuteromycetes (doo″tər-o-mi-se′tēz) In some classification systems, the deuteromycetes or Fungi Imperfecti are a class of fungi. These organisms either lack a sexual stage or it has not yet been discovered. *564*

diatoms (di′ah-toms) Algal protists with siliceous cell walls called frustules. They constitute a substantial subfraction of the phytoplankton. *577*

diauxic growth (di-awk′sik) A biphasic growth pattern or response in which a microorganism, when exposed to two nutrients, initially uses one of them for growth and then alters its metabolism to make use of the second. *281*

differential interference contrast (DIC) microscope A light microscope that employs two beams of plane polarized light. The beams are combined after passing through the specimen and their intereference is used to create the image. *25*

differential media (dif″er-en′shal) Culture media that distinguish between groups of microorganisms based on differences in their growth and metabolic products. *106*

differential staining procedures Staining procedures that divide bacteria into separate groups based on staining properties. *28*

diffusely adhering *E. coli* (DAEC) DAEC strains of *E. coli* adhere over the entire surface of epithelial cells and usually cause diarrheal disease in immunologically naive and malnourished children. *932*

dikaryotic stage (di-kar-e-ot′ik) In fungi, having pairs of nuclei within cells or compartments. Each cell contains two separate haploid nuclei, one from each parent. *557*

dinoflagellate (di″no-flaj′e-lāt) An algal protist characterized by two flagella used in swimming in a spinning pattern. Many are bioluminescent and an important part of marine phytoplankton, some also are important marine pathogens. *579*

diphtheria (dif-the′re-ah) An acute, highly contagious childhood disease that generally affects the membranes of the throat and less frequently the nose. It is caused by *Corynebacterium diphtheriae*. *900*

dipicolinic acid A substance present at high concentrations in the bacterial endospore. It is thought to contribute to the endospore's heat resistance. *69*

diplococcus (dip″lo-kok′us) A pair of cocci. *43*

directed- or adaptive mutation A mutation that seems to be chosen so the organism can better adapt to its surroundings. *246*

disease (di-zez) A deviation or interruption of the normal structure or function of any part of the body that is manifested by a characteristic set of symptoms and signs. *848*

disease syndrome (sin′drŏm) A set of signs and symptoms that are characteristic of the disease. *850*

disinfectant (dis″in-fek′tant) An agent, usually chemical, that disinfects; normally, it is employed only with inanimate objects. *138*

disinfection (dis″in-fek′shun) The killing, inhibition, or removal of microorganisms that may cause disease. It usually refers to the treatment of inanimate objects with chemicals. *138*

disinfection by-products (DBPs) Chlorinated organic compounds formed during chlorine use for water disinfection. Many are carcinogens. *653*

dissimilatory nitrate reduction The process in which some bacteria use nitrate as the electron acceptor at the end of their electron transport chain to produce ATP. The nitrate is reduced to nitrite or nitrogen gas. *190*

dissimilatory reduction The use of a substance as an electron acceptor in energy generation. The acceptor (e.g., sulfate or nitrate) is reduced but not incorporated into organic matter during biosynthetic processes. *614*

diurnal oxygen shifts (di-er′nal) The changes in oxygen levels that occur in waters when algae produce and use oxygen on a cyclic basis during day and night. *650*

DNA ligase An enzyme that joins two DNA fragments together through the formation of a new phosphodiester bond. *239*

DNA microarrays (DNA chips) Solid supports that have DNA attached in highly organized arrays and are normally used to evaluate gene expression. *354, 1018*

DNA polymerase (pol-im′er-ās) An enzyme that synthesizes new DNA using a parental DNA strand as a template. *236*

DNA vaccine A vaccine that contains DNA which encodes antigenic proteins. It is injected directly into the muscle; the DNA is taken up by the muscle cells and encoded protein antigens are synthesized. This produces both humoral and cell-mediated responses. *767*

domains (do-mān′) 1. Compact, self-folding, structurally independent regions of proteins (usually around 100–300 amino acids in length); large proteins may have two or more domains connected by less structured stretches of polypeptide. In the antibody molecule, they are the loops, along with about 25 amino acids on each side, that form compact, globular sections. 2. The primary taxonomic groups above the kingdom level; all living organisms may be placed in one of three domains. *274*, *424, 734*

double diffusion agar assay (Ouchterlony technique) An immunodiffusion reaction in which both antibody and antigen diffuse through

agar to form stable immune complexes, which can be observed visually. *780*

doubling time *See* generation time. *115*

DPT (diphtheria-pertussis-tetanus) vaccine A vaccine containing three antigens that is used to immunize people against diphtheria, pertussis or whooping cough, and tetanus. *901*

droplet nuclei Small particles (1 to 4 μm in diameter) that represent what is left from the evaporation of larger particles (10 μm or more in diameter) called droplets. *856*

***D* value** *See* decimal reduction time. *140*

E

early mRNA Messenger RNA produced early in a virus infection that codes for proteins needed to take over the host cell and manufacture viral nucleic acids. *385*

Ebola virus hemorrhagic fever (a′bo-lə) An acute infection caused by a virus that produces varying degrees of hemorrhage, shock, and sometimes death. *877*

eclipse period (e-klips′) The initial part of the latent period in which infected host bacteria do not contain any complete virions. *383*

ecosystem (ek″o-sis′tem) A self-regulating biological community and its associated physical and chemical environment. *596*

ectomycorrhizal Referring to a mutualistic association between fungi and plant roots in which the fungus surrounds the root tip with a sheath. *681*

ectoparasite (ek″to-par′ah-sīt) A parasite that lives on the surface of its host. *788*

ectoplasm (ek′to-plazm) The outer stiffer portion or region of the cytoplasm in a protozoan, which may be differentiated in texture from the inner portion or endoplasm. *585*

ectosymbiosis A type of symbiosis in which one organism remains outside of the other organism. *701*

effacing lesion (le′zhən) The type of lesion caused by enteropathogenic strains of *E. coli* (EPEC) when the bacteria attach to and destroy the brush border of intestinal epithelial cells. The term AE (attaching-effacing) *E. coli* is now used to designate true EPEC strains that are an important cause of diarrhea in children from developing countries and in traveler's diarrhea. *932*

ehrlichiosis (ar-lik″e-o′sis) A tick-borne (*Dermacentor andersoni, Amblyomma americanum*) rickettsial disease caused by *Ehrlichia chaffeensis.* Once inside leukocytes, a nonspecific illness develops that resembles Rocky Mountain spotted fever. *909*

electron transport chain A series of electron carriers that operate together to transfer electrons from donors such as NADH and $FADH_2$ to acceptors such as oxygen. *184*

electrophoresis (e-lek″tro-fo-re′sis) A technique that separates substances through differences in their migration rate in an electrical field due to variations in the number and kinds of charged groups they have. *327*

electroporation (e-lek″tro-pə-ra′shən) The application of an electric field to create temporary pores in the plasma membrane in order to insert DNA into the cell and transform it. *335*

elementary body A small, dormant body that serves as the agent of transmission between host cells in the chlamydial life cycle. *477*

elongation cycle The cycle in protein synthesis that results in the addition of an amino acid to the growing end of a peptide chain. *270*

Embden-Meyerhof pathway (em′den mi′er-hof) A pathway that degrades glucose to pyruvate; the six-carbon stage converts glucose to fructose 1,6-bisphosphate, and the three-carbon stage produces ATP while changing glyceraldehyde 3-phosphate to pyruvate. *176, A–13*

encystation (en-sis-′ta′shen) The formation of a cyst. *586*

endemic disease (en-dem′ik) A disease that is commonly or constantly present in a population, usually at a relatively steady low frequency. *849*

endemic (murine) typhus (mu′rin ti′fus) A form of typhus fever caused by the rickettsia *Rickettsia typhi* that occurs sporadically in individuals who come into contact with rats and their fleas. *909*

endergonic reaction (end″er-gon′ik) A reaction that does not spontaneously go to completion as written; the standard free energy change is positive, and the equilibrium constant is less than one. *156*

endocytosis (en″do-si-to′sis) The process in which a cell takes up solutes or particles by enclosing them in vesicles pinched off from its plasma membrane. *80*

endogenote (en″do-je′nōt) The recipient bacterial cell's own genetic material into which the donor DNA can integrate. *294*

endogenous infection (en-doj′ĕ-nus in-fek′shun) An infection by a member of an individual's own normal body microbiota. *905*

endogenous pyrogen (en-doj′e-nus pi′ro-jen) A substance such as the lymphokine interleukin-1, which is produced by host cells and induces a fever response in the host. It also is called simply a pyrogen. *801*

endomycorrhizal Referring to a mutualistic association of fungi and plant roots in which the fungus penetrates into the root cells and arbuscules and vesicles are formed. *681*

endoparasite (en″do-par′ah-sīt) A parasite that lives inside the body of its host. *789*

endophyte (en′do-fīt) A microorganism living within a plant, but not necessarily parasitic on it. *679*

endoplasm (en′do-plazm) The central portion of the cytoplasm in a protozoan. *585*

endoplasmic reticulum (en″do-plas′mik rĕ-tik′u-lum) A system of membranous tubules and flattened sacs (cisternae) in the cytoplasmic matrix of eucaryotic cells. Rough or granular endoplasmic reticulum (RER or GER) bears ribosomes on its surface; smooth or agranular endoplasmic reticulum (SER or AER) lacks them. *79*

endosome (en′do-sōm) A membranous vesicle formed by endocytosis. *80*

endospore (en′do-spōr) An extremely heat- and chemical-resistant, dormant, thick-walled spore that develops within bacteria. *68*

endosymbiont (en″do-sim′be-ont) An organism that lives within the body of another organism in a symbiotic association. *596*

endosymbiosis (en″do-sim″bi-o′sis) A type of symbiosis in which one organism is found within another organism. *701*

endosymbiotic theory or **hypothesis** The theory that eucaryotic organelles such as mitochondria and chloroplasts arose when bacteria established an endosymbiotic relationship with the eucaryotic ancestor and then evolved into eucaryotic organelles. *85*, *424*

endotoxin (en″do-tox′sin) The heat-stable lipopolysaccharide in the outer membrane of the cell wall of gram-negative bacteria that is released when the bacterium lyses, or sometimes during growth, and is toxic to the host. *799*

end product inhibition *See* feedback inhibition. *169*

energy The capacity to do work or cause particular changes. *154*

enology The science of wine making. *982*

enteric bacteria (**enterobacteria;** en-ter′ik) Members of the family *Enterobacteriaceae* (gram-negative, peritrichous or nonmotile, facultatively anaerobic, straight rods with simple nutritional requirements); also used for bacteria that live in the intestinal tract. *505*

enterohemorrhagic *E. coli* (EHEC) (en′tər-o-hem″ə-raj′ik) EHEC strains of *E. coli* (0157:H7) produce several cytotoxins that provoke fluid secretion in traveler's diarrhea; however, their mode of action is unknown. *932*

enteroinvasive *E. coli* (EIEC) (en′tər-o-in-va′siv) EIEC strains of *E. coli* cause traveler's diarrhea by penetrating and binding to the intestinal epithelial cells. EIEC may also produce a cytotoxin and enterotoxin. *932*

enteropathogenic *E. coli* (EPEC) (en′tər-o-path-o-jen′ik) EPEC strains of *E. coli* attach to the brush border of intestinal epithelial cells and cause a specific type of cell damage called effacing lesions that lead to traveler's diarrhea. *932*

enterotoxigenic *E. coli* (ETEC) (en′tər-o-tok″sĭ-jen′ik) ETEC strains of *E. coli* produce two plasmid-encoded enterotoxins (which are responsible for traveler's diarrhea) and are distinguished by their heat stability: heat-stable enterotoxin (ST) and heat-labile enterotoxin (LT). *932*

enterotoxin (en″ter-o-tok′sin) A toxin specifically affecting the cells of the intestinal mucosa, causing vomiting and diarrhea. *797*, *927*

Entner-Doudoroff pathway A pathway that converts glucose to pyruvate and glyceraldehyde 3-phosphate by producing 6-phosphogluconate and then dehydrating it. *179, A–15*

entropy (en′tro-pe) A measure of the randomness or disorder of a system; a measure of that part of the total energy in a system that is unavailable for useful work. *156*

envelope (en′vĕ-lōp) 1. All the structures outside the plasma membrane in bacterial cells. 2. In virology it is an outer membranous layer that surrounds the nucleocapsid in some viruses. *55*, *369*

enzootic (en″zo-ot′ik) The moderate prevalence of a disease in a given animal population. *849*

enzyme (en′zīm) A protein catalyst with specificity for both the reaction catalyzed and its substrates. *161*

enzyme-linked immunosorbent assay (ELISA) A technique used for detecting and quantifying specific antibodies and antigens. *778*

eosinophil (e″ o-sin,′o-fil) A polymorphonuclear leukocyte that has a two-lobed nucleus and cytoplasmic granules that stain yellow-red. A mobile phagocyte that is highly antiparasitic. *707*

epidemic (ep″ĭ-dem′ik) A disease that suddenly increases in occurrence above the normal level in a given population. *849*

epidemic (louse-borne) typhus (ep″i-dem′ik ti′fus) A disease caused by *Rickettsia prowazekii* that is transmitted from person to person by the body louse. *909*

epidemiologist (ep″ĭ-de″me-ol′o-jist) A person who specializes in epidemiology. *849*

epidemiology (epi″-de″me-ol′o-je) The study of the factors determining and influencing the frequency and distribution of disease, injury, and other health-related events and their causes in defined human populations. *848*

episome (ep′ĭ-sōm) A plasmid that can exist either independently of the host cell's chromosome or be integrated into it. *294*

epitheca (ep″ĭ-the′kah) The larger of two halves of a diatom frustule (shell). *577*

epitope (ep′i-tōp) An area of the antigen molecule that stimulates the production of, and combines with, specific antibodies; also known as the antigenic determinant site. *731*

epizootic (ep″ĭ-zo-ot′ik) A sudden outbreak of a disease in an animal population. *849*

epizootiology (ep″i-zo-ot″e-ol′o-je) The field of science that deals with factors determining the frequency and distribution of a disease within an animal population. *849*

epsilon-proteobacteria One of the five subgroups of proteobacteria, each with distinctive 16S rRNA sequences. Slender gram-negative rods, some of which are medically important (*Campylobacter* and *Helicobacter*). *514*

equilibrium (e″kwĭ-lib′re-um) The state of a system in which no net change is occurring and free energy is at a minimum; in a chemical reaction at equilibrium, the rates in the forward and reverse directions exactly balance each other out. *156*

ergot (er′got) The dried sclerotium of *Claviceps purpurea*. Also, an ascomycete that parasitizes rye and other higher plants causing the disease called ergotism. *561*

ergotism (er′got-izm) The disease or toxic condition caused by eating grain infected with ergot; it is often accompanied by gangrene, psychotic delusions, nervous spasms, abortion, and convulsions in humans and in animals. *561, 967*

erysipelas (er″ĭ-sip′ĕ-las) An acute inflammation of the dermal layer of the skin, occurring primarily in infants and persons over 30 years of age with a history of streptococcal sore throat. *903*

erythema infectiosum (er″ə-the′-mə) A disease in children caused by the parvovirus B19. This disease is common in children between 4 and 11 years of age and is sometimes called fifth disease, since it was the fifth of six erythematous rash diseases in children in an older classification. *887*

erythromycin (ĕ-rith″ro-mi′sin) An intermediate spectrum macrolide antibiotic produced by *Streptomyces erythreus*. *817*

eschar (es′kar) A slough produced on the skin by a thermal burn, gangrene, or the anthrax bacillus. *914*

Eucarya The domain that contains organisms composed of eucaryotic cells with primarily glycerol fatty acyl diesters in their membranes and eucaryotic rRNA. *424*

eucaryotic cells (u″kar-e-ot′ik) Cells that have a membrane-delimited nucleus and differ in many other ways from procaryotic cells; protists, algae, fungi, plants, and animals are all eucaryotic. *11, 91*

euglenoids (u-gle′noids) A group of algae (the division *Euglenophyta*) or protozoa (order *Euglenida*) that normally have chloroplasts containing chlorophyll *a* and *b*. They usually have a stigma and one or two flagella emerging from an anterior gullet. *576*

Eumycota (u″mi-ko′tə) A division of fungi in some classification systems. These are the true fungi consisting of the Zygomycetes, Ascomycetes, Basidiomycetes, and Chytridiomycetes. *553*

eumycotic mycetoma (mi″se-to′mah) *See* maduromycosis. *945*

eutrophic (u-trof′ik) A nutrient-enriched environment. *648*

eutrophication (u″tro-fĭ-ka′shun) The enrichment of an aquatic environment with nutrients. *648*

evolutionary distance A quantitative indication of the number of positions that differ between two aligned macromolecules, and presumably a measure of evolutionary similarity between molecules and organisms. *433*

excystation (ek″sis-ta′shun) The escape of one or more cells or organisms from a cyst. *586*

exergonic reaction (ek″ser-gon′ik) A reaction that spontaneously goes to completion as written; the standard free energy change is negative, and the equilibrium constant is greater than one. *156*

exfoliative toxin (eks-fo′le-a″tiv) or **exfoliatin** (eks-fō″le-a′tin) An exotoxin produced by *Staphylococcus aureus* that causes the separation of epidermal layers and the loss of skin surface layers. It produces the symptoms of the scaled skin syndrome. *922*

exit site (E site) The location on a ribosome to which an empty tRNA moves from the P site before it finally leaves the ribosome during protein synthesis. *270*

exoenzymes (ek″so-en′zīms) Enzymes that are secreted by cells. *55*

exogenote (eks″o-je′nōt) The piece of donor DNA that enters a bacterial cell during gene exchange and recombination. *294*

exon (eks′on) The region in a split or interrupted gene that codes for RNA which ends up in the final product (e.g., mRNA). *263*

exotoxin (ek″so-tok′sin) A heat-labile, toxic protein produced by a bacterium as a result of its normal metabolism or because of the acquisition of a plasmid or prophage that redirects its metabolism. It is usually released into the bacterium's surroundings. *794*

exponential phase (eks″po-nen′shul) The phase of the growth curve during which the microbial population is growing at a constant and maximum rate, dividing and doubling at regular intervals. *114*

expressed sequence tag (EST) A partial gene sequence unique to a gene that can be used to identify and position the gene during genomic analysis. *354*

expression vector A special cloning vector used to express recombinant genes in host cells; the recombinant gene is transcribed and its protein synthesized. *336*

exteins Polypeptide sequences of precursor self-splicing proteins that are joined together during formation of the final, functional protein. They are separated from one another by intein sequences, which they flank. *275*

extracutaneous sporotrichosis (spo″ro-tri-ko′sis) An infection by the fungus *Sporothrix schenckii* that spreads throughout the body. *945*

extreme barophilic bacteria Bacteria that require a high-pressure environment to function. *624*

extreme environment An environment in which physical factors such as temperature, pH, salinity, and pressure are outside of the normal range for growth of most microorganisms; these conditions allow unique organisms to survive and function. *624*

extremophiles Microorganisms that grow under harsh or extreme environmental conditions such as very high temperatures or low pHs. *121, 624*

extrinsic factor An environmental factor such as temperature that influences microbial growth in food. *964*

F

facilitated diffusion Diffusion across the plasma membrane that is aided by a carrier. *100*

facultative anaerobes (fak′ul-ta″tiv an-a′er-ōbs) Microorganisms that do not require oxygen for growth, but do grow better in its presence. *127*

facultative psychrophile (fak′ul-ta″tiv si′kro-fīl) *See* psychrotroph. *126*

***fas* gene** The gene that is active in target cells which are susceptible to killing by cells expressing the Fas ligand, a member of the TNF family of cytokines and cell surface molecules. *750*

fatty acid synthetase (sin′thĕ-tās) The multienzyme complex that makes fatty acids; the product usually is palmitic acid. *218*

fecal coliform (fe′kal ko′lĭ-form) Coliforms whose normal habitat is the intestinal tract and that can grow at 44.5°C. *654*

fecal enterococci (fe′kal en″ter-o-kok′si) Enterococci found in the intestine of humans and other warm-blooded animals. They are used as indicators of the fecal pollution of water. *656*

feedback inhibition A negative feedback mechanism in which a pathway end product inhibits the activity of an enzyme in the sequence leading to its formation; when the end product accumulates in excess, it inhibits its own synthesis. *169*

fermentation (fer″men-ta′shun) An energy-yielding process in which an energy substrate is oxidized without an exogenous electron acceptor. Usually organic molecules serve as both electron donors and acceptors. *173, 1000*

fever A complex physiological response to disease mediated by pyrogenic cytokines and characterized by a rise in core body temperature and activation of the immune system. *722*

fever blister *See* cold sore. *884*

F factor The fertility factor, a plasmid that carries the genes for bacterial conjugation and makes its *E. coli* host cell the gene donor during conjugation. *295*

fimbria (fim′bre-ah; pl., **fimbriae**) A fine, hairlike protein appendage on some gram-negative bacteria that helps attach them to surfaces. *62*

final host The host on/in which a parasitic organism either attains sexual maturity or reproduces. *789*

first law of thermodynamics Energy can be neither created nor destroyed (even though it can be changed in form or redistributed). *155*

fixation (fik-sa′shun) The process in which the internal and external structures of cells and organisms are preserved and fixed in position. *27*

flagellin (flaj′ĕ-lin) The protein used to construct the filament of a bacterial flagellum. *64*

flagellum (flah-jel′um; pl., **flagella**) A thin, threadlike appendage on many procaryotic and eucaryotic cells that is responsible for their motility. *63, 89*

flat or plane warts Small, smooth, slightly raised warts. *894*

flavin adenine dinucleotide (FAD; fla′vin ad′ĕ-nēn) An electron carrying cofactor often involved in energy production (for example, in the tricarboxylic acid cycle and the β-oxidation pathway). *159*

fluid mosaic model The currently accepted model of cell membranes in which the membrane is a lipid bilayer with integral proteins buried in the lipid, and peripheral proteins more loosely attached to the membrane surface. *47*

fluorescence microscope A microscope that exposes a specimen to light of a specific wavelength and then forms an image from the fluorescent light produced. Usually the specimen is stained with a fluorescent dye or fluorochrome. *25*

fluorescent light (floo″o-res′ent) The light emitted by a substance when it is irradiated with light of a shorter wavelength. *25*

fomite (fo′mīt; pl., **fomites**) An object that is not in itself harmful but is able to harbor and transmit pathogenic organisms. Also called fomes. *792, 857*

food-borne infection Gastrointestinal illness caused by ingestion of microorganisms, followed by their growth within the host. Symptoms arise from tissue invasion and/or toxin production. *926, 973*

food chain The flow of energy and matter in living organisms through a producer-consumer sequence (*See also* food web). *584*

food intoxication Food poisoning caused by microbial toxins produced in a food prior to consumption. The presence of living bacteria is not required. *927, 975*

food poisoning A general term usually referring to a gastrointestinal disease caused by the ingestion of food contaminated by pathogens or their toxins. *926*

food web A network of many interlinked food chains, encompassing primary producers, consumers, decomposers, and detritivores. *584*

F_1 particle Particle on the inner mitochondrial membrane, which is the site of ATP synthesis by oxidative phosphorylation. *83, 187*

F′ plasmid An F plasmid that carries some bacterial genes and transmits them to recipient cells when the F′ cell carries out conjugation; the transfer of bacterial genes in this way is often called sexduction. *305*

fragmentation (frag″men-ta′shun) A type of asexual reproduction in which a thallus breaks into two or more parts, each of which forms a new thallus. *573*

frameshift mutations Mutations arising from the loss or gain of a base or DNA segment, leading to a change in the codon reading frame and thus a change in the amino acids incorporated into protein. *251*

free energy change The total energy change in a system that is available to do useful work as the system goes from its initial state to its final state at constant temperature and pressure. *156*

French polio *See* Guillain-Barré syndrome. *874*

fruiting body A specialized structure that holds sexually or asexually produced spores; found in fungi and in some bacteria. *512, 565*

frustule (frus′tūl) A silicified cell wall in the diatoms. *577*

fungicide (fun′jĭ-sīd) An agent that kills fungi. *138*

fungistatic (fun″jĭ-stat′ik) Inhibiting the growth and reproduction of fungi. *138*

fungus (fung′gus; pl., **fungi**) Achlorophyllous, heterotrophic, spore-bearing eucaryotes with absorptive nutrition; usually, they have a walled thallus. *553*

***F* value** The time in minutes at a specific temperature (usually 250°F) needed to kill a population of cells or spores. *140*

G

gametangium (gam-ĕ-tan′je-um; pl., **gametangia**) A structure that contains gametes or in which gametes are formed. *557*

gamma-proteobacteria One of the five subgroups of proteobacteria, each with distinctive 16S rRNA sequences. This is the largest subgroup and is very diverse physiologically; many important genera are facultatively anaerobic chemoorganotrophs. *498*

gas gangrene (gang′grēn) A type of gangrene that arises from dirty, lacerated wounds infected by anaerobic bacteria, especially species of *Clostridium.* As the bacteria grow, they release toxins and ferment carbohydrates to produce carbon dioxide and hydrogen gas. *915*

gastritis (gas-tri′tis) Inflammation of the stomach. *918*

gastroenteritis (gas″tro-en-ter-i′tis) An acute inflammation of the lining of the stomach and intestines, characterized by anorexia, nausea, diarrhea, abdominal pain, and weakness. It has various causes including food poisoning due to such organisms as *E. coli, S. aureus, Campylobacter* (campylobacteriosis), and *Salmonella* species; consumption of irritating food or drink; or psychological factors such as anger, stress, and fear. Also called enterogastritis. *929*

gas vacuole A gas-filled vacuole found in cyanobacteria and some other aquatic bacteria that provides flotation. It is composed of gas vesicles, which are made of protein. *51*

gene (jēn) A DNA segment or sequence that codes for a polypeptide, rRNA, or tRNA. *241*

gene gun A device that uses high-pressure gas or another propellant to shoot a spray of DNA-coated microprojectiles into cells and transform them. Sometimes it is called a biolistic device. *335*

generalized transduction The transfer of any part of a bacterial genome when the DNA fragment is packaged within a phage capsid by mistake. *308*

general recombination Recombination involving a reciprocal exchange of a pair of homologous DNA sequences; it can occur any place on the chromosome. *292*

generation time The time required for a microbial population to double in number. *115*

genetic engineering The deliberate modification of an organism's genetic information by directly changing its nucleic acid genome. *320*

genital herpes (her′pēz) A sexually transmitted disease caused by the herpes simplex virus type 2. *885*

genital ulcer disease *See* chancroid. *914*

genome (je′nōm) The full set of genes present in a cell or virus; all the genetic material in an organism; a haploid set of genes in a cell. *228*

genomics The study of the molecular organization of genomes, their information content, and the gene products they encode. *345*

genus (je′nəs) A well-defined group of one or more species that is clearly separate from other genera. *426*

geographic information system (GIS) A data management system that organizes and displays digital map data from remote sensing and aids in the analysis of relationships between mapped features. *850*

German measles *See* rubella. *875*

germicide (jer′mĭ-sīd) An agent that kills pathogens and many nonpathogens but not necessarily bacterial endospores. *138*

germination (jer″mĭ-na′shun) The stage following bacterial endospore activation in which the endospore breaks its dormant state. Germination is followed by outgrowth. *71*

Ghon complex (gon) The initial focus of parenchymal infection in primary pulmonary tuberculosis. *908*

giardiasis (je″ar-di′ah-sis) A common intestinal disease caused by the parasitic protozoan *Giardia lamblia.* *953*

gingivitis (jin-jĭ-vi′tis) Inflammation of the gingival tissue. *936*

gingivostomatitis (jin″jĭ-vo-sto″mə-ti′tis) Inflammation of the gingiva and other oral mucous membranes. *884*

gliding motility A type of motility in which a microbial cell glides along when in contact with a solid surface. *66, 482*

global regulatory systems Regulatory systems that simultaneously affect many genes and pathways. *281*

glomerulonephritis (glo-mer″u-lo-nĕ-fri′tis) An inflammatory disease of the renal glomeruli. *905*

glucans Polysaccharides composed of glucose units held together by glycosidic linkages. Some types of glucans have α(1→3) and α(1→6) linkages and bind bacterial cells together on teeth forming a plaque ecosystem. *936*

gluconeogenesis (gloo″ko-ne″o-jen′e-sis) The synthesis of glucose from noncarbohydrate precursors such as lactate and amino acids. *209*

glycocalyx (gli″ko-kal′iks) A network of polysaccharides extending from the surface of bacteria and other cells. *61*

glycogen (gli′ko-jen) A highly branched polysaccharide containing glucose, which is used to store carbon and energy. *49, A–6*

glycolysis (gli-kol′ĭ-sis) The anaerobic conversion of glucose to lactic acid by use of the Embden-Meyerhof pathway. *176*

glycolytic pathway (gli″ko-lit′ik) *See* Embden-Meyerhof pathway. *176, A–13*

glyoxylate cycle (gli-ok′sĭ-lat) A modified tricarboxylic acid cycle in which the decarboxylation reactions are bypassed by the enzymes isocitrate lyase and malate synthase; it is used to convert acetyl-CoA to succinate and other metabolites. *216*

gnotobiotic (no″to-bi-ot′ik) Animals that are germfree (microorganism free) or live in association with one or more known microorganisms. *698*

Golgi apparatus (gol′je) A membranous eucaryotic organelle composed of stacks of flattened sacs (cisternae), which is involved in packaging and modifying materials for secretion and many other processes. *80*

gonococci (gon′o-kok′si) Bacteria of the species *Neisseria gonorrhoeae*—the organism causing gonorrhea. *915*

gonorrhea (gon″o-re′ah) An acute infectious sexually transmitted disease of the mucous membranes of the genitourinary tract, eye, rectum, and throat. It is caused by *Neisseria gonorrhoeae. 915*

graft-versus-host disease A disease that results when mature post-thymic T cells in donor grafts (e.g., bone marrow) recognize the host as foreign and attack it. *773*

Gram stain A differential staining procedure that divides bacteria into gram-positive and gram-negative groups based on their ability to retain crystal violet when decolorized with an organic solvent such as ethanol. *28*

grana (gra′nah) A stack of thylakoids in the chloroplast stroma. *85*

granuloma (gran″u-lo′mə) Term applied to nodular inflammatory lesions containing phagocytic cells. *714*

greenhouse gases Gases released from the earth's surface through chemical and biological processes that interact with the chemicals in the stratosphere to decrease the release of radiation from the earth. It is believed that this leads to global warming. *689*

griseofulvin (gris″e-o-ful′vin) An antibiotic from *Penicillium griseofulvum* given orally to treat chronic dermatophytic infections of skin and nails. *820*

group translocation A transport process in which a molecule is moved across a membrane by carrier proteins while being chemically altered at the same time. *103*

growth An increase in cellular constituents. *113*

growth factors Organic compounds that must be supplied in the diet for growth because they are essential cell components or precursors of such components and cannot be synthesized by the organism. *99*

guanine (gwan′in) A purine derivative, 2-amino-6-oxypurine, found in nucleosides, nucleotides, and nucleic acids. *217*

Guillain-Barré syndrome (ge-yan′bar-ra′) A relatively rare disease affecting the peripheral nervous system, especially the spinal nerves, but also the cranial nerves. The cause is unknown, but it most often occurs after an influenza infection or flu vaccination. Also called French Polio. *874*

gumma (gum′ah) A soft, gummy tumor occurring in tertiary syphilis. *924*

gut-associated lymphoid tissue (GALT) The defensive lymphoid tissue present in the intestines. *See* Peyer's patches. *710*

H

H-2 complex Term for the MHC in the mouse. *745*

halobacteria or **extreme halophiles** A group of archaea that have an absolute dependence on high NaCl concentrations for growth and will not survive at a concentration below about 1.5 M NaCl. *461*

halophile (hal′o-fīl) A microorganism that requires high levels of sodium chloride for growth. *123*

Hansen's disease *See* leprosy. *916*

hantavirus pulmonary syndrome The disease in humans caused by the pulmonary syndrome hantavirus. Deer mice shed the virus in their feces, humans inhale the virus and first develop ordinary flulike aches and pains. Within a few days the hantavirus causes lung damage and capillary leakage. After about a week the infected person enters a crisis phase and may die. *877*

hapten (hap′ten) A molecule not immunogenic by itself but that, when coupled to a macromolecular carrier, can elicit antibodies directed against itself. *731*

harborage transmission The mode of transmission in which an infectious organism does not undergo morphological or physiological changes within the vector. *858*

hay fever Allergic rhinitis; a type of atopic allergy involving the upper respiratory tract. *768*

health (helth) A state of optimal physical, mental, and social well-being, and not merely the absence of disease and infirmity. *848*

healthy carrier An individual who harbors a pathogen, but is not ill. *854*

heat-shock proteins Proteins produced when cells are exposed to high temperatures or other stressful conditions. They protect the cells from damage and often aid in the proper folding of proteins. *273*

helical (hel′ĭ-kal) In virology this refers to a virus with a helical capsid surrounding its nucleic acid. *369*

helicases Enzymes that use ATP energy to unwind DNA ahead of the replication fork. *236*

hemadsorption (hem″ad-sorp′shun) The adherence of red blood cells to the surface of something, such as another cell or a virus. *832*

hemagglutination (hem″ah-gloo″tĭ-na′shun) The agglutination of red blood cells by antibodies. *756*

hemagglutinin (hem″ah-gloo′tĭ-nin) The antibody responsible for a hemagglutination reaction. *756*

hemoflagellate (he″mo-flaj′ĕ-lāt) A flagellated protozoan parasite that is found in the bloodstream. *956*

hemolysin (he-mol′ĭ-sin) A substance that causes hemolysis (the lysis of red blood cells). At least some hemolysins are enzymes that destroy the phospholipids in erythrocyte plasma membranes. *797*

hemolysis (he-mol′ĭ-sis) The disruption of red blood cells and release of their hemoglobin. There are several types of hemolysis when bacteria such as streptococci and staphylococci grow on blood agar. In α-hemolysis, a narrow greenish zone of incomplete hemolysis forms around the colony. A clear zone of complete hemolysis without any obvious color change is formed during β-hemolysis. *531, 797*

hemolytic uremic syndrome A kidney disease characterized by blood in the urine and often by kidney failure. It is caused by enterohemorrhagic strains of *Escherichia coli* O157:H7 that produce a Shiga-like toxin, which attacks the kidneys. *932*

hemorrhagic fever A fever usually caused by a specific virus that may lead to hemorrhage, shock, and sometimes death. *877*

hepatitis (hep″ah-ti′tis) Any infection that results in inflammation of the liver. Also refers to liver inflammation as such. *889*

hepatitis A (formerly infectious hepatitis; hep″ah-ti′tis) A type of hepatitis that is transmitted by fecal-oral contamination; it primarily affects children and young adults, especially in environments where there is poor sanitation and overcrowding. It is caused by the hepatitis A virus, a single-stranded RNA virus. *892*

hepatitis B (formerly serum hepatitis; hep″ah-ti′tis) This form of hepatitis is caused by a double-stranded DNA virus (HBV) formerly called the "Dane particle." The virus is transmitted by body fluids. *889*

hepatitis C About 90% of all cases of viral hepatitis can be traced to either HAV or HBV. The remaining 10% is believed to be caused by one and possibly several other types of viruses. At least one of these is hepatitis C (formerly non-A, non-B). *890*

hepatitis D (formerly delta hepatitis) The liver diseases caused by the hepatitis D virus in those individuals already infected with the hepatitis B virus. *891*

hepatitis E (formerly enteric-transmitted NANB hepatitis) The liver disease caused by the hepatitis E virus. Usually, a subclinical, acute infection results; however, there is a high mortality in women in their last trimester of pregnancy. *892*

herd immunity The resistance of a population to infection and spread of an infectious organism due to the immunity of a high percentage of the population. *851*

herpes labialis *See* cold sore. *884*

herpetic keratitis (her-pet′ik ker″ah-ti′tis) An inflammation of the cornea and conjunctiva of the eye resulting from a herpes simplex virus infection. *884*

heterocysts Specialized cells produced by cyanobacteria that are the sites of nitrogen fixation. *473*

heteroduplex DNA A double-stranded stretch of DNA formed by two slightly different strands that are not completely complementary. *292*

heterogeneous nuclear RNA (hnRNA) The RNA transcript of DNA made by RNA polymerase II; it is then processed to form mRNA. *263*

heterolactic fermenters (het″er-o-lak′tik) Microorganisms that ferment sugars to form lactate, and also other products such as ethanol and CO_2. *181*

heterotroph (het′er-o-trōf″) An organism that uses reduced, preformed organic molecules as its principal carbon source. *96*

heterotrophic nitrification Nitrification carried out by chemoheterotrophic microorganisms. *615*

hexon or **hexamer** A capsomer composed of six protomers. *370*

hexose monophosphate pathway (hek′sōs mon″o-fos′fāt) *See* pentose phosphate pathway. *177*

Hfr strain A bacterial strain that donates its genes with high frequency to a recipient cell during conjugation because the F factor is integrated into the bacterial chromosome. *303*

high-energy molecule A molecule whose hydrolysis under standard conditions makes available a large amount of free energy (the standard free energy change is more negative than about −7 kcal/mole); a high-energy molecule readily decomposes and transfers groups such as phosphate to acceptors. *157*

high oxygen diffusion environment A microbial environment in close contact with air and through which oxygen can move at a rapid rate (in comparison with the slow diffusion rate of oxygen through water). *635*

histone (his′tōn) A small basic protein with large amounts of lysine and arginine that is associated with eucaryotic DNA in chromatin. *234*

histoplasmosis (his″to-plaz-mo′sis) A systemic fungal infection caused by *Histoplasma capsulatum* var *capsulatum.* *947*

hives (hīvz) An eruption of the skin. *769*

holdfast A structure produced by some bacteria and algae that attaches the cell to a solid object. *491*

holoenzyme A complete enzyme consisting of the apoenzyme plus a cofactor. *161*

holozoic nutrition (hol″o-zo′ik) In this type of nutrition, nutrients (such as bacteria) are acquired by phagocytosis and the subsequent formation of a food vacuole or phagosome. *586*

homolactic fermenters (ho″mo-lak′tik) Organisms that ferment sugars almost completely to lactic acid. *181*

horizontal gene transfer The process in which genes are transferred from one mature, independent organism to another. *292*

hormogonia Small motile fragments produced by fragmentation of filamentous cyanobacteria; used for asexual reproduction and dispersal. *473*

host (hōst) The body of an organism that harbors another organism. It can be viewed as a microenvironment that shelters and supports the growth and multiplication of a parasitic organism. *788*

host restriction The degradation of foreign genetic material by nucleases after the genetic material enters a host cell. *294*

human herpesvirus 6 (HHV-6, type A and B) (hər′pēz) HHV-6 was discovered in 1986 and was initially called the human B-lymphotropic virus. The virus was later shown to have a marked tropism for $CD4^+$ T cells and was renamed HHV-6. HHV-6 is genetically similar to cytomegalovirus. HHV-6 causes exanthem subitum (roseola infantum or sixth disease) in infants and has been suspected of involvement in many conditions, including opportunistic infections in immunocompromised patients, hepatitis, lymphoproliferative diseases, synergistic interactions with HIV, lymphadenitis, and chronic fatigue syndrome. *887*

human immunodeficiency virus (HIV) A lentivirus of the family *Retroviridae* that is associated with the onset of AIDS. *878*

human leukocyte antigen complex (HLA) An antigen on the surface of cells of human tissues and organs that is recognized by the immune system cells and therefore is important in graft rejection and regulation of the immune response. This is the same as MHC class II. *745*

humoral (antibody-mediated) immunity (hu′mor-al) The type of immunity that results from the presence of soluble antibodies in blood and lymph; also known as antibody-mediated immunity. *729*

hybridoma (hi″brĭ-do′mah) A fast-growing cell line produced by fusing a cancer cell (myeloma) to another cell, such as an antibody-producing cell. *743*

hydrogenosome (hi-dro-jen′osom) A microbodylike organelle that contains a unique electron transfer pathway in which hydrogenase transfers electrons to protons (which act as the terminal electron acceptors) and molecular hydrogen is formed. *585*

hydrophilic (hi″dro-fil′ik) A polar substance that has a strong affinity for water (or is readily soluble in water). *46*

hydrophobic (hi″dro-fo′bik) A nonpolar substance lacking affinity for water (or which is not readily soluble in water). *46*

hyperendemic disease (hi″per-en-dem′ik) A disease that has a gradual increase in occurrence beyond the endemic level, but not at the epidemic level, in a given population; also may refer to a disease that is equally endemic in all age groups. *849*

hypermutation A rapid production of multiple mutations in a gene or genes through the activation of special mutator genes. The process may be deliberately used to maximize the possibility of creating desirable mutants. *246*

hypersensitivity (hi″per-sen′si-tiv″i-te) A condition of increased immune sensitivity in which the body reacts to an antigen with an exaggerated immune response that usually harms the individual. Also termed an allergy. *768*

hyperthermophile (hi″per-ther′mo-fīl) A bacterium that has its growth optimum between 80°C and about 113°C. Hyperthermophiles usually do not grow well below 55°C. *126, 626*

hypha (hi′fah; pl., **hyphae**) The unit of structure of most fungi and some bacteria; a tubular filament. *556*

hypoferremia (hi″po-fĕ-re′me-ah) Deficiency of iron in the blood. *723*

hypotheca (hi-po-theca) The smaller half of a diatom frustule. *577*

hypothesis A tentative assumption or educated guess developed to explain a set of observations. *8*

hypoxic (hi pok′sik) Having a low oxygen level. *635*

I

icosahedral In virology this term refers to a virus with an icosahedral capsid, which has the shape of a regular polyhedron having 20 equilateral triangular faces and 12 corners. *369*

identification (i-den″tĭ-fĭ-ka′shun) The process of determining that a particular isolate or organism belongs to a recognized taxon. *422*

idiotype (id′e-o-tīp′) A set of one or more unique epitopes in the variable region of an immunoglobulin that distinguishes it from immunoglobulins produced by different plasma cells. *734*

IgA Immunoglobulin A; the class of immunoglobulins that is present in dimeric form in many body secretions (e.g., saliva, tears, and bronchial and intestinal secretions) and protects body surfaces. IgA also is present in serum. *736*

IgD Immunoglobulin D; the class of immunoglobulins found on the surface of many B lymphocytes; thought to serve as an antigen receptor in the stimulation of antibody synthesis. *738*

IgE Immunoglobulin E; the immunoglobulin class that binds to mast cells and basophils, and is responsible for type I or anaphylactic hypersensitivity reactions such as hay fever and asthma. IgE is also involved in resistance to helminth parasites. *738*

IgG Immunoglobulin G; the predominant immunoglobulin class in serum. Has functions such as neutralizing toxins, opsonizing bacteria, activating complement, and crossing the placenta to protect the fetus and neonate. *736*

IgM Immunoglobulin M; the class of serum antibody first produced during an infection. It is a large, pentameric molecule that is active in agglutinating pathogens and activating complement. The monomeric form is present on the surface of some B lymphocytes. *736*

immobilization (im-mo″bil-i-za′shun) The incorporation of a simple, soluble substance into the body of an organism, making it unavailable for use by other organisms. *613*

immune complex (ĭ-mūn′kom′pleks) The product of an antigen-antibody reaction, which may also contain components of the complement system. *756*

immune surveillance (ĭ-mūn′sur-vāl′ans) The still somewhat hypothetical process in which lymphocytes such as natural killer (NK) cells recognize and destroy tumor cells; other cells with abnormal surface antigens (e.g., virus-infected cells) also may be destroyed. *760*

immune system The defensive system in a host consisting of the nonspecific and specific immune responses. It is composed of widely distributed cells, tissues, and organs that recognize foreign substances and microorganisms and acts to neutralize or destroy them. *705*

immunity (ĭ-mu′nĭ-te) Refers to the overall general ability of a host to resist a particular disease; the condition of being immune. *705*

immunoblotting The electrophoretic transfer of proteins from polyacrylamide gels to nitrocellulose sheets to demonstrate the presence of specific proteins through reaction with labeled antibodies. *779*

immunodeficiency (im″u-no-dĕ-fish′en-se; pl., **immunodeficiencies**) The inability to produce a normal complement of antibodies or immunologically sensitized T cells in response to specific antigens. *774*

immunodiffusion A technique involving the diffusion of antigen and/or antibody within a semisolid gel to produce a precipitin reaction where they meet in proper proportions. Often both the antibody and antigen diffuse through the gel; sometimes an antigen diffuses through a gel containing antibody. *779*

immunoelectrophoresis (ĭ-mu″no-e-lek″tro-fo-re′sis; pl., **immunoelectrophoreses**) The electrophoretic separation of protein antigens followed by diffusion and precipitation in gels using antibodies against the separated proteins. *781*

immunofluorescence (im″u-no-floo″o-res′ens) A technique used to identify particular antigens microscopically in cells or tissues by the binding of a fluorescent antibody conjugate. *781*

immunoglobulin (Ig; im″u-no-glob′u-lin) *See* antibody. *734*

immunology (im″u-nol′o-je) The branch of science that deals with the immune system and attempts to understand the many phenomena that are responsible for both acquired and innate immunity. It also includes the use of antibody-antigen reactions in other laboratory work (serology and immunochemistry). *705*

immunopathology (im″u-no-pə-thol′o-je) The study of diseases or conditions resulting from immune reactions. *790*

immunoprecipitation (im″u-no-pre-sip″i-ta′shun) A reaction involving soluble antigens reacting with antibodies to form a large aggregate that precipitates out of solution. *781*

immunotoxin (im′u-no-tok″sin) A monoclonal antibody that has been attached to a specific toxin or toxic agent (antibody + toxin = immunotoxin) and can kill specific target cells. *744*

impetigo (im″pə-ti′go) This superficial cutaneous disease, most commonly seen in children, is characterized by crusty lesions, usually located on the face; the lesions typically have vesicles surrounded by a red border. It is the most frequently diagnosed skin infection caused by *S. pyogenes* (impetigo can also be caused by *S. aureus*). *903*

inclusion bodies Granules of organic or inorganic material lying in the cytoplasmic matrix of bacteria. *49, 410*

inclusion conjunctivitis (in-klu′zhun kon-junk″tĭ-vi′tis) An acute infectious disease that occurs throughout the world. It is caused by *Chlamydia trachomatis* that infects the eye and causes inflammation and the occurrence of large inclusion bodies. *916*

incubation period The period after pathogen entry into a host and before signs and symptoms appear. *850*

incubatory carrier An individual who is incubating a pathogen in large numbers but is not yet ill. *854*

index case The first disease case in an epidemic within a given population. *849*

indicator organism An organism whose presence indicates the condition of a substance or environment, for example, the potential presence of pathogens. Coliforms are used as indicators of fecal pollution. *654*

inducer (in-dūs′er) A small molecule that stimulates the synthesis of an inducible enzyme. *275*

inducible enzyme An enzyme whose level rises in the presence of a small molecule that stimulates its synthesis. *275*

industrial ecology The study of the ecology of industrial societies with a major focus on material cycling, energy flow, and the ecological impacts of such societies. *1022*

infantile paralysis (in′fan-til pah-ral′i-sis) *See* poliomyelitis. *892*

infection (in-fek′shun) The invasion of a host by a microorganism with subsequent establishment and multiplication of the agent. An infection may or may not lead to overt disease. *789*

infection thread A tubular structure formed during the infection of a root by nitrogen-fixing bacteria. The bacteria enter the root by way of the infection thread and stimulate the formation of the root nodule. *676*

infectious disease Any change from a state of health in which part or all of the host's body cannot carry on its normal functions because of the presence of an infectious agent or its products. *789*

infectious disease cycle (chain of infection) The chain or cycle of events that describes how an infectious organism grows, reproduces, and is disseminated. *852*

infectious dose 50 (ID_{50}) Refers to the dose or number of organisms that will infect 50% of an experimental group of hosts within a specified time period. *368, 790*

infectious mononucleosis (mono; mon″o-nu″kle-o′sis) An acute, self-limited infectious disease of the lymphatic system caused by the Epstein-Barr virus and characterized by fever, sore throat, lymph node and spleen swelling, and the proliferation of monocytes and abnormal lymphocytes. *888*

infectivity (in″fek-tiv′i-te) Infectiousness; the state or quality of being infectious or communicable. *790*

inflammation (in″flah-ma′shun) A localized protective response to tissue injury or destruction. Acute inflammation is characterized by pain, heat, swelling, and redness in the injured area. *712*

influenza or **flu** (in″flu-en′zah) An acute viral infection of the respiratory tract, occurring in isolated cases, epidemics, and pandemics. Influenza is caused by three strains of influenza virus, labeled types A, B, and C, based on the antigens of their protein coats. *872*

ingoldian fungi Aquatic hyphomycetes that often have a characteristic tetraradiate hyphal development form and which sporulate under water. Discovered by the British mycologist, C. T. Ingold, in the 1940s. *641*

initial body *See* reticulate body (RB). *477*

innate or **natural immunity** *See* nonspecific resistance. *705*

insertion sequence (in-ser′shun se′kwens) A simple transposon that contains genes only for those enzymes, such as the transposase, that are required for transposition. *298*

integration The incorporation of one DNA segment into a second DNA molecule to form a new hybrid DNA. Integration occurs during such processes as genetic recombination, episome incorporation into host DNA, and prophage insertion into the bacterial chromosome. *394*

integrins (in′tə-grin) A large and broadly distributed family of α/β heterodimers. Integrins are cellular adhesion receptors that mediate cell-cell and cell-substratum interactions. Integrins usually recognize linear amino acid sequences on protein ligands. *712*

inteins Internal intervening sequences of precursor self-splicing proteins that separate exteins and are removed during formation of the final protein. *275*

intercalating agents Molecules that can be inserted between the stacked bases of a DNA double helix, thereby distorting the DNA and inducing insertion and deletion mutations. *248*

interdigitating dendritic cell Special dendritic cells in the lymph nodes that function as potent antigen-presenting cells and develop from Langerhans cells. *710*

interferon (IFN; in″tər-fēr′on) A glycoprotein that has nonspecific antiviral activity by stimulating cells to produce antiviral proteins, which inhibit the synthesis of viral RNA and proteins. Interferons also regulate the growth, differentiation, and/or function of a variety of immune system cells. Their production may be stimulated by virus infections, intracellular pathogens (chlamydiae and rickettsias), protozoan parasites, endotoxins, and other agents. *721, 822*

interleukin (in″tər-loo′kin) A glycoprotein produced by macrophages and T cells that regulates growth and differentiation, particularly of lymphocytes. Interleukins promote cellular and humoral immune responses. *720*

intermediate filaments (in″ter-me′de-it fil′ah-ments) Small protein filaments, about 8 to 10 nm in diameter, in the cytoplasmic matrix of eucaryotic cells that are important in cell structure. *79*

intermediate host (in″ter-me′de-it hōst) The host that serves as a temporary but essential environment for development of a parasite and completion of its life cycle. *789*

interspecies hydrogen transfer The linkage of hydrogen production from organic matter by anaerobic heterotrophic microorganisms to the use of hydrogen by other anaerobes in the reduction of carbon dioxide to methane. This avoids possible hydrogen toxicity. *604*

intertriginous candidiasis A skin infection caused by *Candida* species. Involves those areas of the body, usually opposed skin surfaces, that are warm and moist (axillae, groin, skin folds). *950*

intoxication (in-tok″si-ka′shun) A disease that results from the entrance of a specific toxin into the body of a host. The toxin can induce the disease in the absence of the toxin-producing organism. *794*

intraepidermal lymphocytes T cells found in the epidermis of the skin that express the $\gamma\delta$ T-cell receptor. *710*

intranuclear inclusion body (in″trah-nu′kel-ar) A structure found within cells infected with the cytomegalovirus. *885*

intrinsic factors Food-related factors such as moisture, pH, and available nutrients that influence microbial growth. *964*

intron (in′tron) A noncoding intervening sequence in a split or interrupted gene, which codes for RNA that is missing from the final RNA product. *263*

invasiveness (in-va′siv-nes) The ability of a microorganism to enter a host, grow and reproduce within the host, and spread throughout its body. *790*

ionizing radiation Radiation of very short wavelength or high energy that causes atoms to lose electrons or ionize. *130, 144*

isotype (i′so-tīp) A variant form of an immunoglobulin (e.g., an immunoglobulin class, subclass, or type) that occurs in every normal individual of a particular species. Usually the characteristic antigenic determinant is in the constant region of H and L chains. *734*

J

Jaccard coefficient (S_J) An association coefficient used in numerical taxonomy; it is the proportion of characters that match, excluding those that both organisms lack. *427*

J chain A polypeptide present in polymeric IgM and IgA that links the subunits together. *736*

jock itch *See* tinea cruris. *944*

K

kelp (kelp) A common name for any of the larger members of the order *Laminariales* of the brown algae. *578*

keratinocyte Cell found in skin-associated lymphoid tissue; secretes cytokines that may induce an inflammatory response. *709*

keratitis (ker″ah-ti′tis) Inflammation of the cornea of the eye. *953*

kinetoplast (ki-ne′to-plast) A special structure in the mitochondrion of kinetoplastid protozoa. It contains the mitochondrial DNA. *588*

Kirby-Bauer method A disk diffusion test to determine the susceptibility of a microorganism to chemotherapeutic agents. *809*

Koch's postulates (koks pos′tu-lāts) A set of rules for proving that a microorganism causes a particular disease. *7*

Koplik's spots (kop′liks) Lesions of the oral cavity caused by the measles (rubeola) virus that are characterized by a bluish white speck in the center of each. *874*

Korean hemorrhagic fever An acute infection caused by a virus that produces varying degrees of hemorrhage, shock, and sometimes death. *877*

Krebs cycle *See* tricarboxylic acid (TCA) cycle. *183*

L

lactic acid fermentation (lak′tik) A fermentation that produces lactic acid as the sole or primary product. *179, A–19*

lager Pertaining to the process of aging beers to allow flavor development. *983*

lag phase A period following the introduction of microorganisms into fresh culture medium when there is no increase in cell numbers or mass during batch culture. *113*

laminarin (lam″i-na′rin) One of the principal storage products of the golden-brown algae; a polymer of glucose. *578*

Lancefield system (group; lans′feld) One of the serologically distinguishable groups (as group A, group B) into which streptococci can be divided. *532, 784*

land farming The addition of waste material, such as a hydrocarbon waste, to the soil surface so that it will be degraded. The soil may be moistened or mixed to stimulate the desired degradation process. *1011*

Langerhans cell Cell found in the skin that internalizes antigen and moves in the lymph to lymph nodes where it differentiates into a dendritic cell. *709*

late mRNA Messenger RNA produced later in a virus infection, which codes for proteins needed in capsid construction and virus release. *387*

latent period (la′tent) The initial phase in the one-step growth experiment in which no phages are released. *383*

latent virus infections Virus infections in which the virus quits reproducing and remains dormant for a period before becoming active again. *410*

leader sequence A nontranslated sequence at the 5′ end of mRNA that lies between the operator and the initiation codon; it aids in the initiation and regulation of transcription. *244, 261*

lectin complement pathway (lek′tin) The lectin pathway for complement activation is triggered by the binding of a serum lectin (mannan-binding lectin; MBL) to mannose-containing proteins or to carbohydrates on viruses or bacteria. *716*

legionellosis (le″jə-nel-o′sis) *See* Legionnaires' disease. *901*

Legionnaires' disease (legionellosis) A pulmonary form of legionellosis, resulting from infection with *Legionella pneumophila.* *901*

leishmanias (lēsh″ma′ne-ăs) Zooflagellates, members of the genus *Leishmania,* that cause the disease leishmaniasis. *956*

leishmaniasis (lēsh″mah-ni′ah-sis) The disease caused by the protozoa called leishmanias. *956*

lepromatous (progressive) leprosy (lep-ro′mah-tus lep′ro-se) A relentless, progressive form of leprosy in which large numbers of *Mycobacterium leprae* develop in skin cells, killing the skin cells and resulting in the loss of features. Disfiguring nodules form all over the body. *916*

leprosy (lep′ro-se) or **Hansen's disease** A severe disfiguring skin disease caused by *Mycobacterium leprae.* *916*

lethal dose 50 (LD_{50}) Refers to the dose or number of organisms that will kill 50% of an experimental group of hosts within a specified time period. *368, 790*

leukemia (loo-ke′me-ah) A progressive, malignant disease of blood-forming organs, marked by distorted proliferation and development of leukocytes and their precursors in the blood and bone marrow. Certain leukemias are caused by viruses (HTLV-1, HTLV-2). *887*

leukocidin (loo″ko-si′din) A microbial toxin that can damage or kill leukocytes. *797*

leukocyte (loo′ko-sīt) Any colorless white blood cell. Can be classified into granular and agranular lymphocytes. *705*

lichen (li′ken) An organism composed of a fungus and either green algae or cyanobacteria in a symbiotic association. *598*

Liebig's law of the minimum (le′bigz) Living organisms and populations will grow until lack of a resource begins to limit further growth. *131*

lipopolysaccharide (lip″o-pol″e-sak′ah-rīd) A molecule containing both lipid and polysaccharide, which is important in the outer membrane of the gram-negative cell wall. *58*

liposome (lip′o-som) A spherical particle formed by a lipid bilayer enclosing an aqueous solution. It may be used to administer chemotherapeutic agents or in diagnostic testing. *782*

listeriosis (lis-ter″e-o′sis) A sporadic disease of animals and humans, particularly those who are immunocompromised or pregnant, caused by the bacterium *Listeria monocytogenes.* *931*

lithotroph (lith′o-trōf) An organism that uses reduced inorganic compounds as its electron source. *97*

log phase *See* exponential phase. *114*

lophotrichous (lo-fot′rĭ-kus) A cell with a cluster of flagella at one or both ends. *63*

low oxygen diffusion environment An aquatic environment in which microorganisms are surrounded by deep water layers that limit oxygen diffusion to the cell surface. In contrast, microorganisms in thin water films have good oxygen transfer from air to the cell surface. *635*

LPS-binding protein A special plasma protein that binds bacterial lipopolysaccharides and then attaches to receptors on monocytes, macrophages, and other cells. This triggers the release of IL-1 and other cytokines that stimulate the development of fever and additional endotoxin effects. *801*

Lyme disease (LD, Lyme borreliosis; līm) A tick-borne disease caused by the spirochete *Borrella burgdorferi.* *910*

lymph node A small secondary lymphoid organ that contains lymphocytes, macrophages, and dendritic cells. It serves as a site for (1) filtration and removal of foreign antigens and (2) the activation and proliferation of lymphocytes. *709*

lymphocyte (lim′fo-sīt) A nonphagocytic, mononuclear leukocyte (white blood cell) that is an immunologically competent cell, or its precursor. Lymphocytes are present in the blood, lymph, and lymphoid tissues. *See* B cell and T cell. *705*

lymphogranuloma venereum (LGV; lim″fo-gran″u-lo′mah) A sexually transmitted disease caused by *Chlamydia trachomatis* serotypes L_1–L_3, which affect the lymph organs in the genital area. *917*

lymphokine (lim′fo-kin) A biologically active glycoprotein (e.g., IL-1) secreted by activated lymphocytes, especially sensitized T cells. It acts as an intercellular mediator of the immune response and transmits growth, differentiation, and behavioral signals. *720*

lysis (li′sis) The rupture or physical disintegration of a cell. *61*

lysogenic (li-so-jen′ik) *See* lysogens. *308, 390*

lysogens (li′so-jens) Bacteria that are carrying a viral prophage and have the potential of producing bacteriophages under the proper conditions. *308, 390*

lysogeny (li-soj′e-ne) The state in which a phage genome remains within the bacterial host cell after infection and reproduces along with it rather than taking control of the host and destroying it. *307, 390*

lysosome (li′so-sōm) A spherical membranous eucaryotic organelle that contains hydrolytic enzymes and is responsible for the intracellular digestion of substances. *80*

lysozyme (li′sō-zīm) An enzyme that degrades peptidoglycan by hydrolyzing the $\beta(1 \rightarrow 4)$ bond that joins *N*-acetylmuramic acid and *N*-acetylglucosamine. *61, 710*

lytic cycle (lit′ik) A virus life cycle that results in the lysis of the host cell. *383*

M

M cell Specialized cell of the intestinal mucosa and other sites, such as the urogenital tract, that delivers the antigen from the apical face of the cell to lymphocytes clustered within the pocket in its basolateral face. *710*

macrolide antibiotic (mak′ro-lĭd) An antibiotic containing a macrolide ring, a large lactone ring with multiple keto and hydroxyl groups, linked to one or more sugars. *817*

macromolecule (mak″ro-mol′ĕ-kūl) A large molecule that is a polymer of smaller units joined together. *205*

macromolecule vaccine A vaccine made of specific, purified macromolecules derived from pathogenic microorganisms. *767*

macronucleus (mak″ro-nu′kle-us) The larger of the two nuclei in ciliate protozoa. It is normally polyploid and directs the routine activities of the cell. *585*

macrophage (mak′ro-fāj) The name for a large mononuclear phagocytic cell, present in blood, lymph, and other tissues. Macrophages are derived from monocytes. They phagocytose and destroy pathogens; some macrophages also activate B cells and T cells. *705*

maduromycosis (mah-du′ro-mi-ko′sis) A subcutaneous fungal infection caused by *Madurella mycetoma;* also termed an eumycotic mycetoma. *945*

madurose The sugar derivative 3-O-methyl-D-galactose, which is characteristic of several actinomycete genera that are collectively called maduromycetes. *548*

magnetosomes Magnetite particles in magnetotactic bacteria that are tiny magnets and allow the bacteria to orient themselves in magnetic fields. *52*

maintenance energy The energy a cell requires simply to maintain itself or remain alive and functioning properly. It does not include the energy needed for either growth or reproduction. *121*

major histocompatibility complex (MHC) A large set of cell surface molecules in each individual, encoded by a family of genes, that serves as a unique biochemical marker of individual identity. It can trigger T-cell responses that may lead to rejection of transplanted tissues and organs. MHC molecules are also involved in the regulation of the immune response and the interactions between immune cells. *745*

malaria (mah-la′re-ah) A serious infectious illness caused by the parasitic protozoan *Plasmodium.* Malaria is characterized by bouts of high chills and fever that occur at regular intervals. *954*

malt (mawlt) Grain soaked in water to soften it, induce germination, and activate its enzymes. The malt is then used in brewing and distilling. *983*

Marburg viral hemorrhagic fever An acute infection caused by a virus that produces varying degrees of hemorrhage, shock, and sometimes death. *877*

mash The soluble materials released from germinated grains and prepared as a microbial growth medium. *983*

mashing The process in which cereals are mixed with water and incubated in order to degrade their complex carbohydrates (e.g., starch) to more readily usable forms such as simple sugars. *982*

mast cell A bone marrow–derived cell present in a variety of tissues that resembles peripheral blood-borne basophils and contains an Fc receptor for IgE. It undergoes IgE-mediated degranulation. *707*

mean growth rate constant (k) The rate of microbial population growth expressed in terms of the number of generations per unit time. *116*

measles (rubeola; me′zelz) A highly contagious skin disease that is endemic throughout the world. It is caused by a morbilli virus in the family *Paramyxoviridae,* which enters the body through the respiratory tract or through the conjunctiva. *873*

medical mycology (mi-kol′o-je) The discipline that deals with the fungi that cause human disease. *942*

meiosis (mi-o′sis) The sexual process in which a diploid cell divides and forms two haploid cells. *88*

melting temperature (T_m) The temperature at which double-stranded DNA separates into individual strands; it is dependent on the G + C content of the DNA and is used to compare genetic material in microbial taxonomy. *430*

membrane attack complex (MAC) The complex complement components (C5b–C9) that create a pore in the plasma membrane of a target cell and leads to cell lysis. C9 probably forms most of the actual pore. *716, 758*

membrane-disrupting exotoxin A type of exotoxin that lyses host cells by disrupting the integrity of the plasma membrane. *797*

membrane filter technique The use of a thin porous filter made from cellulose acetate or some other polymer to collect microorganisms from water, air, and food. *118, 654*

memory B cell A lymphocyte capable of initiating the antibody-mediated immune response upon detection of a specific antigen molecule for which it is genetically programmed. It circulates freely in the blood and lymph and may live for years. *741*

meningitis (men″in-ji′tis) A condition that refers to inflammation of the brain or spinal cord meninges (membranes). The disease can be divided into bacterial (septic) meningitis (caused by bacteria) and aseptic meningitis syndrome (caused by nonbacterial sources). *902*

mesophile (mes′o-fīl) A microorganism with a growth optimum around 20 to 45°C, a minimum of 15 to 20°C, and a maximum about 45°C or lower. *126*

messenger RNA (mRNA) Single-stranded RNA synthesized from a DNA template during transcription that binds to ribosomes and directs the synthesis of protein. *230*

metabolic channeling (mĕt″ah-bol′ik) The localization of metabolites and enzymes in different parts of a cell. *165*

metabolic control engineering Modification of the controls for biosynthetic pathways without altering the pathways themselves in order to improve process efficiency. *997*

metabolic pathway engineering (MPE) The use of molecular techniques to improve the efficiency of pathways that synthesize specific products. *997*

metabolism (me-tab′o-lizm) The total of all chemical reactions in the cell; almost all are enzyme catalyzed. *173*

metachromatic granules (met″ah-kro-mat′ik) Granules of polyphosphate in the cytoplasm of some bacteria that appear a different color when stained with a blue basic dye. They are storage reservoirs for phosphate. Sometimes called volutin granules. *52*

metastasis (mĕ-tas′tah-sis) The transfer of a disease like cancer from one organ to another not directly connected with it. *411*

methanogens (meth′ə-no-jens″) Strictly anaerobic archaeons that derive energy by converting CO_2, H_2, formate, acetate, and other compounds to either methane or methane and CO_2. *458*

methylotroph A bacterium that uses reduced one-carbon compounds such as methane and methanol as its sole source of carbon and energy. *491, 502*

Michaelis constant (K_m; mĭ-ka′lis) A kinetic constant for an enzyme reaction that equals the substrate concentration required for the enzyme to operate at half maximal velocity. *163*

microaerophile (mi″kro-a′er-o-fīl) A microorganism that requires low levels of oxygen for growth, around 2 to 10%, but is damaged by normal atmospheric oxygen levels. *127*

microarray technology Profiling of gene expression by measuring binding of RNA from growing cells to an array of function-specific oligonucleotides attached to an inert surface. *354, 1018*

microbial dietary adjuvant A substance added to the diet to stimulate specific microbial processes and populations. *986*

microbial ecology The study of microorganisms in their natural environments, with a major emphasis on physical conditions, processes, and interactions that occur on the scale of individual microbial cells. *596*

microbial transformation (mi-kro′be-al) *See* bioconversion. *1009*

microbial loop The mineralization of organic matter synthesized by photosynthetic phytoplankton through the activity of microorganisms such as bacteria and protozoa. This process "loops" minerals and carbon dioxide back for reuse by the primary producers and makes the organic matter unavailable to higher consumers. *608, 638*

microbial mat A firm structure of layered microorganisms with complementary physiological activities that can develop on surfaces in aquatic environments. *621*

microbiology (mi″kro-bi-ol′o-je) The study of organisms that are usually too small to be seen with the naked eye. Special techniques are required to isolate and grow them. *2*

microbivory The use of microorganisms as a food source by organisms that can ingest or phagocytose them. *672*

microenvironment (mi″kro-en-vi′ron-ment) The immediate environment surrounding a microbial cell or other structure, such as a root. *619*

microfilaments (mi″kro-fil′ah-ments) Protein filaments, about 4 to 7 nm in diameter, that are present in the cytoplasmic matrix of eucaryotic cells and play a role in cell structure and motion. *77*

micronucleus (mi″kro-nu′kle-us) The smaller of the two nuclei in ciliate protozoa. Micronuclei are diploid and involved only in genetic recombination and the regeneration of macronuclei. *585*

micronutrients Nutrients such as zinc, manganese, and copper that are required in very

small quantities for growth and reproduction. Also called trace elements. *96*

microorganism (mi″kro-or′gan-izm) An organism that is too small to be seen clearly with the naked eye. *2*

microtubules (mi″kro-tu′buls) Small cylinders, about 25 nm in diameter, made of tubulin proteins and present in the cytoplasmic matrix and flagella of eucaryotic cells; they are involved in cell structure and movement. *78*

miliary tuberculosis (mil′e-a-re) An acute form of tuberculosis in which small tubercles are formed in a number of organs of the body because of dissemination of *M. tuberculosis* throughout the body by the bloodstream. Also known as reactivation tuberculosis. *908*

mineralization The release of inorganic nutrients from organic matter during microbial growth and metabolism. *504, 613*

minimal inhibitory concentration (MIC) The lowest concentration of a drug that will prevent the growth of a particular microorganism. *809*

minimal lethal concentration (MLC) The lowest concentration of a drug that will kill a particular microorganism. *809*

minus, or negative, strand The virus nucleic acid strand that is complementary in base sequence to the viral mRNA. *374*

missense mutation A single base substitution in DNA that changes a codon for one amino acid into a codon for another. *250*

mitochondrion (mi″to-kon′dre-on) The eucaryotic organelle that is the site of electron transport, oxidative phosphorylation, and pathways such as the Krebs cycle; it provides most of a nonphotosynthetic cell's energy under aerobic conditions. It is constructed of an outer membrane and an inner membrane, which contains the electron transport chain. *83*

mitosis (mi-to′sis) A process that takes place in the nucleus of a eucaryotic cell and results in the formation of two new nuclei, each with the same number of chromosomes as the parent. *87*

mixed acid fermentation A type of fermentation carried out by members of the family *Enterobacteriaceae* in which ethanol and a complex mixture of organic acids are produced. *181, A–17*

mixotrophic (mik″so-trof′ik) Refers to microorganisms that combine autotrophic and heterotrophic metabolic processes (they use inorganic electron sources and organic carbon sources). *98*

modified atmosphere packaging (MAP) Addition of gases such as nitrogen and carbon dioxide to packaged foods in order to inhibit the growth of spoilage organisms. *966*

mold Any of a large group of fungi that cause mold or moldiness and that exist as multicellular filamentous colonies; also the deposit or growth caused by such fungi. Molds typically do not produce macroscopic fruiting bodies. *556*

molecular chaperones Proteins that aid in the proper folding of unfolded polypeptides or partly denatured proteins and often also help transport proteins across membranes. *272*

molecular chronometers Nucleic acid and protein sequences that gradually change over time in a random fashion and at a steady rate, and which therefore can be used to determine phylogenetic relationships. *432*

monoclonal antibody (MAb; mon″o-klōn′al) An antibody of a single type that is produced by a population of genetically identical plasma cells (a clone); a monoclonal antibody is typically produced from a cell culture derived from the fusion product of a cancer cell and an antibody-producing cell (a hybridoma). *743*

monocyte (mon′ o-sīt) A mononuclear phagocytic leukocyte that circulates briefly in the bloodstream before migrating to the tissues where it becomes a macrophage. *705*

monocyte-macrophage system The collection of fixed phagocytic cells (including macrophages, monocytes, and specialized endothelial cells) located in the liver, spleen, lymph nodes, and bone marrow. This system is an important component of the host's general nonspecific defense against pathogens. *705*

monokine (mon′o-kīn) A generic term for a cytokine produced by mononuclear phagocytes (macrophages or monocytes). *720*

monotrichous (mon-ot′rĭ-kus) Having a single flagellum. *63*

morbidity rate (mor-bid′i-te) Measures the number of individuals who become ill as a result of a particular disease within a susceptible population during a specific time period. *849*

mordant (mor′dant) A substance that helps fix dye on or in a cell. *28*

mortality rate (mor-tal′i-te) The ratio of the number of deaths from a given disease to the total number of cases of the disease. *849*

most probable number (MPN) The statistical estimation of the probable population in a liquid by diluting and determining end points for microbial growth. *654*

mucociliary blanket The layer of cilia and mucus that lines certain portions of the respiratory system; it traps microorganisms up to 10 µm in diameter and then transports them by ciliary action away from the lungs. *711*

mucosal-associated lymphoid tissue (MALT) The defensive immune lymphoid tissue located in the intestinal mucosa. *710*

multi-drug-resistant strains of tuberculosis (MDR-TB) A multi-drug-resistant strain is defined as *Mycobacterium tuberculosis* resistant to isoniazid and rifampin, with or without resistance to other drugs. *908*

mumps An acute generalized disease that occurs primarily in school-age children and is caused by a paramyxovirus that is transmitted in saliva and respiratory droplets. The principal manifestation is swelling of the parotid salivary glands. *875*

murein *See* peptidoglycan. *55*

must The juices of fruits, including grapes, that can be fermented for the production of alcohol. *982*

mutagen (mu′tah-jen) A chemical or physical agent that causes mutations. *246*

mutation (mu-ta′shun) A permanent, heritable change in the genetic material. *244*

mutualism (mu′tu-al-izm″) A type of symbiosis in which both partners gain from the association and are unable to survive without it. The mutualist and the host are metabolically dependent on each other. *598*

mutualist (mu′tu-al-ist) An organism associated with another in a relationship that is beneficial to both (and often obligatory). *598*

mycelium (mi-se′le-um) A mass of branching hyphae found in fungi and some bacteria. *43, 556*

mycobiont The fungal partner in a lichen. *598*

mycolic acids Complex 60 to 90 carbon fatty acids with a hydroxyl on the β-carbon and an aliphatic chain on the α-carbon; found in the cell walls of mycobacteria. *543*

mycologist (mi-kol′o-jist) A person specializing in mycology; a student of mycology. *553*

mycology (mi-kol′o-je) The science and study of fungi. *553*

mycoplasma (mi″ko-plaz′mah) Bacteria that are members of the class *Mollicutes* and order *Mycoplasmatales;* they lack cell walls and cannot synthesize peptidoglycan precursors; most require sterols for growth; they are the smallest organisms capable of independent reproduction. *520*

mycoplasmal pneumonia (mi″ko-plaz′mal nu-mo′ne-ah) A type of pneumonia caused by *Mycoplasma pneumoniae.* Spread involves airborne droplets and close contact. *917*

mycorrhizosphere The region around a mycorrhizal fungus in which nutrients released from the fungus increase the microbial population and its activities. *681*

mycosis (mi-ko′sis; pl., **mycoses**) Any disease caused by a fungus. *553, 942*

mycotoxicology (mi-ko′tok″si-kol′o-je) The study of fungal toxins and their effects on various organisms. *553*

myeloma cell (mi″e-lo′mah) A tumor cell that is similar to the cell type found in bone marrow. Also, a malignant, neoplastic plasma cell that produces large quantities of antibodies and can be readily cultivated. *743*

myositis (mi″o-si′tis) Inflammation of a striated or voluntary muscle. *904*

myxamoeba (mik-sah-me′bah; pl., **myxamoebae**) A free-living amoeboid cell that can aggregate with other myxamoeba to form a plasmodium or pseudoplasmodium. Found in cellular slime molds and the myxomycetes. *565*

myxobacteria A group of gram-negative, aerobic soil bacteria characterized by gliding motility, a complex life cycle with the production of fruiting bodies, and the formation of myxospores. *512*

myxospores (mik′so-spōrs) Special dormant spores formed by the myxobacteria. *512*

N

napkin (diaper) candidiasis Typically found in infants whose diapers are not changed frequently and are therefore not kept dry. Caused by *Candida* species of fungi. *950*

narrow-spectrum drugs Chemotherapeutic agents that are effective only against a limited variety of microorganisms. *808*

natural attenuation The decrease in the level of an enviromental contaminant that results from natural chemical, physical, and biological processes. *1016*

natural classification A classification system that arranges organisms into groups whose members share many characteristics and reflect as much as possible the biological nature of organisms. *426*

natural killer (NK) cell A non-T, non-B lymphocyte present in nonimmunized individuals that exhibits MHC-independent cytolytic activity against tumor cells. *723, 760*

naturally acquired active immunity The type of active immunity that develops when an individual's immunologic system comes into contact with an appropriate antigenic stimulus during the course of normal activities; it usually arises as the result of recovering from an infection and lasts a long time. *729*

naturally acquired passive immunity The type of temporary immunity that involves the transfer of antibodies from one individual to another. *729*

necrotizing fasciitis (nek′ro-tīz″ing fas″e-i′tis) A disease that results from a severe invasive group A streptococcus infection. Necrotizing fasciitis is an infection of the subcutaneous soft tissues, particularly of fibrous tissue, and is most common on the extremities. It begins with skin reddening, swelling, pain, and cellulitis, and proceeds to skin breakdown and gangrene after 3 to 5 days. *904*

negative staining A staining procedure in which a dye is used to make the background dark while the specimen is unstained. *28*

Negri bodies (na′gre) Masses of viruses or unassembled viral subunits found within the brain neurons of rabies-infected animals. *888*

neurotoxin (nu″ro-tok′sin) A toxin that is poisonous to or destroys nerve tissue; especially the toxins secreted by *C. tetani, Corynebacterium diphtheriae,* and *Shigella dysenteriae. 797*

neustonic (nu′ston″ik) The microorganisms that live at the atmospheric interface of a water body. *571*

neutrophil (noo′tro-fil) A mature white blood cell in the granulocyte lineage formed in bone marrow. It has a nucleus with three to five lobes and is very phagocytic. *123, 707*

neutrophile (nu′tro-fīl″) Microorganisms that grow best at a neutral pH range between pH 5.5 and 8.0. *123*

niche (nich) The function of an organism in a complex system, including place of the organism, the resources used in a given location, and the time of use. *619*

nicotinamide adenine dinucleotide (NAD$^+$; nik″o-tin′ah-mīd) An electron-carrying coenzyme; it is particularly important in catabolic processes and usually donates its electrons to the electron transport chain under aerobic conditions. *157*

nicotinamide adenine dinucleotide phosphate (NADP$^+$; nik″o-tin′ah-mīd) An electron-carrying coenzyme that most often participates as an electron carrier in biosynthetic metabolism. *158*

nitrification (ni″trĭ-fĭ-ka′shun) The oxidation of ammonia to nitrate. *193, 495, 615*

nitrifying bacteria (ni′trĭ-fi″ing) Chemolithotrophic, gram-negative bacteria that are members of the family *Nitrobacteriaceae* and convert ammonia to nitrate and nitrite to nitrate. *193, 493*

nitrogenase (ni′tro-jen-ās) The enzyme that catalyzes biological nitrogen fixation. *213*

nitrogen fixation The metabolic process in which atmospheric molecular nitrogen is reduced to ammonia; carried out by cyanobacteria, *Rhizobium,* and other nitrogen-fixing bacteria. *212, 616, 676*

nitrogen oxygen demand (*NOD*) The demand for oxygen in sewage treatment, caused by nitrifying microorganisms. *657*

nitrogen saturation point The point at which mineral nitrogen, when added to an ecosystem, can no longer be incorporated into organic matter through biological processes. *686*

nocardioforms Bacteria that resemble members of the genus *Nocardia;* they develop a substrate mycelium that readily breaks up into rods and coccoid elements (a quality sometimes called fugacity). *544*

nomenclature (no′men-kla″tūr) The branch of taxonomy concerned with the assignment of names to taxonomic groups in agreement with published rules. *422*

noncyclic photophosphorylation (fo″to-fos″for-i-la′shun) The process in which light energy is used to make ATP when electrons are moved from water to NADP$^+$ during photosynthesis; both photosystem I and photosystem II are involved. *198*

nongonococcal urethritis (NGU) (u″rə-thri′tis) Any inflammation of the urethra not caused by *Neisseria gonorrhoeae. 918*

nonsense codon A codon that does not code for an amino acid but is a signal to terminate protein synthesis. *241, 270*

nonsense mutation A mutation that converts a sense codon to a nonsense or stop codon. *251*

nonspecific immune response (innate or natural immunity) *See* nonspecific resistance. *705*

nonspecific resistance Refers to those general defense mechanisms that are inherited as part of the innate structure and function of each animal; also known as nonspecific, innate or natural immunity. *705*

normal microbiota (also **indigenous microbial population, microflora, microbial flora;** mi″kro-bi-o′tah) The microorganisms normally associated with a particular tissue or structure. *699*

nosocomial infection (nos″o-ko′me-al) An infection that develops within a hospital (or other type of clinical care facility) and is produced by an infectious organism acquired during the stay of the patient. *866*

nuclear envelope (nu′kle-ar) The complex double-membrane structure forming the outer boundary of the eucaryotic nucleus. It is covered by pores through which substances enter and leave the nucleus. *86*

nucleic acid hybridization (nu-kle′ik) The process of forming a hybrid double-stranded DNA molecule using a heated mixture of single-stranded DNAs from two different sources; if the sequences are fairly complementary, stable hybrids will form. *431*

nucleocapsid (nu″kle-o-kap′sid) The nucleic acid and its surrounding protein coat or capsid; the basic unit of virion structure. *369*

nucleoid (nu′kle-oid) An irregularly shaped region in the procaryotic cell that contains its genetic material. *54*

nucleolus (nu-kle′o-lus) The organelle, located within the eucaryotic nucleus and not bounded by a membrane, that is the location of ribosomal RNA synthesis and the assembly of ribosomal subunits. *87*

nucleoside (nu′kle-o-sīd″) A combination of ribose or deoxyribose with a purine or pyrimidine base. *217*

nucleosome (nu′kle-o-sōm″) A complex of histones and DNA found in eucaryotic chromatin; the DNA is wrapped around the surface of the beadlike histone complex. *235*

nucleotide (nu′kle-o-tīd) A combination of ribose or deoxyribose with phosphate and a purine or pyrimidine base; a nucleoside plus one or more phosphates. *217*

nucleus (nu′kle-us) The eucaryotic organelle enclosed by a double-membrane envelope that contains the cell's chromosomes. *86*

numerical aperture The property of a microscope lens that determines how much light can enter and how great a resolution the lens can provide. *20*

numerical taxonomy The grouping by numerical methods of taxonomic units into taxa based on their character states. *426*

nutrient (nu′tre-ent) A substance that supports growth and reproduction. *96*

nystatin (nis′tah-tin) A polyene antibiotic from *Streptomyces noursei* that is used in the treatment of *Candida* infections of the skin, vagina, and alimentary tract. *820*

O

O antigen A polysaccharide antigen extending from the outer membrane of some gram-negative bacterial cell walls; it is part of the lipopolysaccharide. *58*

obligate aerobes Organisms that grow only in the presence of oxygen. *127*

obligate anaerobes Microorganisms that cannot tolerate the presence of oxygen and die when exposed to it. *127*

odontopathogens Dental pathogens. *933*

Okazaki fragments Short stretches of polynucleotides produced during discontinuous DNA replication. *239*

oligotrophic environment (ol″ĭ-go-trof′ik) An environment containing low levels of nutrients, particularly nutrients that support microbial growth. *131, 648*

oncogene (ong′ko-jēn) A gene whose activity is associated with the conversion of normal cells to cancer cells. *411*

one-step growth experiment An experiment used to study the reproduction of lytic phages in which one round of phage reproduction occurs and ends with the lysis of the host bacterial population. *383*

onychomycosis (on″i-ko-mi-ko′sis) A fungal infection of the nail plate producing nails that are opaque, white, thickened, friable, and brittle. Also called ringworm of the nails and tinea unguium. Caused by *Trichophyton* and other fungi such as *C. albicans. 950*

oocyst (o′o-sist) Cyst formed around a zygote of malaria and related protozoa. *591*

oogonia (o″o-go′ne-a) Mitotically dividing female structures that produce primary oocytes and gametes. *574*

oomycetes (o″o-mi-se′tēz) A collective name for members of the division *Oomycota;* also known as the water molds. *565*

open reading frame (ORF) A reading frame sequence not interrupted by a stop codon; it is usually determined by nucleic acid sequencing studies. *347*

operator The segment of DNA to which the repressor protein binds; it controls the expression of the genes adjacent to it. *276*

operon (op′er-on) The sequence of bases in DNA that contains one or more structural genes together with the operator controlling their expression. *277*

ophthalmia neonatorum (of-thal′me-ah ne″o-nat-or-um) A gonorrheal eye infection in a newborn, which may lead to blindness. Also called conjunctivitis of the newborn. *916*

opportunistic microorganism or **pathogen** A microorganism that is usually free-living or a part of the host's normal microbiota, but which may become pathogenic under certain circumstances, such as when the immune system is compromised. *704, 789, 948*

opsonization (op″so-ni-za′shun) The action of opsonins in making bacteria and other cells more readily phagocytosed. Antibodies, complement (especially C3b), and fibronectin are potent opsonins. *718, 756*

optical tweezer The use of a focused laser beam to drag and isolate a specific microorganism from a complex microbial mixture. *627*

oral candidiasis *See* thrush. *949*

orchitis (or-ki′tis) Inflammation of the testes. *875*

organelle (or″gah-nel′) A structure within or on a cell that performs specific functions and is related to the cell in a way similar to that of an organ to the body. *76*

organotrophs Organisms that use reduced organic compounds as their electron source. *97*

ornithosis *See* psittacosis. *919*

osmophilic microorganisms (oz″mo-fil′ik) Microorganisms that grow best in or on media of high solute concentration. *965*

osmosis (oz-mo′sis) The movement of water across a selectively permeable membrane from a dilute solution (higher water concentration) to a more concentrated solution. *61*

osmotolerant Organisms that grow over a fairly wide range of water activity or solute concentration. *122*

Ouchterlony technique *See* double diffusion agar assay. *780*

outbreak The sudden, unexpected occurrence of a disease in a given population. *849*

outer membrane A special membrane located outside the peptidoglycan layer in the cell walls of gram-negative bacteria. *55*

oxidation-reduction (redox) reactions Reactions involving electron transfers; the reductant donates electrons to an oxidant. *157*

oxidative phosphorylation (fos″for-ĭ-la′shun) The synthesis of ATP from ADP using energy made available during electron transport. *184*

oxidizing agent or oxidant (ok′sĭ-dant) The electron acceptor in an oxidation-reduction reaction. *157*

oxygenic photosynthesis Photosynthesis that oxidizes water to form oxygen; the form of photosynthesis characteristic of eucaryotic algae and cyanobacteria. *199, 468*

P

pacemaker enzyme The enzyme in a metabolic pathway that catalyzes the slowest or rate-limiting reaction; if its rate changes, the pathway's activity changes. *169*

pandemic (pan-dem′ik) An increase in the occurrence of a disease within a large and geographically widespread population (often refers to a worldwide epidemic). *849*

Paneth cell (pah′ net) The granular cell located at the base of glands in the small intestine; it produces the enzyme lysozyme. *711*

pannus (pan′us) A superficial vascularization of the cornea with infiltration of granulation tissue. *926*

panzootic (pan″zo-ot′ik) The wide dissemination of a disease in an animal population. *849*

paralytic shellfish poisoning (par″ə-lit′ik) Dinoflagellates (*Gonyaulax* spp.) produce a powerful neurotoxin called saxitoxin. Shellfish accumulate saxitoxin and are poisonous when consumed by animals and humans. Saxitoxin paralyzes the striated respiratory muscles by inhibiting sodium transport. Paralytic shellfish poisoning is characterized by numbness of the mouth, lips, face, and extremities. *580*

parasite (par′ah-sīt) An organism that lives on or within another organism (the host) and benefits from the association while harming its host. Often the parasite obtains nutrients from the host. *788*

parasitism (par′ah-si″tizm) A type of symbiosis in which one organism adversely affects the other (the host), but cannot live without it. *609, 788*

parenteral route (pah-ren′ter-al) A route of drug administration that is nonoral (e.g., by injection). *812*

parfocal (par-fo′kal) A microscope that retains proper focus when the objectives are changed. *20*

paronychia (par″o-nik′e-ah) Inflammation involving the folds of tissue surrounding the nail; usually caused by *Candida albicans*. *950*

passive diffusion The process in which molecules move from a region of higher concentration to one of lower concentration as a result of random thermal agitation. *100*

passive immunization The induction of temporary immunity by the transfer of immune products, such as antibodies or sensitized T cells, from an immune vertebrate to a nonimmune one. *765*

Pasteur effect (pas-tur′) The decrease in the rate of sugar catabolism and change to aerobic respiration that occurs when microorganisms are switched from anaerobic to aerobic conditions. *189*

pasteurization (pas″ter-ĭ-za′shun) The process of heating milk and other liquids to destroy microorganisms that can cause spoilage or disease. *142, 970*

pathogen (path′o-jən) Any virus, bacterium, or other agent that causes disease. *698, 789*

pathogenicity (path″o-je-nis′ĭ-te) The condition or quality of being pathogenic, or the ability to cause disease. *698, 789*

pathogenicity island A large segment of DNA in some pathogens that contains the genes responsible for virulence; often it codes for the type III secretion system that allows the pathogen to secrete virulence proteins and damage host cells. A pathogen may have more than one pathogenicity island. *794*

pathogenic potential The degree that a pathogen causes morbid signs and symptoms. *790*

pathway architecture The analysis, design, and modification of biochemical pathways to increase process efficiency. *997*

pébrine (pa-brēn′) An infectious disease of silkworms caused by the protozoan *Nosema bombycis*. *591*

ped A natural soil aggregate, formed partly through bacterial and fungal growth in the soil. *670*

pellicle (pel′ĭ-k′l) A relatively rigid layer of proteinaceous elements just beneath the plasma membrane in many protozoa and algae. The plasma membrane is sometimes considered part of the pellicle. *89, 576, 585*

pelvic inflammatory disease (PID) A severe infection of the female reproductive organs. The disease that results when gonococci and chlamydiae infect the uterine tubes and surrounding tissue. *915, 918*

penicillins (pen″ĭ-sil-ins) A group of antibiotics containing a β-lactam ring, which are active against gram-positive bacteria. *61, 814*

penton or pentamer A capsomer composed of five protomers. *370*

pentose phosphate pathway (pen′tōs) The pathway that oxidizes glucose 6-phosphate to ribulose 5-phosphate and then converts it to a variety of three to seven carbon sugars; it forms several important products (NADPH for biosynthesis, pentoses, and other sugars) and also can be used to degrade glucose to CO_2. *177, A–14*

peplomer or spike (pep′lo-mer) A protein or protein complex that extends from the virus envelope and often is important in virion attachment to the host cell surface. *374*

peptic ulcer disease A gastritis caused by *Helicobacter pylori*. *918*

peptide interbridge (pep′tīd) A short peptide chain that connects the tetrapeptide chains in some peptidoglycans. *56*

peptidoglycan (pep″tĭ-do-gli′kan) A large polymer composed of long chains of alternating *N*-acetylglucosamine and *N*-acetylmuramic acid residues. The polysaccharide chains are linked to each other through connections between tetrapeptide chains attached to the *N*-acetylmuramic acids. It provides much of the strength and rigidity possessed by bacterial cell walls. *55, 521*

peptidyl or **donor site (P site)** The site on the ribosome that contains the peptidyl-tRNA at the beginning of the elongation cycle during protein synthesis. *270*

peptidyl transferase The enzyme that catalyzes the transpeptidation reaction in protein synthesis; in this reaction, an amino acid is added to the growing peptide chain. *270*

peptones (pep′tōns) Water-soluble digests or hydrolysates of proteins that are used in the preparation of culture media. *105*

perforin pathway The cytotoxic pathway that uses perforin protein, which polymerizes to form membrane pores that help destroy cells during cell-mediated cytotoxicity. Perforin is produced by cytotoxic T cells and NK cells and stored in granules that are released when a target cell is contacted. *750*

period of infectivity Refers to the time during which the source of an infectious disease is infectious or is disseminating the pathogen. *854*

periodontal disease (per″e-o-don′tal) A disease located around the teeth or in the periodontium—the tissue investing and supporting the teeth, including the cementum, periodontal ligament, alveolar bone, and gingiva. *936*

periodontitis (per″e-o-don-ti′tis) An inflammation of the periodontium. *936*

periodontium (per″e-o-don′she-um) *See* periodontal disease. *936*

periodontosis (per″e-o-don-to′sis) A degenerative, noninflammatory condition of the periodontium, which is characterized by destruction of tissue. *936*

periplasm (per′ĭ-plaz-əm) The substance that fills the periplasmic space. *55*

periplasmic flagella The flagella that lie under the outer sheath and extend from both ends of the spirochete cell to overlap in the middle and form the axial filament. Also called axial fibrils and endoflagella. *479*

periplasmic space (per″i-plas′mik) or **periplasm** (per′ĭ-plazm) The space between the plasma membrane and the outer membrane in gram-negative bacteria, and between the plasma membrane and the cell wall in gram-positive bacteria. *55*

peritrichous (pĕ-rit′rĭ-kus) A cell with flagella evenly distributed over its surface. *63*

permease (per′me-ās) A membrane-bound carrier protein or a system of two or more proteins that transports a substance across the membrane. *100*

pertussis (pər-tus′is) An acute, highly contagious infection of the respiratory tract, most frequently affecting young children, usually caused by *Bordetella pertussis* or *B. parapertussis.* Consists of peculiar paroxysms of coughing, ending in a prolonged crowing or whooping respiration; hence the name whooping cough. *903*

petri dish (pe′tre) A shallow dish consisting of two round, overlapping halves that is used to grow microorganisms on solid culture medium; the top is larger than the bottom of the dish to prevent contamination of the culture. *108*

phage (fāj) *See* bacteriophage. *364*

phagocytic vacuole (fag″o-sit′ik vak′u-ol) A membrane-delimited vacuole produced by cells carrying out phagocytosis. It is formed by the invagination of the plasma membrane and contains solid material. *585*

phagocytosis (fag″o-si-to′sis) The endocytotic process in which a cell encloses large particles in a membrane-delimited phagocytic vacuole or phagosome and engulfs them. *80, 718*

phagolysosome (fag″o-li′so-sōm) The vacuole that results from the fusion of a phagosome with a lysosome. *718*

phagovar (fag′o-var) A specific phage type. *842*

pharyngitis (far″in-ji′tis) Inflammation of the pharynx, often due to a *S. pyogenes* infection. *905*

phase-contrast microscope A microscope that converts slight differences in refractive index and cell density into easily observed differences in light intensity. *22*

phenetic system A classification system that groups organisms together based on the similarity of their observable charactistics. *426*

phenol coefficient test A test to measure the effectiveness of disinfectants by comparing their activity against test bacteria with that of phenol. *149*

phosphatase (fos′fah-tās″) An enzyme that catalyzes the hydrolytic removal of phosphate from molecules. *210*

phosphate group transfer potential A measure of the ability of a phosphorylated molecule such as ATP to transfer its phosphate to water and other acceptors. It is the negative of the $\Delta G^{o\prime}$ for the hydrolytic removal of phosphate. *157*

photoautotroph (fo′to-aw′to-trōf) *See* photolithotrophic autotrophs. *97*

photolithotrophic autotrophs Organisms that use light energy, an inorganic electron source (e.g., H_2O, H_2, H_2S), and CO_2 as a carbon source. *97*

photoorganotrophic heterotrophs Microorganisms that use light energy and organic electron donors, and also employ simple organic molecules rather than CO_2 as their carbon source. *98*

photoreactivation (fo″to-re-ak″tĭ-va′shun) The process in which blue light is used by a photoreactivating enzyme to repair thymine dimers in DNA by splitting them apart. *130, 254*

photosynthesis (fo″to-sin′thĕ-sis) The trapping of light energy and its conversion to chemical energy, which is then used to reduce CO_2 and incorporate it into organic form. *154, 195, 207*

photosystem I The photosystem in eucaryotic cells that absorbs longer wavelength light, usually greater than about 680 nm, and transfers the energy to chlorophyll P700 during photosynthesis; it is involved in both cyclic photophosphorylation and noncyclic photophosphorylation. *196*

photosystem II The photosystem in eucaryotic cells that absorbs shorter wavelength light, usually less than 680 nm, and transfers the energy to chlorophyll P680 during photosynthesis; it participates in noncyclic photophosphorylation. *196*

phototrophs Organisms that use light as their energy source. *97*

phycobiliproteins Photosynthetic pigments that are composed of proteins with attached tetrapyrroles; they are often found in cyanobacteria and red algae. *196*

phycobilisomes Special particles on the membranes of cyanobacteria that contain photosynthetic pigments and electron transport chains. *471*

phycobiont (fi″ko-bi′ont) The algal or cyanobacterial partner in a lichen. *599*

phycocyanin (fi″ko-si′an-in) A blue phycobiliprotein pigment used to trap light energy during photosynthesis. *196*

phycoerythrin (fi″ko-er′i-thrin) A red photosynthetic phycobiliprotein pigment used to trap light energy. *196*

phycology (fi-kol′o-je) The study of algae; algology. *571*

phyllosphere The surface of plant leaves. *674*

phylogenetic or **phyletic classification system** (fi″lo-jĕ-net′ik, fi-let′ik) A classification system based on evolutionary relationships rather than the general similarity of contemporary characteristics. *428*

phylogenetic tree A graph made of nodes and branches, much like a tree in shape, that shows phylogenetic relationships between groups of organisms and sometimes also indicates the evolutionary development of groups. *433*

phytoplankton (fi″to-plank′ton) A community of floating photosynthetic organisms, largely composed of algae and cyanobacteria. *571, 638*

phytoremediation The use of plants and their associated microorganisms to remove, contain, or degrade environmental contaminants. *1014*

piedra (pe-a′drah) A fungal disease of the hair in which white or black nodules of fungi form on the shafts. *943*

pinocytosis (pi″no-si-to′sis) The endocytotic process in which a cell encloses a small amount of the surrounding liquid and its solutes in tiny pinocytotic vesicles or pinosomes. *80*

pitched Pertaining to inoculation of a nutrient medium with yeast, for example, in beer brewing. *983*

plague (plāg) An acute febrile, infectious disease, caused by the bacillus *Yersinia pestis,* which has a high mortality rate; the two major types are bubonic plague and pneumonic plague. *911*

plankton (plank′ton) Free-floating, mostly microscopic microorganisms that can be found in almost all waters; a collective name. *571, 584*

planktonic (adj.) *See* plankton. *571*

plaque (plak) 1. A clear area in a lawn of bacteria or a localized area of cell destruction in a layer of animal cells that results from the lysis of the bacteria by bacteriophages or the destruction of the animal cells by animal viruses. 2. The term also refers to dental plaque, a film of food debris, polysaccharides, and dead cells that cover the teeth. It provides a medium for the growth of bacteria (which may be considered a part of the plaque), leading to a microbial plaque ecosystem that can produce dental decay. *364, 934*

plasma cell A mature, differentiated B lymphocyte chiefly occupied with antibody synthesis and secretion; a plasma cell lives for only 5 to 7 days. *709*

plasma membrane The selectively permeable membrane surrounding the cell's cytoplasm; also called the cell membrane, plasmalemma, or cytoplasmic membrane. *46*

plasmid (plaz′mid) A double-stranded DNA molecule that can exist and replicate independently of the chromosome or may be integrated with it. A plasmid is stably inherited, but is not required for the host cell's growth and reproduction. *54, 294, 819*

plasmid fingerprinting A technique used to identify microbial isolates as belonging to the same strain because they contain the same number of plasmids with the identical molecular weights and similar phenotypes. *843*

plasmodial (acellular) slime mold (plaz-mo′de-al) A member of the division *Myxomycota* that exists as a thin, streaming, multinucleate mass of protoplasm, which creeps along in an amoeboid fashion. *564*

plasmodium (plaz-mo′de-um; pl., **plasmodia**) A stage in the life cycle of myxomycetes (plasmodial slime molds); a multinucleate mass of protoplasm surrounded by a membrane. Also, a parasite of the genus *Plasmodium.* *565*

plasmolysis (plaz-mol′ĭ-sis) The process in which water osmotically leaves a cell, which causes the cytoplasm to shrivel up and pull the plasma membrane away from the cell wall. *61*

plastid (plas′tid) A cytoplasmic organelle of algae and higher plants that contains pigments such as chlorophyll, stores food reserves, and often carries out processes such as photosynthesis. *85*

pleomorphic (ple″o-mor′fik) Refers to bacteria that are variable in shape and lack a single, characteristic form. *44*

plus strand or **positive strand** The virus nucleic-acid strand that is equivalent in base sequence to the viral mRNA. *374*

pneumocystis pneumonia, *Pneumocystis carinii* pneumonia (PCP); (noo″mo-sis-tis) A type of pneumonia caused by the protist *Pneumocystis carinii.* *950*

pneumonic plague *See* plague. *911*

point mutation A mutation that affects only a single base pair in a specific location. *249*

polar flagellum A flagellum located at one end of an elongated cell. *63*

poliomyelitis (po″le-o-mi″e-li′tis) An acute, contagious viral disease that attacks the central nervous system, injuring or destroying the nerve cells that control the muscles and sometimes causing paralysis; also called polio or infantile paralysis. *892*

poly-β-hydroxybutyrate (hi-drok″se-bu′tĭ-rāt) A linear polymer of β-hydroxybutyrate used as a reserve of carbon and energy by many bacteria. *49*

polymerase chain reaction (PCR) An in vitro technique used to synthesize large quantities of specific nucleotide sequences from small amounts of DNA. It employs oligonucleotide primers complementary to specific sequences in the target gene and special heat-stable DNA polymerases. *326*

polymorphonuclear leukocyte (PMN) (pol″e-mor″fo-noo′kle-ər) A leukocyte that has a variety of nuclear forms. *707*

polyphasic taxonomy An approach in which taxonomic schemes are developed using a wide range of phenotypic and genotypic information. *435*

polyribosome (pol″e-ri′bo-sōm) A complex of several ribosomes with a messenger RNA; each ribosome is translating the same message. *83, 266*

Pontiac fever A bacterial disease caused by *Legionella pneumophila* that resembles an allergic disease more than an infection. First described from Pontiac, Michigan. *See* Legionnaires' disease. *902*

population An assemblage of organisms of the same type. *596*

porin proteins Proteins that form channels across the outer membrane of gram-negative bacterial cell walls. Small molecules are transported through these channels. *60*

postherpetic neuralgia The severe pain after a herpes infection. *872*

posttranscriptional modification The processing of the initial RNA transcript, heterogeneous nuclear RNA, to form mRNA. *263*

potable (po′tah-b′l) Refers to water suitable for drinking. *654*

pour plate A petri dish of solid culture medium with isolated microbial colonies growing both on its surface and within the medium, which has been prepared by mixing microorganisms with cooled, still liquid medium and then allowing the medium to harden. *107*

precipitation (or **precipitin**) **reaction** (pre-sip″ĭ-ta′shun) The reaction of an antibody with a soluble antigen to form an insoluble precipitate. *756*

precipitin (pre-sip′ĭ-tin) The antibody responsible for a precipitation reaction. *756*

prevalence rate Refers to the total number of individuals infected at any one time in a given population regardless of when the disease began. *849*

Pribnow box A special base sequence in the promoter that is recognized by the RNA polymerase and is the site of initial polymerase binding. *244, 262*

primary amebic meningoencephalitis An infection of the meninges of the brain by the free-living amoebae *Naegleria* or *Acanthamoeba.* *953*

primary (frank) pathogen Any organism that causes a disease in the host by direct interaction with or infection of the host. *789*

primary metabolites Microbial metabolites produced during the growth phase of an organism. *1002*

primary producer Photoautotrophic and chemoautotrophic organisms that incorporate carbon dioxide into organic carbon and thus provide new biomass for the ecosystem. *622*

primary production The incorporation of carbon dioxide into organic matter by photosynthetic organisms and chemoautotrophic bacteria. *622*

primary treatment The first step of sewage treatment, in which physical settling and screening are used to remove particulate materials. *658*

prion (pri′on) An infectious particle that is the cause of slow diseases like scrapie in sheep and goats; it has a protein component, but no nucleic acid has yet been detected. *416*

probe (prōb) A short, labeled nucleic acid segment complementary in base sequence to part of another nucleic acid, which is used to identify or isolate the particular nucleic acid from a mixture through its ability to bind specifically with the target nucleic acid. *322, 976*

probiotic (1) The oral administration of either living microorganisms or substances to promote the health and growth of an animal or human. (2) A living organism that may provide health benefits beyond its nutritional value when it is ingested. *703, 986*

procaryotic cells (pro″kar-e-ot′ik) Cells that lack a true, membrane-enclosed nucleus; bacteria are procaryotic and have their genetic material located in a nucleoid. *11, 91*

procaryotic species A collection of strains that share many stable properties and differ significantly from other groups of strains. *425*

prodromal stage (pro-dro′məl) The period during the course of a disease in which there is the appearance of signs and symptoms, but they are not yet distinctive and characteristic enough to make an accurate diagnosis. *850*

progametangium (pro-gam-ĕ″tan′je-um; pl., **progametangia**) The cell that gives rise to a gametangium and a proximal suspensor during the early stages of sexual reproduction in zygomycetous fungi. *560*

proliferative kidney disease (pro-lif′er-a-tiv) A protozoan disease caused by an unclassified myxozoan in salmonids throughout the world. *591*

promoter The region on DNA at the start of a gene that the RNA polymerase binds to before beginning transcription. *242, 262*

propagated epidemic An epidemic that is characterized by a relatively slow and prolonged rise and then a gradual decline in the number of individuals infected. It usually results from the introduction of an infected individual into a susceptible population, and the pathogen is transmitted from person to person. *851*

prophage (pro′fāj) The latent form of a temperate phage that remains within the lysogen, usually integrated into the host chromosome. *308, 390*

prostheca (pros-the′kah) An extension of a bacterial cell, including the plasma membrane and cell wall, that is narrower than the mature cell. *490*

prosthetic group (pros-thet′ik) A tightly bound cofactor that remains at the active site of an enzyme during its catalytic activity. *161*

protease (pro′te-ās) An enzyme that hydrolyzes proteins to their constituent amino acids. Also called a proteinase. *192*

proteasome A large, cylindrical protein complex that degrades ubiquitin-labeled proteins to peptides in an ATP-dependent process. *82*

protein engineering (pro′tēn) The rational design of proteins by constructing specific amino acid sequences through molecular techniques, with the objective of modifying protein characteristics. *994*

protein splicing The post-translational process in which part of a precursor polypeptide is removed before the mature polypeptide folds into its final shape; it is carried out by self-splicing proteins that remove inteins and join the remaining exteins. *275*

proteobacteria (pro″te-o-bak-tēr′-e-ah) A large group of bacteria, primarily gram-negative, that 16S rRNA sequence comparisons show to be phylogenetically related; proteobacteria contain the purple photosynthetic bacteria and their relatives and are composed of the α, β, γ, δ, and ϵ subgroups. *487*

proteome The complete collection of proteins that an organism produces. *356*

protists (pro′tist) Eucaryotes with unicellular organization, either in the form of solitary cells or colonies of cells lacking true tissues. *438*

protocooperation A positive, but not obligatory, interaction between two different organisms in which both parties benefit. *604*

protomer An individual subunit of a viral capsid; a capsomer is made of protomers. *369*

proton motive force (PMF) The force arising from a gradient of protons and a membrane potential that is thought to power ATP synthesis and other processes. *187*

protoplast (pro′to-plast) A bacterial or fungal cell with its cell wall completely removed. It is spherical in shape and osmotically sensitive. *49, 61*

protoplast fusion The joining of cells that have had their walls weakened or completely removed. *994*

protothecosis (pro″to-the-ko′sis; pl., **protothecoses**) A disease of humans and animals produced by the green alga *Prototheca moriformis.* *575*

prototroph (pro′to-trōf) A microorganism that requires the same nutrients as the majority of naturally occurring members of its species. *245*

protozoan or **protozoon** (pro″to-zo′an, pl. **protozoa**) A microorganism belonging to the *Protozoa* subkingdom. A unicellular or acellular eucaryotic protist whose organelles have the functional role of organs and tissues in more complex forms. Protozoa vary greatly in size, morphology, nutrition, and life cycle. *584*

protozoology (pro″to-zo-ol′o-je) The study of protozoa. *584*

proviral DNA Viral DNA that has been integrated into host cell DNA. In retroviruses it is the double-stranded DNA copy of the RNA genome. *407*

pseudomurein A modified peptidoglycan lacking D-amino acids and containing *N*-acetyltalosaminuronic acid instead of *N*-acetylmuramic acid; found in methanogenic archaea. *452*

pseudoplasmodium (soo″do-plaz-mo′de-um; pl., **pseudoplasmodia**) A sausage-shaped amoeboid structure consisting of many myxamoebae and behaving as a unit; the result of myxamoebal aggregation in the cellular slime molds; also called a slug. *565*

pseudopodium or **pseudopod** (soo″do-po′de-um) A nonpermanent cytoplasmic extension of the cell body by which amoebae and amoeboid organisms move and feed. *586*

psittacosis (ornithosis; sit″ah-ko′sis) A disease due to a strain of *Chlamydia psittaci,* first seen in parrots and later found in other birds and domestic fowl (in which it is called ornithosis). It is transmissible to humans. *919*

psychrophile (si′kro-fīl) A microorganism that grows well at 0°C and has an optimum growth temperature of 15°C or lower and a temperature maximum around 20°C. *126*

psychrotroph A microorganism that grows at 0°C, but has a growth optimum between 20 and 30°C, and a maximum of about 35°C. *126*

puerperal fever (pu-er′per-al) An acute, febrile condition following childbirth; it is characterized by infection of the uterus and/or adjacent regions and is caused by streptococci. *857*

pulmonary anthrax (pul′mo-ner″e) A form of anthrax involving the lungs. Also known as woolsorter's disease. *913*

pulmonary syndrome hantavirus *See* hantavirus pulmonary syndrome. *877*

pure culture A population of cells that are identical because they arise from a single cell. *106*

purine (pu′rin) A basic, heterocyclic, nitrogen-containing molecule with two joined rings that occurs in nucleic acids and other cell constituents; most purines are oxy or amino derivatives of the purine skeleton. The most important purines are adenine and guanine. *216*

purple membrane An area of the plasma membrane of *Halobacterium* that contains bacteriorhodopsin and is active in photosynthetic light energy trapping. *461*

putrefaction (pu″trĕ-fak′shun) The microbial decomposition of organic matter, especially the anaerobic breakdown of proteins, with the production of foul-smelling compounds such as hydrogen sulfide and amines. *965*

pyrenoid (pi′rĕ-noid) The differentiated region of the chloroplast that is a center of starch formation in green algae and stoneworts. *85, 573*

pyrimidine (pi-rim′i-dēn) A basic, heterocyclic, nitrogen-containing molecule with one ring that occurs in nucleic acids and other cell constituents; pyrimidines are oxy or amino derivatives of the pyrimidine skeleton. The most important pyrimidines are cytosine, thymine, and uracil. *216*

Q

Q fever An acute zoonotic disease caused by the rickettsia *Coxiella burnetii.* *912*

Quellung reaction The increase in visibility or the swelling of the capsule of a microorganism in the presence of antibodies against capsular antigens. *784*

quorum sensing The process in which bacteria monitor their own population density by sensing the levels of signal molecules that are released by the microorganisms. When these signal molecules reach a threshold concentration, the population density has attained a critical level or quorum, and quorum-dependent genes are expressed. *132*

R

rabies (ra′bēz) An acute infectious disease of the central nervous system, which affects all warm-blooded animals (including humans). It is caused by an ssRNA virus belonging to the genus *Lyssavirus* in the family *Rhabdoviridae.* *888*

racking The removal of sediments from wine bottles. *982*

radappertization The use of gamma rays from a cobalt source for control of microorganisms in foods. *972*

radioimmunoassay (RIA; ra″de-o-im″u-no-as′a) A very sensitive assay technique that uses a purified radioisotope-labeled antigen or antibody to compete for antibody or antigen with unlabeled standard and samples to determine the concentration of a substance in the samples. *783*

reactivation tuberculosis *See* miliary tuberculosis. *908*

reading frame The way in which nucleotides in DNA and mRNA are grouped into codons or groups of three for reading the message contained in the nucleotide sequence. *241*

reagin (re′ah-jin) Antibody that mediates immediate hypersensitivity reactions. IgE is the major reagin in humans. *768*

recombinant DNA technology The techniques used in carrying out genetic engineering; they involve the identification and isolation of a specific gene, the insertion of the gene into a vector such as a plasmid to form a recombinant molecule, and the production of large quantities of the gene and its products. *320*

recombinant-vector vaccine The type of vaccine that is produced by the introduction of one or more of a pathogen's genes into attenuated viruses or bacteria. The attenuated virus or bacterium serves as a vector, replicating within the vertebrate host and expressing the gene(s) of the pathogen. The pathogen's antigens induce an immune response. *767*

recombination (re″kom-bĭ-na′shun) The process in which a new recombinant chromosome is formed by combining genetic material from two organisms. *292*

recombination repair A DNA repair process that repairs damaged DNA when there is no remaining template; a piece of DNA from a sister molecule is used. *255*

Redfield ratio The carbon-nitrogen-phosphorus ratio of aquatic microorganisms. This ratio is important for predicting limiting factors for microbial growth. *638*

red tides Red tides occur frequently in coastal areas and often are associated with population blooms of dinoflagellates. Dinoflagellate pigments are responsible for the red color of the water. Under these conditions, the dinoflagellates often produce saxitoxin, which can lead to paralytic shellfish poisoning. *580*

reducing agent or **reductant** (re-duk′tant) The electron donor in an oxidation-reduction reaction. *157*

reductive dehalogenation The cleavage of carbon-halogen bonds by anaerobic bacteria that creates a strong electron-donating environment. *1010*

refraction (re-frak′shun) The deflection of a light ray from a straight path as it passes from one medium (e.g., glass) to another (e.g., air). *18*

refractive index (re-frak′tiv) The ratio of the velocity of light in the first of two media to that in the second as it passes from the first to the second. *18*

regulator T cell Regulator T cells control the development of effector T cells. Two types exist: T-helper cells ($CD4^+$ cells) and T-suppressor cells. There are three subsets of T-helper cells: T_H1, T_H2, and T_H0. T_H1 cells produce IL-2, IFN-γ, and TNF-β. They effect cell-mediated immunity and are responsible for delayed-type hypersensitivity reactions and macrophage activation. T_H2 cells produce IL-4, IL-5, IL-6, IL-10, IL-13. They are helpers for B-cell antibody responses and humoral immunity; they also support IgE responses and eosinophilia. T_H0 cells exhibit an unrestricted cytokine profile. *751*

regulatory mutants Mutant organisms that have lost the ability to limit synthesis of a product, which normally occurs by regulation of activity of an earlier step in the biosynthetic pathway. *1005*

regulon A collection of genes or operons that is controlled by a common regulatory protein. *281*

replica plating A technique for isolating mutants from a population by plating cells from each colony growing on a nonselective agar medium onto plates with selective media or environmental conditions, such as the lack of a nutrient or the presence of an antibiotic or a phage; the location of mutants on the original plate can be determined from growth patterns on the replica plates. *252*

replication (rep″lĭ-ka′shun) The process in which an exact copy of parental DNA or RNA is made with the parental molecule serving as a template. *230*

replication fork The Y-shaped structure where DNA is replicated. The arms of the Y contain template strand and a newly synthesized DNA copy. *235*

replicative form A double-stranded form of nucleic acid that is formed from a single-stranded virus genome and used to synthesize new copies of the genome. *388, 406*

replicon (rep′lĭ-kon) A unit of the genome that contains an origin for the initiation of replication and in which DNA is replicated. *235, 294*

repressible enzyme An enzyme whose level drops in the presence of a small molecule, usually an end product of its metabolic pathway. *276*

repressor protein (re-pres′or) A protein coded for by a regulator gene that can bind to the operator and inhibit transcription; it may be active by itself or only when the corepressor is bound to it. *276*

reservoir (rez′er-vwar) A site, alternate host, or carrier that normally harbors pathogenic organisms and serves as a source from which other individuals can be infected. *791, 854*

reservoir host An organism other than a human that is infected with a pathogen that can also infect humans. *789*

residuesphere The region surrounding organic matter such as a seed or plant part in which microbial growth is stimulated by increased organic matter availability. *690*

resolution (rez″o-lu′shun) The ability of a microscope to separate or distinguish between small objects that are close together. *20*

respiration (res″ pĭ-ra′ shən) An energy-yielding process in which the energy substrate is oxidized using an exogenous or externally derived electron acceptor. *173*

respiratory burst The respiratory burst occurs when an activated phagocytic cell increases its oxygen consumption to support the increased metabolic activity of phagocytosis. The burst generates highly toxic oxygen products such as singlet oxygen, superoxide radical, hydrogen peroxide, hydroxyl radical, and hypochlorite. *720*

respiratory syncytial virus (RSV; sin-sish′al) A member of the family *Paramyxoviridae* and genus *Pneumovirus;* it is a negative-sense ssRNA virus that causes respiratory infections in children. *875*

restricted transduction A transduction process in which only a specific set of bacterial genes are carried to another bacterium by a temperate phage; the bacterial genes are acquired because of a mistake in the excision of a prophage during the lysogenic life cycle. *309*

restriction enzymes Enzymes produced by host cells that cleave virus DNA at specific points and thus protect the cell from virus infection; they are used in carrying out genetic engineering. *320, 386*

reticulate body (RB) The form in the chlamydial life cycle whose role is growth and reproduction within the host cell. *477*

retroviruses (re″tro-vi′rus-es) A group of viruses with RNA genomes that carry the enzyme reverse transcriptase and form a DNA copy of their genome during their reproductive cycle. *407*

reverse transcriptase (RT) An RNA-dependent DNA polymerase that uses a viral RNA genome as a template to form a DNA copy; this is a reverse of the normal flow of genetic information, which proceeds from DNA to RNA. *407, 879*

reversible covalent modification A mechanism of enzyme regulation in which the enzyme's activity is either increased or decreased by the reversible covalent addition of a group such as phosphate or AMP to the protein. *167*

Reye's syndrome An acute, potentially fatal disease of childhood that is characterized by severe edema of the brain and increased intracranial pressure, vomiting, hypoglycemia, and liver dysfunction. The cause is unknown but is almost always associated with a previous viral infection (e.g., influenza or varicella-zoster virus infections). *874*

R factors or **R plasmids** Plasmids bearing one or more drug resistant genes. *297, 819*

rheumatic fever (roo-mat′ik) An autoimmune disease characterized by inflammatory lesions involving the heart valves, joints, subcutaneous tissues, and central nervous system. The disease is associated with hemolytic streptococci in the body. It is called rheumatic fever because two common symptoms are fever and pain in the joints similar to that of rheumatism. *905*

rhizosphere A region around the plant root where materials released from the root increase the microbial population and its activities. *675*

rho factor (ro) The protein that helps RNA polymerase dissociate from the terminator after it has stopped transcription. *263*

rhoptry Saclike, electron dense structure in the anterior portion of a zoite of a member of the phylum *Apicomplexa;* perhaps involved in the penetration of host cells. *591*

ribonucleic acid (RNA; ri″bo-nu-kle′ik) A polynucleotide composed of ribonucleotides joined by phosphodiester bridges. *230*

ribosomal RNA (rRNA) The RNA present in ribosomes; ribosomes contain several sizes of single-stranded rRNA that contribute to ribosome structure and are also directly involved in the mechanism of protein synthesis. *261*

ribosome (ri′bo-sōm) The organelle where protein synthesis occurs; the message encoded in mRNA is translated here. *52, 267*

ribotyping Ribotyping is the use of *E. coli* rRNA to probe chromosomal DNA in Southern blots for typing bacterial strains. This method is based on the fact that rRNA genes are scattered throughout the chromosome of most bacteria and therefore polymorphic restriction endonuclease patterns result when chromosomes are digested and probed with rRNA. *843*

ribulose-1,5-bisphosphate carboxylase (ri′bu-lōs) The enzyme that catalyzes the incorporation of CO_2 in the Calvin cycle. *208*

ringworm (ring′werm) The common name for a fungal infection of the skin, even though it is not caused by a worm and is not always ring-shaped in appearance. *943*

rise period or **burst** The period during the one-step growth experiment when host cells lyse and release phage particles. *383*

RNA polymerase The enzyme that catalyzes the synthesis of mRNA under the direction of a DNA template. *261*

Rocky Mountain spotted fever A disease caused by *Rickettsia rickettsii.* *913*

rolling-circle mechanism A mode of DNA replication in which the replication fork moves around a circular DNA molecule, displacing a strand to give a tail that is also copied to produce a new double-stranded DNA. *236*

root nodule Gall-like structures on roots that contain endosymbiotic nitrogen-fixing bacteria (e.g., *Rhizobium* or *Bradyrhizobium* is present in legume nodules). *676*

roseola infantum (ro-ze′o-lə) A skin eruption that produces a rose-colored rash in infants. Caused by the human herpesvirus 6. The disease is short-lived and characterized by a high fever of 3 to 4 days' duration. *887*

rubella A moderately contagious skin disease that occurs primarily in children 5 to 9 years of age that is caused by the rubella virus, which is acquired by droplet inhalation into the respiratory system; German measles. *875*

rubeola *See* measles. *873*

rumen (roo-men) The expanded upper portion or first compartment of the stomach of ruminants. *602*

ruminant (roo′mĭ-nant) An herbivorous animal that has a stomach divided into four compartments and chews a cud consisting of regurgitated, partially digested food. *602*

run The straight line movement of a bacterium. *67*

S

salmonellosis (sal″mo-nel-o′sis) An infection with certain species of the genus *Salmonella,* usually caused by ingestion of food containing salmonellae or their products. Also known as *Salmonella* gastroenteritis or *Salmonella* food poisoning. *931*

sanitization (san″ĭ-ti-za′shun) Reduction of the microbial population on an inanimate object to levels judged safe by public health standards; usually, the object is cleaned. *138*

saprophyte (sap′ro-fit) An organism that takes up nonliving organic nutrients in dissolved form and usually grows on decomposing organic matter. *557*

saprozoic nutrition (sap″ro-zo′ik) Having the type of nutrition in which organic nutrients are taken up in dissolved form; normally refers to animals or animal-like organisms. *586*

satellite phenomenon *See* syntrophism. *604*

scaffolding proteins Special proteins that are used to aid procapsid construction during the assembly of a bacteriophage capsid and are removed after the completion of the procapsid. *388*

scale (skāl) A platelike organic structure found on the surface of some cells (chrysophytes). *577*

scanning electron microscope (SEM) An electron microscope that scans a beam of electrons over the surface of a specimen and forms an image of the surface from the electrons that are emitted by it. *34*

scanning probe microscope A microscope used to study surface features by moving a sharp probe over the object's surface (e.g., the scanning tunneling microscope). *38*

scanning tunneling microscope A type of scanning probe microscope used to image a surface by moving a fine probe over it at a constant height, which is maintained by keeping a constant electron flow (tunneling current) between the tip and surface. *38*

scarlatina (skahr″la-te′nah) *See* scarlet fever. *905*

scarlet fever (scarlatina; skar′let) A disease that results from infection with a strain of *Streptococcus pyogenes* that carries a lysogenic phage with the gene for erythrogenic (rash-inducing) toxin. The toxin causes shedding of the skin. This is a communicable disease spread by respiratory droplets. *905*

schizogony (skĭ-zog′o-ne) Multiple asexual fission. *591*

secondary metabolites Products of metabolism that are synthesized after growth has been completed. *1002*

secondary treatment The biological degradation of dissolved organic matter in the process of sewage treatment; the organic material is either mineralized or changed to settleable solids. *659*

second law of thermodynamics Physical and chemical processes proceed in such a way that the entropy of the universe (the system and its surroundings) increases to the maximum possible. *156*

secretory IgA (sIgA) The primary immunoglobulin of the secretory immune system. *See* IgA. *738*

secretory vacuole In protists and some animals, these organelles usually contain specific enzymes that perform various functions such as excystation. Their contents are released to the cell exterior during exocytosis. *585*

segmented genome A virus genome that is divided into several parts or fragments, each probably coding for the synthesis of a single polypeptide; segmented genomes are very common among the RNA viruses. *374*

selectins (sə-lek′tins) A family of cell adhesion molecules that are displayed on activated endothelial cells; examples include P-selectin and E-selectin. Selectins mediate leukocyte binding to the vascular endothelium. *712*

selective media Culture media that favor the growth of specific microorganisms; this may be accomplished by inhibiting the growth of undesired microorganisms. *105*

selective toxicity The ability of a chemotherapeutic agent to kill or inhibit a microbial pathogen while damaging the host as little as possible. *807*

self-assembly The spontaneous formation of a complex structure from its component molecules without the aid of special enzymes or factors. *65, 207*

sepsis (sep′sis) Systemic response to infection. This systemic response is manifested by two or more of the following conditions as a result of infection: temperature >38 or <36°C; heart rate >90 beats per min; respiratory rate >20 breaths per min, or $pCO_2 < 32$ mm Hg; leukocyte count $>12{,}000$ cells per ml^3 or $>10\%$ immature (band) forms. Sepsis also has been defined as the presence of pathogens or their toxins in blood and other tissues. *933*

septate (sep′tāt) Divided by a septum or cross wall; also with more or less regular occurring cross walls. *556*

septic shock (sep′tik) Sepsis associated with severe hypotension despite adequate fluid resuscitation, along with the presence of perfusion abnormalities that may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status. Gram-positive bacteria, fungi, and endotoxin-containing gram-negative bacteria can initiate the pathogenic cascade of sepsis leading to septic shock. *933*

septicemia (sep″tĭ-se′me-ah) A disease associated with the presence in the blood of pathogens or bacterial toxins. *514, 793*

septic tank (sep′tik) A tank used to process small quantities of domestic sewage. Solid material settles out and is partially degraded by anaerobic bacteria as sewage slowly flows through the tank. The outflow is further treated or dispersed in aerobic soil. *663*

septum (sep′tum; pl., **septa**) A partition or cross-wall that occurs between two cells in a bacterial (e.g., actinomycete) or fungal filament, or which partitions off fungal structures such as spores. Septa also divide parent cells into two daughter cells during bacterial binary fission. *286, 556*

serology (se-rol′o-je) The branch of immunology that is concerned with in vitro reactions involving one or more serum constituents (e.g., antibodies and complement). *774*

serotyping A technique or serological procedure that is used to differentiate between strains (serovars or serotypes) of microorganisms that have differences in the antigenic composition of a structure or product. *784*

serum (se′rum; pl., **serums** or **sera**) The clear, fluid portion of blood lacking both blood cells and fibrinogen. It is the fluid remaining after coagulation of plasma, the noncellular liquid faction of blood. *742*

serum resistance The type of resistance that occurs with bacteria such as *Neisseria gonorrhoeae* because the pathogen interferes with membrane attack complex formation during the complement cascade. *801*

settling basin A basin used during water purification to chemically precipitate out fine particles, microorganisms, and organic material by coagulation or flocculation. *652*

sex pilus (pi′lus) A thin protein appendage required for bacterial mating or conjugation. The cell with sex pili donates DNA to recipient cells. *63, 303*

sheath (shēth) A hollow tubelike structure surrounding a chain of cells and present in several genera of bacteria. *496*

shigellosis (shĭ′gəl-o′sis) The diarrheal disease that arises from an infection with a member of the genus *Shigella.* Often called bacillary dysentery. *931*

SHIME system (simulated human intestinal microbial ecosystem) A set of connected chemostat-like reactors that provide a sequence of environments similar to the human digestive system. *987*

Shine-Dalgarno sequence A segment in the leader of procaryotic mRNA that binds to a special sequence on the 16S rRNA of the small ribosomal subunit. This helps properly orient the mRNA on the ribosome. *244*

shingles (zoster; shing′g′lz) A reactivated form of chickenpox caused by the varicella-zoster virus. *872*

siderophore (sid′er-o-for″) A small molecule that complexes with ferric iron and supplies it to a cell by aiding in its transport across the plasma membrane. *104*

sigma factor A protein that helps the RNA polymerase core enzyme recognize the promoter at the start of a gene. *262*

sign An objective change in a diseased body that can be directly observed (e.g., a fever or rash). *850*

silage Fermented plant material with increased palatability and nutritional value for animals, which can be stored for extended periods. *986*

silent mutation A mutation that does not result in a change in the organism's proteins or phenotype even though the DNA base sequence has been changed. *249*

simple matching coefficient (S_{SM}) An association coefficient used in numerical taxonomy; the proportion of characters that match regardless of whether or not the attribute is present. *426*

single radial immunodiffusion (RID) assay An immunodiffusion technique that quantitates antigens by following their diffusion through a gel containing antibodies directed against the test antigens. *779*

site-specific recombination Recombination of nonhomologous genetic material with a chromosome at a specific site. *292*

skin-associated lymphoid tissue (SALT) The lymphoid tissue in the skin that forms a first-line defense as a part of nonspecific immunity. *709*

slash-and-burn agriculture The cutting down and burning of tropical vegetation to make mineral nutrients available for use by introduced agricultural crops. *672*

S-layer A regularly structured layer composed of protein or glycoprotein that lies on the surface of many bacteria. It may protect the bacterium and help give it shape and rigidity. *62*

slime The viscous extracellular glycoproteins or glycolipids produced by staphylococci and *Pseudomonas aeruginosa* bacteria that allows them to adhere to smooth surfaces such as prosthetic medical devices and catheters. More generally, the term often refers to an easily removed, diffuse, unorganized layer of extracellular material that surrounds a bacterial cell. *61, 919*

slime layer A layer of diffuse, unorganized, easily removed material lying outside the bacterial cell wall. *61*

slime mold A common term for members of the divisions *Acrasiomycota* and *Myxomycota.* *564*

slow sand filter A bed of sand through which water slowly flows; the gelatinous microbial layer on the sand grain surface removes waterborne microorganisms, particularly *Giardia,* by adhesion to the gel. This type of filter is used in some water purification plants. *653*

slow virus disease A progressive, pathological process caused by a transmissible agent (virus or prion) that remains clinically silent during a prolonged incubation period of months to years after which progressive clinical disease becomes apparent. *410, 893*

sludge (sluj) A general term for the precipitated solid matter produced during water and sewage treatment; solid particles composed of organic matter and microorganisms that are involved in aerobic sewage treatment (activated sludge). *658*

smallpox (variola; smawl′poks) Once a highly contagious, often fatal disease caused by a poxvirus. Its most noticeable symptom was the appearance of blisters and pustules on the skin. Vaccination has eradicated smallpox throughout the world. *876*

snapping division A distinctive type of binary fission resulting in an angular or a palisade arrangement of cells, which is characteristic of the genera *Arthrobacter* and *Corynebacterium.* *542*

sorocarp The fruiting structure of the Acrasiomycetes. *565*

sorus A type of fruiting structure composed of a mass of spores or sporangia. *565*

SOS repair A complex, inducible repair process that is used to repair DNA when extensive damage has occurred. *255*

source The location or object from which a pathogen is immediately transmitted to the host, either directly or through an intermediate agent. *854*

Southern blotting technique The procedure used to isolate and identify DNA fragments from a complex mixture. The isolated, denatured fragments are transferred from an agarose electrophoretic gel to a nitrocellulose filter and identified by hybridization with probes. *322*

specialized transduction *See* restricted transduction. *309*

species (spe′shēz) Species of higher organisms are groups of interbreeding or potentially interbreeding natural populations that are reproductively isolated. Bacterial species are collections of strains that have many stable properties in common and differ significantly from other groups of strains. *425*

specific immune response (acquired or specific immunity) *See* acquired immunity. *705*

spermosphere The region surrounding a germinating seed where released organic matter stimulates microbial growth. *974*

spheroplast (sfēr′o-plast) A relatively spherical cell formed by the weakening or partial removal of the rigid cell wall component (e.g., by penicillin treatment of gram-negative bacteria). Spheroplasts are usually osmotically sensitive. *61*

spike *See* peplomer. *374*

spirillum (spi-ril′um) A rigid, spiral-shaped bacterium. *44*

spirochete (spi′ro-kēt) A flexible, spiral-shaped bacterium with periplasmic flagella. *44, 479*

spleen (splēn) A secondary lymphoid organ where old erythrocytes are destroyed and blood-borne antigens are trapped and presented to lymphocytes. *708*

split or interrupted gene A structural gene with DNA sequences that code for the final RNA product (expressed sequences or exons) separated by regions coding for RNA absent from the mature RNA (intervening sequences or introns). *263*

spongiform encephalopathies Degenerative central nervous system diseases in which the brain has a spongy appearance; they appear due to prions. *893*

spontaneous generation (spon-ta′ne-us) The hypothesis that living organisms can arise from nonliving matter. *2*

sporadic disease (spo-rad′ik) A disease that occurs occasionally and at random intervals in a population. *849*

sporangiospore (spo-ran′je-o-spōr) A spore born within a sporangium. *539, 557*

sporangium (spo-ran′je-um; pl., **sporangia**) A saclike structure or cell, the contents of which are converted into an indefinite number of spores. It is borne on a special hypha called a sporangiophore. *68, 557*

spore (spōr) A differentiated, specialized form that can be used for dissemination, for survival of adverse conditions because of its heat and dessication resistance, and/or for reproduction. Spores are usually unicellular and may develop into vegetative organisms or gametes. They may be produced asexually or sexually and are of many types. *573*

sporogenesis (spor′o-jen′ĕ-sis) *See* sporulation. *69*

sporotrichosis (spo″ro-tri-ko′sis) A subcutaneous fungal infection caused by the dimorphic fungus *Sporothrix schenckii.* *945*

sporulation (spor″u-la′shun) The process of spore formation. *69*

spread plate A petri dish of solid culture medium with isolated microbial colonies growing on its surface, which has been prepared by spreading a dilute microbial suspension evenly over the agar surface. *106*

sputum (spu′tum) The mucous secretion from the lungs, bronchi, and trachea that is ejected (expectorated) through the mouth. *829*

stalk (stawk) A nonliving bacterial appendage produced by the cell and extending from it. *490*

standard free energy change The free energy change of a reaction at 1 atmosphere pressure when all reactants and products are present in their standard states; usually the temperature is 25°C. *156*

standard reduction potential A measure of the tendency of a reductant to lose electrons in an oxidation-reduction (redox) reaction. The more negative the reduction potential of a compound, the better electron donor it is. *157*

staphylococcal food poisoning (staf″i-lo-kok′al) A type of food poisoning caused by ingestion of improperly stored or cooked food in which *Staphylococcus aureus* has grown. The bacteria produce exotoxins that accumulate in the food. *932*

staphylococcal scalded skin syndrome (SSSS) A disease caused by staphylococci that produce an exfoliative toxin. The skin becomes red (erythema) and sheets of epidermis may separate from the underlying tissue. *922*

starter culture An inoculum, consisting of a mixture of carefully selected microorganisms, used to start a commercial fermentation. *978*

stationary phase (sta′shun-er″e) The phase of microbial growth in a batch culture when population growth ceases and the growth curve levels off. *114*

statistics (stah-tis′tiks) The mathematics of the collection, organization, and interpretation of numerical data. *849*

stem-nodulating rhizobia Rhizobia (members of the genera *Rhizobium, Bradyrhizobium,* and *Azorhizobium*) that produce nitrogen-fixing structures above the soil surface on plant stems. These most often are observed in tropical plants and produced by *Azorhizobium.* *682*

sterilization (ster″ĭ-lĭ-za′shun) The process by which all living cells, viable spores, viruses, and viroids are either destroyed or removed from an object or habitat. *137*

stigma (stig′mah) A light-sensitive eyespot, which is found in some algae and photosynthetic protozoa; it is believed to be involved in phototaxis, at least in some cases. *575*

stoneworts A group of approximately 250 species of algae that have a complex growth pattern, with nodal regions from which whorls of branches arise; they are abundant in fresh to brackish waters. *576*

strain A population of organisms that descends from a single organism or pure culture isolate. *425*

streak plate A petri dish of solid culture medium with isolated microbial colonies growing on its surface, which has been prepared by spreading a microbial mixture over the agar surface, using an inoculating loop. *107*

streptococcal pneumonia An endogenous infection of the lungs caused by *Streptococcus pneumoniae* that occurs in predisposed individuals. *905*

streptococcal sore throat (strep″to-kok′al) One of the most common bacterial infections of humans. It is commonly referred to as "strep throat." The disease is spread by droplets of saliva or nasal secretions and is caused by *Streptococcus* spp. (particularly group A streptococci). *905*

streptolysin-O (SLO) (strep-tol′ĭ-sin) A specific hemolysin produced by *Streptococcus pyogenes* that is inactivated by oxygen (hence the "O" in its name). SLO causes beta-hemolysis of blood cells on agar plates incubated anaerobically. *797*

streptolysin-S (SLS) A product produced by *Streptococcus pyogenes* that is bound to the bacterial cell but may sometimes be released. SLS causes beta hemolysis on aerobically incubated blood-agar plates and can act as a leukocidin by killing leukocytes that phagocytose the bacterial cell to which it is bound. *797*

streptomycin (strep′to-mi″sin) A bactericidal aminoglycoside antibiotic produced by *Streptomyces griseus.* *816*

strict anaerobes *See* obligate anaerobes. *127*

stroma (stro′mah) The chloroplast matrix that is the location of the photosynthetic carbon dioxide fixation reactions. *85*

stromatolite (stro″mah-to′līt) Dome-like microbial mat communities consisting of filamentous photosynthetic bacteria and occluded sediments (often calcareous or siliceous). They usually have a laminar structure. Many are fossilized, but some modern forms occur. *423*

structural gene A gene that codes for the synthesis of a polypeptide or polynucleotide with a nonregulatory function. *277*

subacute sclerosing panencephalitis Diffuse inflammation of the brain resulting from virus and prion infections. *874*

subgingival plaque (sub-jin′jĭ-val) The plaque that forms at the dentogingival margin and extends down into the gingival tissue. *936*

substrate-level phosphorylation The synthesis of ATP from ADP by phosphorylation coupled with the exergonic breakdown of a high-energy organic substrate molecule. *177*

subsurface biosphere The region below the plant root zone where microbial populations can grow and function. *691*

sulfate reduction (sul′fāt) The process of sulfate use as an oxidizing agent, which results in the accumulation of reduced forms of sulfur such as sulfide, or incorporation of sulfur into organic molecules, usually as sulfhydryl groups. *614*

sulfonamide (sul-fon′ah-mīd) A chemotherapeutic agent that has the SO_2-NH_2 group and is a derivative of sulfanilamide. *812*

superantigen Superantigens are bacterial proteins that stimulate the immune system much more extensively than do normal antigens. They stimulate T cells to proliferate nonspecifically through simultaneous interaction with class II MHC proteins on antigen-presenting cells and variable regions on the β chain of the T-cell receptor complex. Examples include streptococcal scarlet fever toxins, staphylococcal toxic shock syndrome toxin-1, and streptococcal M protein. *732*

superinfection (soo″per-in-fek′shun) A new bacterial or fungal infection of a patient that is resistant to the drug(s) being used for treatment. *819*

superoxide dismutase (SOD; soo″per-ok′sīd dis-mu′tas) An enzyme that protects many microorganisms by catalyzing the destruction of the toxic superoxide radical. *128*

suppressor mutation A mutation that overcomes the effect of another mutation and produces the normal phenotype. *248*

Svedberg unit (sfed′berg) The unit used in expressing the sedimentation coefficient; the greater a particle's Svedberg value, the faster it travels in a centrifuge. *52*

swab (swahb) A wad of absorbent material usually wound around one end of a small stick and used for applying medication or for removing material from an area; also, a dacron-tipped polystyrene applicator. *827*

swarm cell A flagellated cell; the term is usually applied to the motile cells of the *Myxomycota*. *565*

symbiosis (sim″bi-o′sis) The living together or close association of two dissimilar organisms, each of these organisms being known as a symbiont. *596*

symbiosome The final nitrogen-fixing form of *Rhizobium* that is active within root nodule cells. *676*

symptom (simp′təm) A change during a disease that a person subjectively experiences (e.g., pain, bodily discomfort, fatigue, or loss of appetite). Sometimes the term symptom is used more broadly to include any observed signs. *850*

syndrome *See* disease syndrome. *850*

synthetic medium *See* defined medium. *105*

syntrophism (sin′trōf-izəm) The association in which the growth of one organism either depends on, or is improved by, the provision of one or more growth factors or nutrients by a neighboring organism. Sometimes both organisms benefit. This type of mutualism is also known as cross-feeding or the satellite phenomenon. *604*

syphilis (sif′ĭ-lis) *See* venereal syphilis. *923*

systematic epidemiology The field of epidemiology that focuses on the ecological and social factors that influence the development of emerging and reemerging infectious diseases. *859*

systematics (sis″te-mat′iks) The scientific study of organisms with the ultimate objective being to characterize and arrange them in an orderly manner; often considered synonymous with taxonomy. *422*

systemic lupus erythematosus (loo′pus er″ĭ-them-ah-to′sus) An autoimmune, inflammatory disease that may affect every tissue of the body. *770*

T

taxon (tak′son) A group into which related organisms are classified. *422*

taxonomy (tak-son′o-me) The science of biological classification; it consists of three parts: classification, nomenclature, and identification. *422*

TB skin test Tuberculin hypersensitivity test for a previous or current infection with *Mycobacterium tuberculosis*. *771*

T cell or **T lymphocyte** A type of lymphocyte derived from bone marrow stem cells that matures into an immunologically competent cell under the influence of the thymus. T cells are involved in a variety of cell-mediated immune reactions. *705, 745*

T-cell antigen receptor (TCR) The receptor on the T cell surface consisting of two antigen-binding peptide chains; it is associated with a large number of other glycoproteins. Binding of antigen to the TCR, usually in association with MHC, activates the T cell. *745*

T-dependent antigen An antigen that effectively stimulates B-cell response only with the aid of T-helper cells that produce interleukin-2 and B-cell growth factor. *753*

teichoic acids (ti-ko′ik) Polymers of glycerol or ribitol joined by phosphates; they are found in the cell walls of gram-positive bacteria. *56*

temperate phages Bacteriophages that can infect bacteria and establish a lysogenic relationship rather than immediately lysing their hosts. *308, 390*

template strand (tem′plat) A strand of DNA or RNA that specifies the base sequence of a newly synthesized complementary strand of DNA or RNA. *242*

terminator A sequence that marks the end of a gene and stops transcription. *244, 263*

tertiary treatment (ter′she-er-e) The removal from sewage of inorganic nutrients, heavy metals, viruses, etc., by chemical and biological means after microorganisms have degraded dissolved organic material during secondary sewage treatment. *661*

test A loose-fitting shell of an amoeba. *590*

tetanolysin (tet″ah-nol′ĭ-sin) A hemolysin that aids in tissue destruction and is produced by *Clostridium tetani*. *925*

tetanospasmin (tet″ah-no-spaz′min) The neurotoxic component of the tetanus toxin, which causes the muscle spasms of tetanus. Tetanospasmin production is under the control of a plasmid gene. *924*

tetanus (tet′ah-nus) An often fatal disease caused by the anaerobic, spore-forming bacillus *Clostridium tetani*, and characterized by muscle spasms and convulsions. *924*

tetracyclines (tet″rah-si′klēns) A family of antibiotics with a common four-ring structure, which are isolated from the genus *Streptomyces* or produced semisynthetically; all are related to chlortetracycline or oxytetracycline. *815*

tetrapartite associations (tet″rah-par′tīt) A mutualistic association of the same plant with three different types of microorganisms. *685*

T_H1 cell *See* regulator T cell. *751*

T_H2 cell *See* regulator T cell. *751*

T_H0 cell *See* regulator T cell. *751*

thallus (thal′us) A type of body that is devoid of root, stem, or leaf; characteristic of some algae, many fungi, and lichens. *537, 554, 573*

T-helper (T_H) cell A cell that is needed for T-cell–dependent antigens to be effectively presented to B cells. It also promotes cell-mediated immune responses. *751*

theory A set of principles and concepts that have survived rigorous testing and that provide a systematic account of some aspect of nature. *8*

thermal death time (TDT) The shortest period of time needed to kill all the organisms in a microbial population at a specified temperature and under defined conditions. *140*

thymus (thi′məs) A primary lymphoid organ in the chest that is necessary in early life for the development of immunological functions. T-cell maturation takes place here. *708*

thermoacidophiles A group of bacteria that grow best at acid pHs and high temperatures; they are members of the *Archaea*. *457*

thermophile (ther′mo-fīl) A microorganism that can grow at temperatures of 55°C or higher; the minimum is usually around 45°C. *126*

thrush (thrush) Infection of the oral mucous membrane by the fungus *Candida albicans;* also known as oral candidiasis. *949*

thylakoid (thi′lah-koid) A flattened sac in the chloroplast stroma that contains photosynthetic pigments and the photosynthetic electron transport chain; light energy is trapped and used to form ATP and NAD(P)H in the thylakoid membrane. *85*

thymine (thi′min) The pyrimidine 5-methyluracil that is found in nucleosides, nucleotides, and DNA. *217*

T-independent antigen An antigen that triggers a B cell into immunoglobulin production without T-cell cooperation. *754*

Ti or Ri plasmid A plasmid obtained from *Agrobacterium tumefaciens* that is used to insert genes into plant cells. *339, 684*

tinea (tin′e-ah) A name applied to many different kinds of superficial fungal infections of the skin, nails, and hair, the specific type (depending on characteristic appearance, etiologic agent, and site) usually designated by a modifying term. *943*

tinea capitis A fungal infection of scalp hair caused by species of *Trichophyton* or *Microsporum*. *943*

tinea corporis A fungal infection of the smooth parts of the skin caused by either *Trichophyton rubrum, T. mentagrophytes,* or *Microsporum canis*. *943*

tinea cruris A fungal infection of the groin caused by either *Epidermophyton floccosum, Trichophyton mentagrophytes,* or *T. rubrum;* also known as jock itch. *944*

tinea manuum A fungal infection of the hand caused by *Trichophyton rubrum, T. mentagrophytes,* or *E. floccosum*. *944*

tinea pedis A fungal infection of the foot caused by *Trichophyton rubrum, T. mentagrophytes,* or *E. floccosum;* also known as athlete's foot. *944*

tinea unguium A fungal infection of the nail bed caused by either *Trichophyton rubrum* or *T. mentagrophytes*. *944*

tinea versicolor A fungal infection caused by the yeast, *Malassezia furfur,* that forms brownish-red scales on the skin of the trunk, neck, face, and arms. *943*

titer (ti′ter) Reciprocal of the highest dilution of an antiserum that gives a positive reaction in the test being used. *742*

T lymphocyte *See* T cell. *705*

tonsillitis (ton′si-li′tis) Inflammation of the tonsils, especially the palatine tonsils often due to *S. pyogenes* infection. *905*

toxemia (tok-se′me-ah) The condition caused by toxins in the blood of the host. *794*

toxic shock-like syndrome (TSLS) A disease caused by an invasive group A streptococcus infection that is characterized by a rapid drop in blood pressure, failure of many organs, and a very high fever. It probably results from the release of one or more streptococcal pyrogenic exotoxins. *904*

toxic shock syndrome (tok′sik) A staphylococcal disease that most commonly affects females who

use certain types of tampons during menstruation. It is associated with the production of toxic shock syndrome toxin by certain strains of *Staphylococcus aureus*. *922*

toxigenicity (tok″sĭ-jĕ-nis′i-tē) The capacity of an organism to produce a toxin. *790*

toxin (tok′sin) A microbial product or component that can injure another cell or organism at low concentrations. Often the term refers to a poisonous protein, but toxins may be lipids and other substances. *794*

toxin neutralization The inactivation of toxins by specific antibodies, called antitoxins, that react with them. *756*

toxoid (tok′soid) A bacterial exotoxin that has been modified so that it is no longer toxic but will still stimulate antitoxin formation when injected into a person or animal. *767, 796*

toxoplasmosis (tok″so-plaz-mo′sis) A disease of animals and humans caused by the parasitic protozoan, *Toxoplasma gondii*. *957*

trachoma (trah-ko′mah) A chronic infectious disease of the conjunctiva and cornea, producing pain, inflammation and sometimes blindness. It is caused by *Chlamydia trachomatis* serotypes A–C. *925*

transamination (trans″am-i-na′shun) The removal of amino acid's amino group by transferring it to an α-keto acid acceptor. *192*

transcriptase (trans-krip′tās) An enzyme that catalyzes transcription; in viruses with RNA genomes, this enzyme is an RNA-dependent RNA polymerase that is used to make RNA copies of the RNA genomes. *406*

transcription (trans-krip′shun) The process in which single-stranded RNA with a base sequence complementary to the template strand of DNA or RNA is synthesized. *230*

transduction (trans-duk′shun) The transfer of genes between bacteria by bacteriophages. *308*

transfer host (trans′fer) A host that is not necessary for the completion of a parasite's life cycle, but is used as a vehicle for reaching a final host. *789*

transfer RNA (tRNA) A small RNA that binds an amino acid and delivers it to the ribosome for incorporation into a polypeptide chain during protein synthesis. *261*

transformation (trans″for-ma′shun) A mode of gene transfer in bacteria in which a piece of free DNA is taken up by a bacterial cell and integrated into the recipient genome. *228, 305*

transgenic animal or **plant** An animal or plant that has gained new genetic information from the insertion of foreign DNA. It may be produced by such techniques as injecting DNA into animal eggs, electroporation of mammalian cells and plant cell protoplasts, or shooting DNA into plant cells with a gene gun. *335*

transient carrier *See* casual carrier. *854*

transition mutations (tran-zish′un) Mutations that involve the substitution of a different purine base for the purine present at the site of the mutation or the substitution of a different pyrimidine for the normal pyrimidine. *246*

translation (trans-la′shun) Protein synthesis; the process by which the genetic message carried by mRNA directs the synthesis of polypeptides with the aid of ribosomes and other cell constituents. *230*

transmission electron microscope (trans-mish′un) A microscope in which an image is formed by passing an electron beam through a specimen and focusing the scattered electrons with magnetic lenses. *30*

transovarian passage (trans″o-va′re-an) The passage of a microorganism such as a rickettsia from generation to generation of hosts through tick eggs. (No humans or other mammals are needed as reservoirs for continued propagation of the rickettsias.) *913*

transpeptidation 1. The reaction that forms the peptide cross-links during peptidoglycan synthesis. 2. The reaction that forms a peptide bond during the elongation cycle of protein synthesis. *223, 270*

transposable elements *See* transposon. *298*

transposition (trans″po-zish′un) The movement of a piece of DNA around the chromosome. *298*

transposon (tranz-po′zon) A DNA segment that carries the genes required for transposition and moves about the chromosome; if it contains genes other than those required for transposition, it may be called a composite transposon. Often the name is reserved only for transposable elements that also contain genes unrelated to transposition. *298*

transversion mutations (trans-ver′zhun) Mutations that result from the substitution of a purine base for the normal pyrimidine or a pyrimidine for the normal purine. *246*

traveler's diarrhea A type of diarrhea resulting from ingestion of certain viruses, bacteria, or protozoa normally absent from the traveler's environment. One of the major pathogens is enterotoxigenic *Escherichia coli*. *932*

tricarboxylic acid cycle (TCA) The cycle that oxidizes acetyl coenzyme A to CO_2 and generates NADH and $FADH_2$ for oxidation in the electron transport chain; the cycle also supplies carbon skeletons for biosynthesis. *183, A–16*

trichome (tri′kōm) A row or filament of bacterial cells that are in close contact with one another over a large area. *472*

trichomoniasis (trik″o-mo-ni′ah-sis) A sexually transmitted disease caused by the parasitic protozoan *Trichomonas vaginalis*. *958*

trickling filter A bed of rocks covered with a microbial film that aerobically degrades organic waste during secondary sewage treatment. *659*

trihalomethanes (THMs) Halogenated one-carbon compounds formed during water disinfection; many of these compounds are potential carcinogens. *653*

tripartite associations (tri-par′tīt) A mutualistic association of the same plant with two types of microorganisms. *685*

trophozoite (trof″ o-zo′īt) The active, motile feeding stage of a protozoan organism; in the malarial parasite, the stage of schizogony between the ring stage and the schizont. *586*

tropism (tro′piz-əm) The movement of living organisms toward or away from a focus of heat, light, or other stimulus. *791*

trypanosome (tri-pan′o-sōm) A protozoan of the genus *Trypanosoma*. Trypanosomes are parasitic flagellate protozoa that often live in the blood of humans and other vertebrates and are transmitted by insect bites. *589, 957*

trypanosomiasis (tri-pan″o-so-mi′ah-sis) An infection with trypanosomes that live in the blood and lymph of the infected host. *957*

tubercle (too′ber-k′l) A small, rounded nodular lesion produced by *Mycobacterium tuberculosis*. *908*

tuberculoid (neural) leprosy (too-ber′ku-loid) A mild, nonprogressive form of leprosy that is associated with delayed-type hypersensitivity to antigens on the surface of *Mycobacterium leprae*. It is characterized by early nerve damage and regions of the skin that have lost sensation and are surrounded by a border of nodules. *916*

tuberculosis (too-ber″ku-lo′sis) An infectious disease of humans and other animals resulting from an infection by a species of *Mycobacterium* and characterized by the formation of tubercles and tissue necrosis, primarily as a result of host hypersensitivity and inflammation. Infection is usually by inhalation, and the disease commonly affects the lungs (pulmonary tuberculosis), although it may occur in any part of the body. *906*

tuberculous cavity (too-ber′ku-lus) An air-filled cavity that results from a tubercle lesion caused by *M. tuberculosis*. *908*

tularemia (too″lah-re′me-ah) A plaguelike disease of animals caused by the bacterium *Francisella tularensis* subsp. *tularensis* (Jellison type A), which may be transmitted to humans. *926*

tumble Random turning or tumbling movements made by bacteria when they stop moving in a straight line. *67*

tumor (too′mor) A growth of tissue resulting from abnormal new cell growth and reproduction (neoplasia). *411*

turbidostat A continuous culture system equipped with a photocell that adjusts the flow of medium through the culture vessel so as to maintain a constant cell density or turbidity. *121*

twiddle *See* tumble. *67*

two-component phosphorelay system A signal transduction regulatory system that uses the transfer of phosphoryl groups to control gene transcription and protein activity. It has two major components: a sensor kinase and a response regulator. *283*

type I hypersensitivity A form of immediate hypersensitivity arising from the binding of antigen to IgE attached to mast cells, which then release anaphylaxis mediators such as histamine. Examples: hay fever, asthma, and food allergies. *768*

type II hypersensitivity A form of immediate hypersensitivity involving the binding of antibodies to antigens on cell surfaces followed by destruction of the target cells (e.g., through complement attack, phagocytosis, or agglutination). *769*

type III hypersensitivity A form of immediate hypersensitivity resulting from the exposure to excessive amounts of antigens in which antibodies bind to the antigens and produce antibody-antigen complexes. These activate complement and trigger an acute inflammatory response with subsequent tissue damage. Examples: poststreptococcal glomerulonephritis, serum sickness, and farmer's lung disease. *770*

type IV hypersensitivity A delayed hypersensitivity response (it appears 24 to 48 hours after antigen exposure). It results from the binding of antigen to activated T lymphocytes, which then release cytokines and trigger inflammation and macrophage attacks that damage tissue. Type IV hypersensitivity is seen in contact dermitits from poison ivy, leprosy, and tertiary syphilis. *771*

type III secretion system *See* pathogenicity island. *794*

typhoid fever (ti-foid) A bacterial infection transmitted by contaminated food, water, milk, or shellfish. The causative organism is *Salmonella typhi,* which is present in human feces. *933*

U

ultramicrobacteria Bacteria that can exist normally in a miniaturized form or which are capable of miniaturization under low-nutrient conditions. They may be 0.2 μm or smaller in diameter. *640*

ultraviolet (UV) radiation (ul″trah-vi′o-let) Radiation of fairly short wavelength, about 10 to 400 nm, and high energy. *130, 144*

uracil (u′rah-sil) The pyrimidine 2,4-dioxypyrimidine, which is found in nucleosides, nucleotides, and RNA. *217*

V

vaccine (vak′sēn) A preparation of either killed microorganisms; living, weakened (attenuated) microorganisms; or inactivated bacterial toxins (toxoids). It is administered to induce development of the immune response and protect the individual against a pathogen or a toxin. *764*

vaccinomics The application of genomics and bioinformatics to vaccine development. *766*

valence (va′lens) The number of antigenic determinant sites on the surface of an antigen or the number of antigen-binding sites possessed by an antibody molecule. *731*

variable region (V_L and V_H) The region at the N-terminal end of immunoglobulin heavy and light chains whose amino acid sequence varies between antibodies of different specificity. Variable regions form the antigen binding site. *734*

vasculitis (vas″ku-li′tis) Inflammation of a blood vessel. *909*

vector (vek′tor) 1. In genetic engineering, another name for a cloning vector. A DNA molecule that can replicate (a replicon) and is used to transport a piece of inserted foreign DNA, such as a gene, into a recipient cell. It may be a plasmid, phage, cosmid or artificial chromosome. 2. In epidemiology, it is a living organism, usually an arthropod or other animal, that transfers an infective agent from one host to another. *322, 791, 854*

vector-borne transmission The transmission of an infectious pathogen between hosts by means of a vector. *857*

vehicle (ve′ĭ-k′l) An inanimate substance or medium involved in the transmission of a pathogen. *857*

venereal syphilis (ve-ne′re-al sif′ĭ-lis) A contagious, sexually transmitted disease caused by the spirochete *Treponema pallidum.* *923*

venereal warts *See* anogenital condylomata. *894*

verrucae vulgaris (v′ĕ-roo′se vul-ga′ris; s. **verruca vulgaris**) The common wart; a raised, epidermal lesion with horny surface caused by an infection with a human papillomavirus. *894*

vibrio (vib′re-o) A rod-shaped bacterial cell that is curved to form a comma or an incomplete spiral. *43*

viral hemagglutination (vi′ral hem″ah-gloo″tĭ-na′shun) The clumping or agglutination of red blood cells caused by some viruses. *776*

viral neutralization An antibody-mediated process in which IgA, IgM, and IgA antibodies bind to some viruses during their extracellular phase and inactivate or neutralize them. *756*

viremia (vi-re′me-ə) The presence of viruses in the blood stream. *791*

viricide (vir′i-sīd) An agent that inactivates viruses so that they cannot reproduce within host cells. *138*

virion (vi′re-on) A complete virus particle that represents the extracellular phase of the virus life cycle; at the simplest, it consists of a protein capsid surrounding a single nucleic acid molecule. *363*

virioplankton Viruses that occur in waters; high levels are found in marine and freshwater environments. *643*

viroid (vi′roid) An infectious agent of plants that is a single-stranded RNA not associated with any protein; the RNA does not code for any proteins and is not translated. *416*

virology (vi-rol′o-je) The branch of microbiology that is concerned with viruses and viral diseases. *362*

virulence (vir′u-lens) The degree or intensity of pathogenicity of an organism as indicated by case fatality rates and/or ability to invade host tissues and cause disease. *790*

virulence factor A bacterial product, usually a protein or carbohydrate, that contributes to virulence or pathogenicity. *792*

virulent bacteriophages (vir′u-lent bak-te′re-o-fājs″) Bacteriophages that lyse their host cells during the reproductive cycle. *390*

virus (vi′rus) An infectious agent having a simple acellular organization with a protein coat and a single type of nucleic acid, lacking independent metabolism, and reproducing only within living host cells. *363*

vitamin (vi′tah-min) An organic compound required by organisms in minute quantities for growth and reproduction because it cannot be synthesized by the organism; vitamins often serve as enzyme cofactors or parts of cofactors. *99*

volutin granules (vo-lu′tin) *See* metachromatic granules. *52*

W

wart (wort) An epidermal tumor of viral origin. *894*

wastewater treatment The use of physical and biological processes to remove particulate and dissolved material from sewage and to control pathogens. *658*

water activity (a_w) A quantitative measure of water availability in the habitat; the water activity of a solution is one-hundredth its relative humidity. *122*

water mold A common term for a member of the division *Oomycota.* *564*

Weil-Felix reaction A test for the diagnosis of typhus and certain other rickettsial diseases. In this test, the blood serum of a patient with suspected rickettsial disease is tested against certain strains of *Proteus vulgaris* (OX-2, OX-19, OX-K). The agglutination reactions, based on antigens common to both organisms, determine the presence and type of rickettsial infection. *910*

white piedra A fungal infection caused by the yeast *Trichosporon beigelii* that forms light-colored nodules on the beard and mustache. *943*

whole-genome shotgun sequencing An approach to genome sequencing in which the complete genome is broken into random fragments, which are then individually sequenced. Finally the fragments are placed in the proper order using sophisticated computer programs. *346*

whole-organism vaccine A vaccine made from complete pathogens, which can be of four types: inactivated viruses; attenuated viruses; killed microorganisms; and live, attenuated microorganisms. *766*

Widal test (ve-dahl′) A test involving agglutination of typhoid bacilli when they are mixed with serum containing typhoid antibodies from an individual having typhoid fever; used to detect the presence of *Salmonella typhi* and *S. paratyphi.* *775*

Winogradsky column A glass column with an anaerobic lower zone and an aerobic upper zone, which allows growth of microorganisms under conditions similar to those found in a nutrient-rich lake. *637*

woolsorter's disease *See* anthrax. *913*

wort The filtrate of malted grains used as the substrate for the production of beer and ale by fermentation. *982*

X

xenograft (zen′o-graft) A tissue graft between animals of different species. *773*

xerophilic microorganisms (ze″ro-fil′ik) Microorganisms that grow best under low a_w conditions, and may not be able to grow at high a_w values. *965*

Y

yeast (yēst) A unicellular fungus that has a single nucleus and reproduces either asexually by budding or fission, or sexually through spore formation. *554*

yeast artificial chromosome (YAC) A stretch of DNA that contains all the elements required to propagate a chromosome in yeast and which is used to clone foreign DNA fragments in yeast cells. *335*

yellow fever An acute infectious disease caused by a flavivirus, which is transmitted to humans by mosquitoes. The liver is affected and the skin turns yellow in this disease. *878*

YM shift The change in shape by dimorphic fungi when they shift from the yeast (Y) form in the animal body to the mold or mycelial form (M) in the environment. *556*

© The McGraw–Hill Companies, 2002

Z

zooflagellates (zo″o-flăj′-e-lāts) Flagellate protozoa that do not have chlorophyll and are either holozoic, saprozoic, or symbiotic. *588*

zoonosis (zo″o-no′sis; pl. *zoonoses*) A disease of animals that can be transmitted to humans. *849*

zooplankton (zo″o-plank′ton) A community of floating, aquatic, minute animals and nonphotosynthetic protists. *571*

zoospore (zo′o-spōr) A motile, flagellated spore. *573*

zooxanthella (zo″o-zan-thel′ah) A dinoflagellate found living symbiotically within cnidarians and other invertebrates. *579, 599*

zoster *See* shingles. *872*

z **value** The increase in temperature required to reduce the decimal reduction time to one-tenth of its initial value. *140*

zygomycetes (zi″go-mi-se′tez) A division of fungi that usually has a coenocytic mycelium with chitinous cell walls. Sexual reproduction normally involves the formation of zygospores. The group lacks motile spores. *560*

zygospore (zi′go-spōr) A thick-walled, sexual, resting spore characteristic of the zygomycetous fungi. *558*

zygote (zi′gōt) The diploid (2n) cell resulting from the fusion of male and female gametes. *574*

INDEX

In this index, page numbers followed by a t designate tables; page numbers followed by an f refer to figures; page numbers set in boldface refer to major discussions.
