If blood is to be given, it is essential to be certain that the donor has a normal packed cell volume. An animal in the same environment may be as anemic as the patient, but the individual may be more capable of dealing with the anemia. In lambs weighing less than 45 kg, 1 unit of whole blood (approximately 450 mL) is often sufficient to survive a crisis, provided *H. contortus* has been controlled.

■ **Populations at Risk.** Young animals are most susceptible to infection and clinical manifestations of disease. Lambs and kids may become heavily infected with parasites and shed large numbers of nematode eggs. In sheep, some degree of immunity develops as the animal approaches 1 year of age. Adult animals typically have complete immunity against *Nematodirus* and variable resistance to *Trichostrongylus* species. Some immunity to *Haemonchus* and *Ostertagia* species develops with age; compared with lambs or kids, adults are more resistant to infection with these species. However, even mature animals may succumb to parasitic infection when malnourished or challenged with heavily contaminated pasture. A PPR in fecal egg production is seen in ewes and does.

Goats are more susceptible to GIN infections than are sheep. The difference lies in part in the host's immunologic responses to nematode antigens. Goats prefer to browse on brush and trees, and they graze grass only when forced to by management. Under natural conditions, goats would have a low level of exposure to infective larvae, and this might explain their lower level of natural immunity compared with sheep.^{204,205}

■ **Refugia.** Biologically, *refugia* refers to isolated populations of once widespread animal or plant, or in this case parasite, species. Most parasitologists now consider levels of refugia as the single most important factor contributing to selection for anthelmintic-resistant parasites.^{206,207} Worms in refugia provide a pool of genes susceptible to anthelmintics, thus diluting the frequency of resistant genes. For many years parasitologists and veterinarians have recommended that all animals should be treated with an anthelmintic at the same time. However, this strategy has proven problematic, and a selective approach is now recommended. Only those animals in danger of severe parasitism should actually receive medication. This selective

approach is highly compatible with host-parasite dynamics, as 20% to 30% of animals harbor approximately 80% of the parasites.²⁰⁸ Animals with low worm burdens are an important source of refugia, are not in danger of the negative effects of parasitism, and should not be treated.

■ **Management of Gastrointestinal Nematodes in Small Ruminants.** The traditional approaches of deworming often, rotating classes of anthelmintics, and moving to clean pastures have allowed anthelmintic resistance to all classes of drugs to develop and the resistant parasites to disseminate over a wide area. It is obvious that drastic changes in the management of GINs in sheep and goats are long overdue.

FAMACHA OR SMART DRENCHING METHOD.²⁰⁹ In order to maintain adequate levels of refugia, it is necessary to leave a portion of the herd or flock untreated. FAMACHA is a selective approach that targets the portion of the herd or flock with high worm burdens, including those animals that are poorly resilient to worm infections.²¹⁰ This approach will successfully control parasites in the entire group while significantly reducing drug costs and delaying the development of anthelmintic resistance. The use of this system is not without risks, as individuals are not routinely treated with anthelmintics. Failure to observe animals closely for clinical signs may result in the death of some individuals. It is necessary to know which anthelmintics are effective before beginning this system. The differences among farms in overall quality of management, stocking rates, breeds of animals, preexisting levels and spectrum of anthelmintic resistance, presence of nematode species other than *H. contortus*, and production targets need to be considered while FAMACHA is implemented on individual farms.

FAMACHA is a novel system developed in South Africa for identifying sheep that are anemic; the system has been extended to use in goats.²¹¹ In this method the ocular mucous membranes of sheep and goats are categorized by comparison with a laminated color chart bearing pictures of sheep conjunctivae classified into five categories ranging from red (A/1; normal) to practically white (E/5; severe anemia). Because anemia is the primary pathologic effect of infection with *H. contortus*, this system can be an effective tool for identifying animals that require treatment (but only for *H. contortus*). FAMACHA has been tested extensively and validated in both sheep and goats in South Africa and in the southern United States.^{212,213} In all studies the number of false-negative results was very low, suggesting that when FAMACHA is used according to recommended guidelines, death from anemia would be rare.

Based on the results of recent studies in the United States and numerous studies performed in South Africa, guidelines for using FAMACHA have been developed, and it is suggested that these guidelines be read in their entirety before FAMACHA is practiced.²⁰⁹ It is recommended that treatment be withheld until animals score 4 or 5 as long as animals are in good body condition and good overall general health, animals are examined frequently (e.g., every 2 weeks), and good husbandry is used to identify animals in need of treatment (e.g., unthrifty, anorexic, lagging behind, bottle jaw) between FAMACHA examinations. When this approach is used, the number of anthelmintic treatments administered will be reduced greatly, resulting in significantly diminished selection pressure for resistance and therefore a reduction in drug costs. Owing to the increased handling of animals, labor costs will be

increased. *Only adult animals should be managed with this system.* Lambs and kids have comparatively small blood volumes, poor immunity, and poor resilience and can progress rapidly from moderate to severe anemia. This precaution should be extended also to ewes and does during the periparturient and early lactation period, because these animals have decreased immunity to GINs.^{209,214-216} These and other animals that may be stressed by disease or in poor body condition should always be treated if scored as 3. Alternatively, in the northern parts of the country where *H. contortus* is an important problem but resistance prevalence is much lower, it may be reasonable to be more liberal when making treatment decisions (e.g., treat all animals with scores of 3, 4, and 5). Many more treatments are given when all animals with scores of 3 and higher are dewormed, but a significant number of animals will remain untreated to supply refugia. These refugia combined with a relatively short transmission and treatment period are likely to produce a very slow evolution of resistance, but the more intensive treatment protocols will improve animal productivity.

On farms where low to moderate levels of resistance to one or more drugs have been diagnosed (60% to 95% reduction in FEC), a useful strategy to help gain the full benefits of both treatment and resistance prevention could be to use these "less-effective" drugs either singly or in combination on all animals scored as 3. Using drugs that are less effective in this group is unlikely to lead to clinical problems because the few 3 scores that are moderately anemic and in need of treatment should receive a sufficient reprieve from infection until the next FAMACHA examination, and the majority of the animals with scores of 3 that are not anemic do not need to be treated. This strategy will help preserve the efficacy of the drugs that are still fully effective by saving them for only the animals in the 4 and 5 categories and also will help to decrease egg contamination of pastures.

Training of producers is critical in the use of this method. It is the responsibility of veterinarians and other animal health professionals to ensure that standards of training are maintained. When FAMACHA is used, it is extremely important that efficacy of anthelmintics is known because animals are not treated until they become anemic. Treating anemic animals with a drug that has moderate to poor efficacy owing to worm resistance may result in animal deaths. Other important precautions for using FAMACHA include but are not limited to the following: (1) the card is an aid in the control of *Haemonchus* species only; (2) the system should be used by producers only where technical assistance is available from a veterinarian or other animal health professional; (3) other management-based worm control practices must be maintained; (4) smart drenching principles should be used; (5) paleness or reddening of the conjunctivae may have other causes; (6) animals should always be scored with the help of the chart, not from memory; (7) animals are examined at least every 2 to 3 weeks at the beginning of the expected period of *Haemonchus* species challenge in climates where a seasonal incidence of infection occurs, and during critical periods weekly examinations may be needed; (8) the card is protected from light when not in use and replaced after 1 year of use.^{197,217}

Maintaining treatment records that are included with the FAMACHA kits gives the owner the ability to rate the genetic merits of individuals on the premises. Host resistance to infection with *H. contortus* measured on the basis of FEC and packed cell volume (PCV) is a moderately heritable trait, and it has been demonstrated that the same animals

tend to exhibit the highest FEC and lowest PCV on each occasion they are measured.²¹⁸⁻²²⁰ Of importance, data from recent investigations examining the heritability of resistance and resilience of merino sheep to infection with *H. contortus* indicate a high heritability for the clinical estimates of FAMACHA scores.²¹² Removing the most susceptible animals from the breeding pool each year will have the long-term effect of improving the overall innate genetic resistance and/or resilience of the herd or flock to *H. contortus*.

GRAZING STRATEGIES. The goal of pasture management is to provide safe pastures for grazing by reducing the exposure of susceptible hosts to infective larvae.^{224,225} A safe pasture is one that has had no sheep or goats grazed on it for 6 months during cool and cold weather or 3 months during hot, dry weather. Weaning sheep and goats at 2 months of age and rotating them through pastures ahead of the adults while forage is longer will minimize the exposure of susceptible animals to infective larvae. Pastures should be subdivided into smaller lots to allow longer rest periods between grazings. Pastures that are overgrown provide a good environment for larval survival, as ultraviolet light and dry conditions are effective in killing larvae. Keeping pastures clipped will assist in weed and parasite control. Short-duration grazing carries pasture rotation to a level that maximizes forage production and harvesting by controlled animal grazing. It is management intensive but can be effective in controlling parasite burdens. Tilling and reseeding a heavily contaminated pasture will convert it to a safe pasture and gives an opportunity to improve the forage quality. Taking a cutting of hay from a pasture assists in reduction of infective larvae, but one report indicates GINs and tapeworms developing in "worm-free" lambs after they were fed hay from heavily infected pastures. During the most dangerous part of the grazing season it may be necessary to drylot the flock and feed hay and grain from elevated feeders.

Stocking rate is an important consideration in parasite control, as it affects the exposure to infective larvae and the contamination of the pasture. It is impossible to make a general recommendation on stocking rate, as this will vary according to the type of pasture, the time of year, the current weather conditions, and the type of animal being grazed. Rules of thumb are that five to seven goats or five sheep are the equivalent of one cow and suggest five to seven goats per acre. Goats prefer to browse brush and trees, whereas sheep prefer to graze near the ground. Pasture management must include monitoring the condition of herbage to ensure that overgrazing does not occur and to maintain a productive pasture.

In the early spring or at the onset of the rainy season, reduced pasture contamination is the most important aspect of control. The ewe or doe in the periparturient relaxation of resistance, even if she has the genetic capacity for resistance, will be a source of eggs for the environment. Strategic deworming to remove arrested or recently emerged larvae before they contaminate the pasture will have a great impact on pasture contamination. Treatment 2 weeks after a rain that removes recently acquired worms before they can begin passing eggs will also decrease pasture contamination. Providing sufficient dietary protein is vital during the periparturient period and during rapid growth so that animals will tolerate the worm burden better as their immunity is strengthened.²²³⁻²²⁵ A strong link between nutrition and parasitism has been illustrated between protein intake and resistance to GIN infection. The most dramatic has been the abolishment of the periparturient egg rise in lambing ewes by providing protein at 130% of requirements. Immunity is closely related to protein repletion. GINs

increase the demand for amino acids by the sheep. Lambs will voluntarily select a higher protein diet when infected with GINs compared with uninfected lambs. There is conflicting documentation that sheep will decrease feed intake when initially infected with GINs. Some authors hypothesize that the decrease in intake may be caused by stimulation of the immune system or that the host is becoming selective in its diet.

Pastures may be used for hay cropping and grazed during the last half of the grazing season to effectively reduce GIN challenge. When plants high in condensed tannins are grazed, there is evidence that the incoming larvae are adversely affected by condensed tannins, which also provide bypass protein for the host.²²⁶⁻²²⁸ There is growing evidence in work from New Zealand and Europe that grazing or feeding of plants containing condensed tannins can reduce FEC, larval development in feces, and adult worm numbers in the abomasum and small intestine. Preliminary tests with sericea lespedeza (*Lespedeza cuneata*), a perennial warm-season legume, have shown positive effects of reduced FECs in grazing goats, and in sheep and goats in confinement when the forage was fed as hay. In addition, an effect on reducing worm burden has also been reported. Similar results have been observed using quebracho extract for small intestinal worms but not abomasal worms. In addition to its potential use in controlling worms, sericea lespedeza is a useful crop for limited resource producers in the southern United States. It is adapted to hot climatic conditions and drought and acidic, infertile soils unsuitable for crop production or growth of high-input forages, such as alfalfa. It can be overseeded on existing pasture or grown in pure stands for grazing or hay. In addition to hay, sericea lespedeza is being evaluated in the form of meal, pellets, and cubes to be fed as a supplement to grazing animals or as a deworming method under temporary short-term confinement. The physical structure of some plants may challenge larvae to ascend vegetation or may provide protection from adverse pasture conditions. If animals are allowed to browse, their chances of acquiring larvae diminish as the distance from the ground increases. Most infective larvae are found within 2 inches (50 mm) of the soil surface.

Alternate grazing or co-grazing with other species of livestock may harvest *Haemonchus* larvae from the pasture. Small ruminants can graze after cattle and this is considered to be a safe pasture, assuming adequate parasite control in the cattle. For the most part, each livestock species harbors its own parasite fauna, with the exception of overlap between sheep and goats. Only *T. axei*, a minor abomasal worm, is found in all livestock species. In general, the *Haemonchus* organisms in sheep and goats do not do well in cattle, and vice versa. However, some populations of *H. contortus* may thrive in calves. If practical, cattle and small ruminants can be grazed together where each consumes the parasites of the other, which reduces available infective larvae for the preferred host species.

Anthelmintic administration should be coordinated with the weather. During hot, dry weather, there will be little or no exposure to infective larvae. As soon as there is significant rainfall ($\frac{1}{2}$ to 1 inch) larvae exposure goes up exponentially, as previously inactive larvae become active and new larvae are hatched. The producers should be trained to plan deworming within 3 weeks of significant rain after a dry spell. Similar strategies can be used during cool weather. Once ambient temperatures drop below 50° F, the flock can be dewormed and no further treatments are necessary until temperatures become favorable to larval development and activity.

ALTERNATIVE THERAPIES

1. Copper oxide wire particles (COWPs) have been marketed for years as a supplement for livestock being managed in copper-deficient areas.²²⁹ COWPs come in adult cattle, calf, and ewe boluses (25, 12.5, and 4 g, respectively). Only the cattle boluses are available in the United States. Owing to potential toxicity in sheep, only one dose per year is recommended. It is also well known that copper has some anthelmintic activity against abomasal worms but not other GI worms. That makes COWPs a very narrow-spectrum product. However, in view of anthelmintic resistance in *H. contortus*, recent work has revisited the possibility of using COWPs to specifically target *H. contortus*. Such work has shown that as little as 1 g or less and 2 g may remove substantial numbers of *H. contortus* organisms in lambs and ewes, respectively. Similar work in goats has not been tested adequately to establish what is needed, but similar doses may be appropriate. As mentioned, copper has to be used cautiously in sheep because toxicity can develop as a result of liver accumulation. Toxicity may not be an issue in goats, as they have been reported as not being as sensitive to excess copper intake. Therefore higher doses and/or more treatments during haemonchosis season may be useful in goats.
2. Other nutritional considerations include phosphorus, cobalt, and molybdenum. Supplementation with phosphorus has been shown to prevent worm establishment. Cobalt deficiency has also been associated with reduced immunity to GIN. The addition of molybdenum at 6 to 10 mg/day to the diet decreased worm burdens in lambs. This effect was not attributable to the expected copper deficiency. Molybdenum may have a role in increasing jejunal mast cells and blood eosinophil numbers.
3. The use of nematode-trapping fungi included in feed or supplements has demonstrated potential for biologic control of the free-living stages of GIN parasites under experimental and natural conditions.²³⁰⁻²³² These fungi naturally inhabit soil throughout the world where they feed on a variety of free-living soil nematodes. These fungi capture nematodes by producing sticky traps on their growing hyphae. Of the various fungi tested, *Duddingtonia flagrans* possesses the greatest potential for survival in the GI tract of ruminants. After passing through the GI tract, spores geminate and looped hyphae trap the developing larval stages in the fecal environment. This technology has been applied successfully under field conditions and is an environmentally safe biologic approach for control of worms under sustainable, forage-based feeding systems. The major drawback is that the fungal spores must be fed daily. Daily feeding that ensures that all animals consume an equivalent amount of feed is necessary. For adequate control of larvae during the transmission season, spores must be fed for a minimum of 60 days. This can be expensive and time-consuming. A bolus prototype is being developed and would allow a single administration; spores would then be slowly released over a 60-day period. This product is not available in the United States at this time.
4. Vaccines have been explored for management of the negative consequences of parasitism.²³³⁻²³⁵ Successful vaccines have been developed for lungworms in cattle and tapeworms in sheep. The most promising vaccine for small ruminant worms has been what is called a "hidden gut" antigen and specifically targets *H. contortus*. This antigen is derived from the gut of the worm, and when the antigen is administered to the animal,

antibodies are produced. When the worm ingests blood during feeding, it also ingests these antibodies. The antibodies then attack the target gut cells of the worm and disrupt the worm's ability to process the nutrients necessary to maintain proper growth and maintenance, thereby killing the worms. This vaccine has been tested successfully in sheep under experimental conditions but has had limited success under field conditions. Vaccines for other worms that do not feed on blood have focused on using antigens found in worm secretory and excretory products. Protection has been quite variable, and marketing of such products has not been pursued.

5. Genetic improvement in resistance to nematode infection is most likely based on inheritance of genes that play a primary role in expression of host immunity.²³⁶⁻²³⁸ Based on survival-of-the-fittest management conditions, several breeds around the globe are known to be relatively resistant to infection. Such breeds include Scottish Blackface, Red Maasai, Romanov, St. Croix, Barbados Blackbelly, and the Gulf Coast Native. Katahdin sheep have been considered as being more parasite resistant, but studies to document this are few and not conclusive. Using such breeds exclusively or in cross-breeding programs would certainly lead to improved resistance to worm infection, but some level of production might be sacrificed. Selection of more resistant stock can be accelerated by identifying sires that produce relatively resistant offspring. Computer programs have been used in New Zealand and Australia to rank sire genetics, but change takes up to 8 to 10 years. Heritabilities for FEC, a common measurement for assessing parasite burden, range from 0.22 to 0.40, which is high. Therefore selection for resistance using a measurement such as FEC has been moderately successful.

ANTHELMINTIC USE. Discussion of anthelmintics has deliberately been left until the end of this section because drugs cannot be considered the most important aspect of a parasite control program. Guidelines for drug doses are contained in Table 49-3. At this time, only oral administration of anthelmintics is recommended in small ruminants. In general, goats require 1.5 to 2 times the doses of sheep, with the exception of levamisole, owing to more rapid GI transit times. It is critical that producers accurately assess weights of individual animals and determine the dose appropriately. If an approximate dose is going to be used in all animals, that dose should be for the lightest animal in the group.

The challenge of anthelmintic resistance is life-threatening in small ruminants. There is no point in repeatedly deworming with expensive drugs if the drugs are no longer effective. See the following section on monitoring parasite control programs for information on detecting anthelmintic resistance. On farms where low to moderate levels of resistance to one or more drugs have been diagnosed (60% to 95% reduction in FEC), a useful strategy to help gain the full benefits of both treatment and resistance prevention could be to use these "less-effective" drugs either singly or in combination. Drugs in the BZD family may be effective if multiple-day administration regimens are used.

LUNGWORM INFECTION IN LARGE ANIMALS

LORA RICKARD BALLWEBER

Lungworms traditionally are those nematode parasites that reside in the lung as adults. In ruminant and equine species, most clinical cases of lungworm involves the genus

Dictyocaulus. Species of *Dictyocaulus* tend to be host specific with *Dictyocaulus viviparus*, *Dictyocaulus arnfieldi*, and *Dictyocaulus filaria* found in the bronchi of cattle, equids (horses, ponies, donkeys), and small ruminants, respectively. Sheep and goats may also be infected with *Protostrongylus rufescens* and *Muellerius capillaris*.²³⁹ This section focuses on *Dictyocaulus* infection, with a brief discussion of other lungworm parasites found in small ruminants.

Because verminous pneumonia requires specific treatment, it is important to distinguish it from diseases caused by other infectious agents. Often the role of lungworm in the cause of respiratory disease may be obscured by a parasite-induced hypersensitivity response or by superimposed secondary bacterial infections.

■ **Life-Cycle.** The life-cycle of *D. viviparus* is direct, with no intermediate host involved. Adults produce embryonated eggs that hatch shortly after oviposition. L₁ are passed in the feces, where they develop to L₂ and L₃ within a week under optimal environmental conditions. After the infective L₃ are ingested, they migrate through the wall of the intestine to the mesenteric lymph nodes and through lymphatics into the bloodstream and finally arrive, as L₄, in the lung as early as 7 days after ingestion. Larvae may then develop to sexually mature adult worms or they may arrest development as late L₄ or immature adults. Arrested development can prolong the normal prepatent period from 3 to 4 weeks to approximately 5 months.²³⁹

Most problems with cattle lungworms in North America occur in areas of moist climates where larvae on pasture are protected from desiccation and larval migration away from the fecal pat onto herbage is facilitated. Under favorable conditions, infective L₃ can survive on pasture for approximately 11 months.^{240,241} These larvae plus the larvae produced from carrier animals harboring small numbers of adults or adults developing from arrested larvae can result in high levels of contamination on spring pastures. In subtropical climates, larvae are virtually absent during the hot summers; larval contamination of the pasture peaks in the autumn as a result of carrier animals.²⁴²

The life-cycle of *D. filaria* is similar to that of *D. viviparus* including the ability of the larvae to arrest development. The prepatent period is approximately 26 days, with peak larval output occurring 39 to 57 days postinfection. As with *D. viviparus*, *D. filaria* is more prevalent in moist climates and larvae can survive on pasture throughout the winter. Spring pastures contaminated with overwintering larvae and larvae produced from adults developing from arrested larvae in carrier animals are sources of infection for susceptible lambs or kids.^{239,243-245}

The life-cycle of *D. arnfieldi* is similar to that of other species of *Dictyocaulus* except that, in addition to L₁, larvated eggs may be passed with the feces. The prepatent period is 2 months.²⁴⁶

Unlike species of *Dictyocaulus*, *M. capillaris* and *P. rufescens* have indirect life-cycles that involve intermediate molluscan hosts. Adults, occurring in the parenchyma (*M. capillaris*) or small bronchioles (*P. rufescens*), produce eggs that develop and hatch. L₁ are passed with the feces; once on pasture, larvae invade the foot of a susceptible species of snail or slug and develop to infective L₃. Sheep and goats become infected when inadvertently ingesting the mollusk while grazing. The larvae penetrate the intestine and migrate to the lung in much the same manner as *Dictyocaulus*. Early L₄, developing L₄, and adult *M. capillaris* become embedded within a fibrous nodule within the parenchyma. *Protostrongylus* larvae mature in the alveoli and enter the bronchioles as adults. The prepatent period is 5 to 6 weeks, although

arrested development may prolong the prepatent period of *M. capillaris*.^{239,243-247}

■ **Pathophysiology.** Although infections with few worms may be inapparent, *D. viviparus* often results in parasitic pneumonia and bronchitis. The disease process is divided into four phases: penetration, prepatent, patent, and postpatent. In the penetration phase (days 1 to 7), no clinical sign or significant respiratory pathology occurs as the larvae migrate to the lungs. During the prepatent phase (days 7 to 25), clinical signs and lesions become evident. An eosinophilic infiltrate blocks bronchioles; excess mucous production and alveolar collapse occurs. The patent phase (days 25 to 55) is associated with egg-laying adults in the bronchi and trachea. Bronchial and tracheal epithelial damage occurs, air passages are blocked by exudate, and consolidation of lobules results from aspiration of eggs and L₁ into bronchioles and alveoli. Bronchitis, tracheitis and pneumonia follow. During the postpatent phase (after day approximately day 50), surviving animals recover and adult worms die off. Peribronchial fibrosis and epithelialization of alveoli may remain. Secondary bacterial infections resulting from weakened pulmonary defenses may also occur.²³⁹

Goats tend to be more susceptible to infection with *D. filaria* and more severely affected than sheep, although individual susceptibility to infections does occur. Heavy infections in both species produce bronchitis, pulmonary edema, atelectasis, and emphysema, although death is uncommon.^{239,243,244} As with *D. viviparus*, secondary bacterial infections can occur.

In donkeys, whether *D. arnfieldi* causes pathologic lesions on its own is controversial because of the presence of other pathologic agents; however, in healthy infected individuals, pathologic changes include discrete circular areas of overinflation surrounding affected bronchi. Histologically these areas contain a small bronchus packed with nematodes. The small airways are often occluded with exudate. Small amounts of mucus surround adult worms in the main bronchi with little cellular reaction. L₁ are surrounded by an intense mucopurulent reaction. In addition to these types of lesions in horses, many immature nematodes are present in smaller bronchi, accompanied by bronchial epithelial hyperplasia with large amounts of mucus and pus. Many areas of alveolar hemorrhage and edema are also present.²⁴⁶

Although morbidity with *M. capillaris* may be high in most flocks, massive infections with *M. capillaris* or *P. rufescens* are not common. Pathologic changes caused by *P. rufescens* are similar to chronic, low-grade *Dictyocaulus* infection. Heavy infections with *M. capillaris* infection in goats can result in interstitial pneumonia, bronchopneumonia, or fibrinous pleuritis. In sheep and goats, distinct subpleural nodules containing adults and L₁ are common. Secondary bacterial infections can also occur.^{239,248-251}

■ **Populations at Risk.** Clinical disease occurs most frequently in pastured calves, lambs, and kids in the first year of life. The disease is also reported in housed cattle, related either to heavily contaminated bedding material or to synchronous maturation of large numbers of hypobiotic larvae. Clinical lungworm infestation is more of a problem in cattle than in sheep, possibly because lambs are treated for GINs more frequently than are calves under most management systems.

Immunity to lungworm infection occurs after first exposure and can develop before the end of the first grazing season. However, it is variable in both degree and duration. In cattle, exposed animals may be immune for 7 to 12 months after infection. In subsequent infections most larvae are

either killed before reaching the lung or are inhibited from maturing into adults. Usually the immunity developed during the first grazing season is boosted by exposure in subsequent years and prevents manifestations of disease. However, without reexposure to infective larvae, immunity wanes and disease can occur in adult cattle.²³⁹

Occasionally, outbreaks of acute lungworm disease are seen in adult cattle on pasture whose immunity is overwhelmed by exposure to very large numbers of larvae. This condition is called the *reinfection syndrome*. Although most ingested larvae are killed or fail to mature, some reach the lung and incite an acute, immune-mediated reaction.

Both sheep and goats develop a strong immunity to *D. filaria*; disease is more common in young animals. As with cattle, continued immunity in sheep depends on reexposure.^{239,252}

Individual horse susceptibility to infection with *D. arnfieldi* is evident. Infections can occur during any time in the life of the horse. Donkeys apparently do not develop an immunity to infection, with larval excretion increasing with age.^{246,253}

Although immunity to *M. capillaris* appears to be incomplete (adult nematodes can live for up to 4.5 years), responses to subsequent exposures do limit the numbers of adults that develop and the numbers of larvae shed in the feces. However, reexposure may be cumulative, resulting in older animals harboring larger numbers of worms.²³⁹

■ **Clinical Manifestations.** Clinical disease ("husk") caused by lungworm infection in cattle can occur within 1 or 2 weeks of the introduction of susceptible animals to contaminated pasture. However, clinical disease most often occurs 2 to 4 months into the grazing season. Affected animals develop either an acute or a subacute form of the disease, depending on the number of larvae ingested and the animal's level of immunity. With acute verminous pneumonia in calves, dyspnea and cough are prominent signs. Auscultation of the lungs initially reveals vesicular murmurs and bronchial tones that progress to moist rales as fluid accumulates. The animal may expectorate froth. Occasionally, emphysema occurs and crackling noises are heard on auscultation. Fever may be as high as 40.5° C (105° F). Mortality rates are high, and animals may die before a patent infection has been established.²³⁹ The similarity between this presentation and that of bacterial pneumonia or shipping fever should be noted.

The subacute or chronic manifestation of disease is more common. In all species the primary signs are coughing, dyspnea, and loss of condition. The animals show elevated respiratory rates but initially are afebrile. Bronchial irritation caused by adult worms and fluid accumulations produces paroxysmal coughing. Animals with the subacute form of lungworm disease are susceptible to bacterial pneumonia. In fact, the subacute form is easily confused with enzootic pneumonia in calves. Signs of reinfection syndrome in adult cattle include severe cough, tachypnea, harsh respiratory sounds, and, for dairy cattle, a sudden drop in milk production approximately 2 weeks after exposure to heavily contaminated pastures.²³⁹

In horses, lungworm infection typically causes a syndrome similar to chronic obstructive pulmonary disease, although asymptomatic infections may also occur. Clinical signs include persistent coughing, nasal discharge, and respiratory distress; death is uncommon. Donkeys, the source of infection in most cases of lungworm disease in horses, tend to remain asymptomatic, although harsh lung sounds may be auscultated.^{246,253}

Infections with *M. capillaris* are generally asymptomatic; however, impaired pulmonary gas exchange, reduced weights

and breeding performance, and increased mortality have been reported.^{248,249,254}

■ **Control of Lungworm Infection.** Management strategies designed to decrease exposure to infective larvae are most effective in preventing dictyocaulosis. Young animals should not be overstocked or allowed to graze in moist, low-lying pastures. It is often helpful to rotate pastures so that successive calf crops do not graze the same area. Young stock should not be grazed with older, clinically immune animals that may serve as a source of infective larvae. Horses should not be grazed with donkeys. If they are, then donkeys should be monitored for L₁ and treated to reduce larval output and pasture contamination. Limiting contact with intermediate hosts and provision of mollusk-free housing will decrease infections with parasites that require these intermediate hosts.

ANTHELMINTICS. Several anthelmintics are effective against lungworm. Drugs for the treatment and control of lungworm are presented in Table 49-4.^{239,246} The avermectins and milbemycins are particularly effective against both adult and larval stages and have prolonged residual activity that prevents appearance of larvae in the feces for at least 60 days.^{255,262} Strategic use of these products, such as treatment at turnout and again 8 weeks later, can substantially reduce pasture infectivity with lungworm larvae. Concerns that such highly efficacious anthelmintics would prevent induction of immunity in first-season grazing animals appear to be largely unfounded, with the possible exception of sustained-release intraruminal devices (see later). The immune response may be attenuated, but exposed animals still develop some degree of immunity to lungworm infection despite prophylactic treatment with these drugs.^{256,257,263-265}

Young, susceptible stock may be given a prophylactic treatment in mid-spring or early summer to prevent or limit clinical disease. Housed animals, in particular 1- to 2-year-olds with subclinical but potentially patent infections, should be

TABLE 49-4

Drugs Used to Control Lungworm

Drug	Dose
AVERMECTINS AND MILBEMYCINS	
Ivermectin, abamectin, doramectin, eprinomectin, moxidectin	0.2 mg/kg PO, SC, IM*; 0.5 mg/kg topically ("pour-on"); intraruminal sustained-release device (ivermectin)
OTHERS	
Albendazole	5 mg/kg PO (O, C); 7.5-10 mg/kg PO (B)
Fenbendazole	5 mg/kg PO (O, C); 5-10 mg/kg PO (B); 30 mg/kg PO (E); intraruminal sustained-release device (B)
Mebendazole	15-20 mg/kg PO (O, C)
Netobimin	7.5 mg/kg PO (B, O, C)
Oxfendazole	4.5-7.5 mg/kg PO (B, O, C)
Levamisole	7.5-10 mg/kg PO, SC; 10 mg/kg topically ("pour-on") (B, O, C)
Diethylcarbamazine	22 mg/kg IM daily for 3 days or 44 mg/kg IM once (B)

B, Bovine; C, caprine; E, equine; IM, intramuscularly; O, ovine; PO, by mouth; SC, subcutaneously.

*Route depends on the product and species; follow manufacturers' recommendations.

treated before being turned out to pasture in the spring. All early clinical cases should be treated in an effort to limit disease severity and decrease pasture contamination.

Intraruminal SRDs containing ivermectin, levamisole, or a BZD can prevent clinical disease for several weeks or months during the grazing season.²⁶⁵⁻²⁷¹ However, some studies have shown that these devices impaired the development of immunity in treated calves.^{265,269} SRDs may interfere with development of natural immunity by killing ingested larvae before they can penetrate the intestine and thus stimulate an immune response. However, other studies using these devices have shown that treated calves can develop immunity during the grazing season.²⁷²

VACCINES. An effective vaccine has been developed against *D. viviparus* in cattle and is available in the United Kingdom and parts of western Europe. Two doses of irradiated larvae are administered by mouth 4 weeks apart. The larvae migrate to mesenteric lymph nodes and provoke an immune response but die before they reach the lung. Management considerations associated with the use of the vaccine include the following: (1) calves must be at least 2 months old; (2) vaccinated calves should not be placed on pasture for at least 2 weeks after the second dose; (3) vaccinated calves must not be exposed to heavily infected pastures, nor should they be mixed with animals showing signs of lungworm disease or with unvaccinated calves; (4) immunity is not long-lasting, so animals must continue to be exposed to low levels of infective larvae to maintain immunity; and (5) the vaccine has a short shelf-life and it is relatively expensive. Farms with contaminated grazing areas and a history of lungworm disease benefit most from vaccination, and it is best used in young nursing calves before exposure to pasture.²⁷³

■ **Evaluation of Preventive Programs.** The efficacy of preventive programs is best assessed by evaluating the number of susceptible animals that demonstrate signs of infection. Because total eradication of the parasite is difficult and low numbers of parasites produce minimum problems, a useful goal is the control of clinical signs such as cough and loss of condition. Fecal larval counts are an unreliable means of evaluating the severity of lungworm infection in an individual animal.

■ Clinical Management

DIAGNOSIS. As with many parasitic diseases, lungworm is often diagnosed on the basis of farm history, seasonal prevalence, clinical presentation, and response to treatment.^{239,246,253} Verminous pneumonia may mimic respiratory diseases caused by other agents that require specific treatment. Although definitive diagnosis is difficult, it is important.

To document the presence of lungworm infection, it is necessary to demonstrate larvae, adult worms, or eggs. In cattle and small ruminants, the presence of L₁ in fresh feces indicates lungworm infection.²³⁹ In horses, L₁ may be present in feces; however, patent infections in horses do not always occur, and antemortem diagnosis may best be achieved by examining donkeys co-grazing with the horses.^{246,253} The Baermann technique is the technique of choice to detect L₁ in the feces. However, in acute outbreaks animals may succumb before infections are patent. Transtracheal wash may demonstrate a large number of eosinophils, which is supportive of verminous pneumonia; eggs or larvae are occasionally seen with patent infections. This procedure can also help rule out bacterial pneumonia. Finding of nematodes at postmortem examination is definitive. At necropsy, adult *Dictyocaulus* organisms are usually apparent in the bronchi or bronchioles, whereas adult *P. rufescens*

organisms tend to be in the bronchioles and adult *M. capillaris* organisms are found in subpleural nodules on the dorsal aspect of the diaphragmatic lobes. Nematodes and the eggs may also be found in histologic section of the lung.

TREATMENT. In subacute or chronic forms of the disease, removal of the adult parasites with anthelmintics may result in recovery. However, if the infection is heavy and lung damage is severe, anthelmintic treatment is unlikely to result in complete recovery. In some animals, anthelmintic treatment worsens the signs, and some heavily infected animals die. In severely affected individuals, antihistamines and antibiotics should be included in the therapeutic regimen.

EVALUATION OF PARASITE CONTROL PROGRAMS

SHERRILL A. FLEMING

The efficacy of a given parasite control program should not be assumed; it should be assessed on a regular basis. The routine performance of quantitative tests for parasite burdens allows veterinarians to identify the development of anthelmintic resistance. Although fecal floatation is useful in identifying the presence of parasites, the use of the McMaster technique allows an estimation of the numbers of parasites. Both procedures are relatively simple and can easily be performed in the practice setting. Other specialized laboratory procedures are also discussed. Once resistance has been documented it is important to identify the species involved through larval identification.

FEC and FEC Reduction Tests²⁷⁴⁻²⁷⁶ (Box 49-1)

Determining numbers of nematode eggs in feces is the simplest and least invasive way to evaluate a parasite control program. Fecal examination may be of limited value in an individual animal because animals dying of parasitic infection may have no eggs in the feces, whereas animals with high FECs may be clinically normal. Nevertheless, FECs can provide information on the level of infection present in an individual animal, particularly when egg counts are repeated over the course of 2 to 3 weeks. Herd average FECs are more useful and provide an accurate reflection of the degree of environmental contamination and rate of infection. Pretreatment and posttreatment FECs can also be used to establish the efficacy of an anthelmintic in a particular group of animals. A quantitative McMaster or Stolley technique, rather than simple floatation, is crucial for accurate monitoring.

It is suggested that guidelines published by the World Association for the Advancement of Veterinary Parasitology (WAAVP) be used to perform and evaluate data from an FECRT test, applying practical modifications to fit the situation on the farm.²⁷⁶ Briefly, groups of 15 animals that have not been treated within the past 8 weeks are randomly allocated to treatment groups, and FECs are performed using a modified McMaster technique 10 to 14 days after treatment. An untreated control group must be included. If fewer than 12 to 15 animals per group are available, then treatment groups should be balanced by performing a pretreatment FEC. Animals are then stratified by FEC from highest to lowest, blocked by number of treatment groups, and then within each block are randomly assigned to treatment. Alternatively, where *Haemonchus* is the primary parasite, animals may be scored using the FAMACHA method as they come through the chute, blocked by FAMACHA score, and then randomly assigned to treatment within blocks. This approach is a bit more complicated but will result in

BOX 49-1

Modified McMaster Technique (Fecal Egg Count)

This is one method for performing a McMaster fecal egg count. Similar protocols are used routinely in many laboratories, so you may see a slightly different procedure recommended elsewhere. The important point is to use the same procedure each time.

The first step is to collect freshly passed feces uncontaminated by soil or bedding. The best way is to wear a rubber glove and extract feces directly from the rectum. Alternatively, feces can be picked up off the ground if done soon after deposition. The collection container should be labeled with the identification of the animal and the date of collection. Fresh samples work best, but accurate results can be obtained if the sample is refrigerated during the interim. If samples are not refrigerated, the eggs will hatch within 12 to 24 hours. Once hatched, eggs cannot be counted.

MATERIALS

Compound microscope
Scale
Saturated sodium chloride (table salt)
50-mL centrifuge tube, with screw cap and marked with milliliter increments
Pipette (1-mL syringe or eye dropper works well)
McMaster egg counting slide*
Paper towels
A fresh fecal sample, refrigerated until tested

PROCEDURE

1. Weigh out 2 g of feces into a 50-mL centrifuge tube and fill to 30-mL line with salt solution. It is recommended to purchase a small scale and weigh feces, but if you do not have a scale you can still get a close estimation by putting 28 mL of salt solution into a 50-mL centrifuge tube first and then adding feces until a volume of 30 mL is achieved.
2. Pour off approximately 25 mL of the salt solution into another small container, keeping feces in the tube (use tongue depressor).
3. Soak feces for a few minutes and mix (soft feces) or break up (fecal pellets) with tongue depressor.
4. Add back approximately one half of the salt solution and mix well, breaking up any remaining feces as well as possible.
5. Add back the remaining salt solution and screw the cap back onto the tube.
6. Shake tube vigorously for approximately 1 minute to disrupt any remaining feces as much as possible.
7. Set tube aside for a few minutes to let bubbles dissipate.
8. Wet McMaster chamber with water and dry top and bottom on paper towels.
9. Rock (do not shake) tube several times to thoroughly mix solution without causing large air bubbles to form.
10. Immediately pipette (using 1-mL syringe or eye dropper) a sample of the suspension and fill both sides of counting chamber. Work quickly. If it takes more than a few seconds to load the first chamber, then mix fecal solution again and refill pipette before loading the second chamber.
11. Let stand for 1 to 2 minutes to allow eggs to float.
12. Count all eggs inside of grid areas (>½ of eggs inside grid) using low power (10×) objective. Focus on the top layer, which contains very small air bubbles (small black circles; if numerous large air bubbles are visible, remove the fluid and refill).
13. Count only trichostrongyle and strongyle eggs (oval shaped, approximately 80 to 90 microns long). Do not count *Strongyloides* species (oval, approximately 50 microns long), tapeworm eggs (triangular or D-shaped), or coccidia (various sizes). Note the presence of other species, but count only the trichostrongyle and strongyle eggs.
14. Once filled, the chambers can sit for no longer than 60 minutes before counting without causing problems. After 60 minutes, drying and crystal formation may begin.
15. Total egg count (both chambers) × 50 = egg (eggs per gram).

NOTES

This is a dilution technique, and theoretically this ratio of feces to flotation solution will not detect infections with less than 50 eggs per gram of feces (one egg seen on slide), so it is not very accurate for samples with low numbers of eggs. On a practical level this is not important, because from a clinical standpoint slight differences in results when egg counts are low do not matter.

Fairly soon after counting is complete, thoroughly rinse out the McMaster chamber with warm running water. Doing so will keep the chamber clean and ready it to be used again. If fecal solution dries in the chamber do not soak in soapy water for long periods, as this will cause the chamber to become cloudy. If the chamber gets dirty, soak for only a few minutes in water containing dish soap and then rinse completely with tap water.

*Chalex Corporation, Issaquah, WA, chalexcorp@att.net; www.vetslides.com

groups that are balanced, which will result in a more accurate test. Calculations are performed using the following formula:

$$\text{FECR}\% = 100 \left(1 - \frac{X_t}{X_c} \right)$$

where X_t and X_c are the arithmetic mean number of eggs per gram (epg) in the treated (t) and untreated control (c) groups, respectively. Software is available for free that performs all calculations and gives data interpretation.²⁷⁷ If the RESO calculator is used, the assignment of resistance status is based both on percent reduction and the 95% confidence intervals. If the RESO calculator is not used, the following guidelines can be applied: reductions of greater than 95% indicate sensitivity, reductions of 90%

to 95% indicate low or suspected resistance, and reductions of <90% indicates resistance. FECRT yields reliable data only if FECs are sufficiently high to properly measure a reduction from treatment. If the control group's mean FECs are below 150 epg, then objective assessment of resistance will not be reliable. Group mean FECs of less than 150 epg can be common in adult sheep; therefore when FECRT is performed on a sheep farm it is preferable to use weaned lambs if available. With goats, low FECs are usually not a problem.

Larval Identification

Ideally, if there is <90% egg count reduction, the eggs should be hatched and the larvae species identified. In the majority of cases these will be *H. contortus*, but

other species, especially *Trichostrongylus* species, readily develop resistance as well. One can sometimes be fooled into an improper interpretation of egg count reduction results if mixed species are present and only one is resistant.

Egg Hatch Assays and Larval Development Tests²⁷⁶

Eggs from feces are incubated with concentrations of the anthelmintic to be tested, and the eggs hatched. A dose-response curve is generated (DrenchRite test from Horizon Technology).²⁷⁵ The advantage of this test is that a single fecal sample can be tested for all available classes of anthelmintics simultaneously. The cost of this test has recently increased and may discourage owners from pursuing this diagnostic. However, when compared with the cost of using anthelmintics that are ineffective, it is easy to justify the use of this test. It is important to read instructions for submitting this test and scheduling a testing date before the samples are collected.

Larval Culture

Larval cultures can be used to distinguish between large and small strongyles in horses and to identify the various nematode species in ruminants. Most parasitology laboratories can perform this examination. It requires submission of 200 to 400 g of fresh feces. Pooled samples from several herd members are often used.

Pasture Larval Counts

Counts of parasitic larvae on herbage are useful to indicate the level of exposure experienced by the grazing animal. This examination is somewhat tedious but can be performed by many university laboratories. A 2-kg sample of forage is gathered for submission to the laboratory. The grass is sampled by walking a V pattern across the acreage and stopping every three paces to sample grass. The samples are subsequently washed and passed through screening to isolate and identify larvae.

Necropsy Evaluation

The nature and magnitude of parasitic infections can be established by necropsy examination. Gross examination and an estimate of adult worm population in the gut lumen are often sufficient. Many worms detach from the mucosa as the carcass cools; however, the damage done by the parasites can be seen on gross or histologic examination. Occasionally it is necessary to use digestion techniques or histologic examination to document the presence of hypobiotic larvae.

ANTHELMINTIC USE

CHRISTINE A. UHLINGER

Anthelmintic drugs are administered to treat, control, and prevent parasitic infections and to minimize the economic losses associated with parasitic infection. Anthelmintics are also used for the treatment of an individual animal exhibiting clinical signs of parasitic disease.

Drug Action

To use an anthelmintic properly, it is necessary to consider its mode of action, spectrum of activity, and duration of effect. Efficacy for a given drug may be defined as its ability to kill adult or larval parasites, suppress parasitic egg production, or promote the expulsion of worms from the GI tract.

Because of the emergence of drug-resistant strains of nematodes, it is difficult to predict how a particular drug will perform in a specific animal or herd. Package inserts should be regarded as guidelines rather than gospel. It is prudent to run periodic pretreatment and posttreatment fecal examinations to assess the performance of commonly used drugs on a given farm. Readers should refer to the sections on horses, cattle, and small ruminants for more specific recommendations.

ANTHELMINTIC DRUGS

Avermectins and Milbemycins

The avermectins and milbemycins are macrocyclic lactones. They act by increasing the permeability of parasite cell membranes to chloride ions, which results in nonspastic paralysis and death of the parasite. These drugs may also act by potentiating presynaptic release of γ -aminobutyric acid (GABA), an inhibitory neurotransmitter, although this theory has been challenged.

These products have a high level and broad spectrum of activity against adult and larval nematodes. They are also effective against various ectoparasites such as mites, lice, ticks, bots, and cattle grubs; however, they are ineffective against flukes and tapeworms. These drugs suppress nematode egg production for longer than other anthelmintics. Because of its long duration of effect, moxidectin suppresses fecal egg counts and protects against reinfection for longer than ivermectin. Concern has been expressed about the environmental impact of these long-acting anthelmintics in grazing animals.

Several products have been developed for use in animals. The avermectins include ivermectin, abamectin, doramectin, and eprinomectin. The milbemycins include nemadectin and moxidectin. Oral (drench, sustained-release intraruminal device), topical ("pour-on"), and injectable formulations are available, depending on the drug. Ivermectin is safe to use during pregnancy, but currently it is not approved for use in lactating dairy animals or females of breeding age. Similarly, doramectin and moxidectin are not approved for use in female dairy cattle of breeding age. Eprinomectin is unique in that it has no withholding period for milk or meat, so there are no restrictions on its use in cattle. At labeled doses, moxidectin is a safe drug; however, accidental overdosage has caused neurologic signs in foals and miniature horses.

Benzimidazoles

BZDs comprise a large class of anthelmintics that interfere with parasitic carbohydrate metabolism by inhibiting the enzyme fumarate reductase. Many BZDs have been developed and marketed. They include albendazole, fenbendazole, mebendazole, oxfendazole, oxibendazole, parbendazole, ricobendazole, thiabendazole, triclabendazole, and the probenzimidazole drugs febantel and netobimin.

BZDs are widely used in horses and ruminants. In general they exhibit a high degree of safety and a broad spectrum of activity against GINs and lungworms. Some members of this class (e.g., albendazole) are also active against liver flukes and certain cestodes in ruminants. Albendazole and netobimin can cause teratogenicity and embryo toxicity in sheep when given during early pregnancy. Fenbendazole, oxfendazole, and oxibendazole are considered to be safe for use in pregnant animals.

Resistance to BZDs has been documented in certain equine, ovine, and caprine parasites. In general a strain of parasite resistant to one BZD drug quickly develops

resistance to other BZDs or pro-BZDs, a phenomenon known as *side resistance*.

Levamisole

Levamisole acts by causing neuromuscular depolarization and paralysis of the parasite. It has been widely used in ruminants to treat GIN and lungworm infections. However, levamisole resistance has become a problem in many areas.

The dose of levamisole should be calculated carefully because toxic doses are only one to two times therapeutic doses. Signs of toxicity may mimic those of OP toxicity, including muscle fasciculations around the lips and eyelids, hypersalivation, spastic movements, depression, and diarrhea. In ruminants, muzzle foam may develop after oral administration of the drug but usually disappears within a few hours after administration. In horses, transitory excitement has been seen after treatment. Levamisole is not recommended for use as an anthelmintic in horses. Concurrent administration of morantel, pyrantel, diethylcarbamazine, or OPs could enhance the toxic effects of levamisole.

Morantel and Pyrantel

The tetrahydropyrimidines morantel and pyrantel are cholinergic agonists that exert their anthelmintic effect by depolarizing neuromuscular junctions and causing irreversible paralysis of susceptible parasites. Morantel is slower in its onset of action but much more potent than pyrantel. These products are effective against many species of adult nematodes but do not appear to be active against larval stages. Pyrantel is also effective against tapeworms in horses when given at twice the recommended dose. The margin of safety is relatively wide, and there is no contraindication to use with other cholinergic drugs. However, it is recommended that morantel and pyrantel not be used concurrently and that neither be given with levamisole. Piperazine antagonizes the effects of morantel and pyrantel, so it should not be used with either of these drugs. Resistance to morantel and pyrantel has been documented in strains of *H. contortus* and in some cyathostomes (equine small strongyles).

Organophosphates

OPs block neurotransmission by inhibiting acetylcholinesterase. Various formulations of OP drugs are available for treating GI nematodiasis. Commonly used OPs include haloxon, coumaphos, trichlorfon, and dichlorvos. Toxicity occurs with these products in a dose-related manner, so dosages should be calculated with care. In addition, the potential danger to humans administering these products should not be overlooked. Atropine is recommended in cases of overdose in livestock.

Phenothiazine

The mode of action of phenothiazine (PTH) has not been clarified; it is thought to interfere with anaerobic metabolism of nematodes. The various formulations of PTH differ in purity and particle size. The purified product (99% PTH) with small particle size (2 μ m) is the most effective.

Although PTH is effective against a wide spectrum of GINs, resistant strains of parasites have emerged in several species. The drug is synergistic with piperazine; combinations of these drugs have effective activity against PTH-resistant nematodes. PTH used in combination with piperazine can be administered at a much lower dose.

PTH toxicity has been reported. Toxic reactions include corneal inflammation, abortion, ataxia, hemolytic anemia, photosensitization, and nephrotoxicity. The drug should not be administered to debilitated or anemic animals or to animals in the last month of pregnancy.

Piperazine

Piperazine salts block neuromuscular transmission, resulting in paralysis of susceptible GINs. The worms are then passively removed from the GI tract by intestinal peristalsis. Piperazines have low toxicity and are safe in young or pregnant animals. However, their spectrum of activity is limited, in practical terms, to ascarids. Piperazine must be used with caution in horses heavily infested with ascarids because the paralyzed ascarids can cause an impaction that may culminate in bowel rupture. Diethylcarbamazine is a piperazine derivative that has been used to control lungworm infection in sheep and cattle.

Praziquantel

Praziquantel is a cestocidal drug that causes spastic paralysis, decreased glucose uptake, and disruption of the tapeworm's tegument. Although not approved for this use, praziquantel is effective for treating tapeworm infestation in horses. It has also been used to control various cestodes in small ruminants.

COCCIDIOSIS IN FOOD ANIMALS

LORA RICKARD BALLWEBER

Coccidiosis causes serious economic losses in a variety of food animal species. Regular infections with a mixture of species generally occur throughout the life of the animal. Infections tend to be asymptomatic and self-limiting unless management or other factors allow the abnormal concentration of oocysts in the environment or when host defenses are compromised. Kids are especially susceptible to coccidiosis and may develop chronic diarrhea as a consequence. In many production operations, coccidiosis is an annual event.

■ **Life-Cycle.** Coccidiosis in ruminants is caused by intracellular parasites of the genus *Eimeria*. Essentially all of the species of *Eimeria* occurring in ruminants are rigidly host-specific. The life-cycle is complex, involving both sexual and asexual phases within the same host. Single-cell oocysts are passed in the feces and subsequently sporulate in the external environment to become infective. The sporulated oocysts are ingested by the host with contaminated food or water. Digestive enzymes activate the sporozoites within the oocysts, which excyst in the intestine and enter intestinal cells. The asexual phase of development, in which two or more cycles of merogony occurs, is then initiated. Asexual fission results in the production of merozoites. As the meronts mature, they rupture, releasing the merozoites, which enter other cells and repeat the cycle or progress to the sexual phase of development (gamogony). In this phase, merozoites enter new cells and produce macrogametes and microgametes. Microgametes are released by cell rupture and fertilize a macrogamete to form a zygote. A cyst wall then forms around the zygote, resulting in the next generation of oocysts. Once again the host cell ruptures, releasing oocysts into the lumen of the intestine, where they are then passed with the feces. The prepatent period is approximately 2 to 3 weeks and varies with the particular species of *Eimeria*.^{278,279}

■ **Pathophysiology.** Most intestinal *Eimeria* organisms develop in the epithelial cells of the lamina propria, although a few exceptions (e.g., *Eimeria bovis*) do exist. As a result of the developmental cycle, particularly the sexual phase, infected host cells are destroyed. However, the degree of damage depends on the species of *Eimeria* involved, the number of oocysts ingested, and various host factors including age, physical condition, genetic susceptibility, and immunity from previous exposure.^{278,279} If the number of oocysts ingested is low, nonimmune healthy animals may tolerate infection and show no signs of disease. Intestinal cells are destroyed, but because they normally are replaced at a rapid rate the damage done to the gut is minimal. However, if nonimmune animals are exposed to many oocysts, widespread rupture and exfoliation of intestinal cells alters gut function; causes loss of blood, fluid, albumin, and electrolytes into the gut; and allows secondary bacterial invasion. Sections of sloughed intestinal mucosa and fibrin casts may be seen in the feces, and the feces may be blood tinged.

Neurologic signs have been reported during coccidiosis outbreaks caused by *Eimeria zuernii* in calves and weaned beef cattle.^{279,280} The pathophysiology of this manifestation has not been definitively established, and conflicting theories have been proposed, including copper imbalance, plasma electrolyte imbalances, a labile neurotoxin, and a combination of stressors in which coccidia are only one factor.^{279,281-283}

■ **Populations at Risk.** Infections with mixtures of pathogenic and nonpathogenic species of *Eimeria* occur regularly throughout the life of mature animals; hence they provide the source of oocyst contamination leading to infections in young animals. After an initial period of infection the host acquires species-specific immunity. The degree of immunity acquired depends on the quantity of oocysts ingested and is boosted by continuous exposure to oocysts. It is possible that when exposed to few or moderate numbers of oocysts, a nonprotective immune response may occur; however, initial exposure is generally sufficient and animals are usually protected against clinical disease on reexposure to the same species.^{278,279} Clinical coccidiosis is therefore primarily a disease of young, nonimmune animals crowded together in areas such as feedlots, small pastures, shady creek bottoms during hot summer weather, or areas near feed or water tanks or salt licks. Under these conditions the environment is highly contaminated with oocysts from the immune animals, which pose a significant threat to other young, immunologically naive animals in the same areas. Stress, such as from shipping, weaning, dietary changes, and/or adverse weather (e.g., blizzards), appears to facilitate outbreaks.^{278,279} Corticosteroid treatment or concurrent illness can also precipitate a peracute form of coccidiosis.

Although outbreaks have been reported in range animals, coccidiosis is chiefly a disease of confinement. Clinical disease usually occurs in cattle less than 1 year of age. In dairy cattle, coccidiosis is most common in calves when they are taken from hutches into group calf pens or mini-free-stall barns. In beef cattle the disease is most prevalent in feedlot calves. In sheep, disease is usually limited to lambs less than 6 months old. Coccidiosis is most common in intensively reared lambs, although suckling lambs on pasture in constant use at high stocking rates are also at risk. Young kids appear particularly susceptible to coccidiosis, with clinical disease especially prevalent 2 to 3 weeks after weaning.²⁸⁴ Previously exposed animals may show clinical signs under conditions of stress and heavy infections. Occasionally, adult animals develop coccidiosis when moved into a new herd

and exposed to different species of the parasite to which they are not yet immune.

■ **Clinical Manifestations.** The destruction of epithelial cells and subsequent loss of blood, albumin, fluid, and electrolytes typically cause a profuse, sometimes bloody, catarrhalic diarrhea. Dehydration may occur, but most animals continue to drink water and can meet their fluid requirements. Despite the blood loss, anemia is not usually apparent. Typical of infections in dairy cattle, light infections tend to cause watery feces, poor condition, and reduced weight gain. Severe infections cause projectile, bloody diarrhea with mucus, rectal tenesmus, inappetence, dehydration, and weight loss. Clinical signs last approximately 1 week. In lambs, clinical signs are similar to those of cattle except blood and tenesmus do not usually occur. In kids, clinical signs include pasty, watery diarrhea and dehydration.²⁸⁴ Sudden death can occur in both lambs and kids, but the case fatality rate is usually low in most outbreaks. After recovery from the disease the gut does not return to normal function for several weeks, and appetite may be suppressed concurrently, leading to poor growth and/or stunting. Animals that develop "nervous" coccidiosis may exhibit muscle tremors, hyperesthesia, convulsions, nystagmus, and blindness. The mortality rate is high.

Control of Coccidiosis

The spread of coccidiosis depends on the prevalence of oocysts in the environment. The level of infection is directly related to the level of fecal contamination. Houses and pens used for sequential groups of young animals often become highly contaminated and serve as the source of infection for subsequent groups. Therefore minimizing exposure of susceptible animals to infective oocysts depends on management techniques that focus on either sanitation to avoid the buildup of fecal contamination or the elimination of environmental conditions conducive to oocyst survival or both. Decreased stocking rates, proper manure disposal, and elevated feed bunks will help reduce contamination and exposure to oocysts. Sunlight, low humidity, and treatment with formaldehyde, ammonia, or methylbromide will kill oocysts. Reduction of average temperatures in barns to 15° C and of humidity to a maximum of 80% has significantly decreased clinical coccidiosis in some areas.²⁷⁸ Prophylactic use of coccidiostats is inevitable if conditions of animal husbandry cannot or do not improve.

DRUGS. The various drugs that have been used to prevent or treat coccidiosis in ruminants are listed in Table 49-5.²⁸⁵⁻²⁹⁰ These drugs are most often administered in the feed or water. Therapeutic anticoccidials are used in acute outbreaks; however, the gamonts are the main target of these drugs. Because the life-cycle of the parasite is essentially complete and most of the intestinal damage is done by the time anticoccidial therapy is administered, it is of limited value. In acute outbreaks, scouring calves should be removed from the group. Supportive therapy, including electrolytes, glucose, and antidiarrheals, may help improve survival.^{278,284}

To prevent losses from coccidiosis, it is best to treat exposed animals prophylactically or metaphylactically rather than therapeutically. Often outbreaks of coccidiosis can be predicted based on farm history. Administration of coccidiostats during this time does not completely prevent infections; rather, they prevent clinical infections without interfering with the production of protective immunity. Drugs in this category tend to target merogony, preventing multiplication and subsequent mucosal damage.^{278,279}

TABLE 49-5

Drugs Used for Treatment and Prevention of Coccidiosis in Ruminants

Drug	Treatment*	Prevention*
Amprolium	10 mg/kg bwt for 5 days (B) 25-40 mg/kg bwt for 5 days (O, C) 65 mg/kg bwt once	5 mg/kg bwt for 21 days (B) 50 mg/kg bwt for 21 days (O)
Decoquinatate Diclazuril		0.5 mg/kg bwt for 28-30 days 1 mg/kg bwt once; a second dose can be given 14 days later
Lasalocid		1 mg/kg bwt continuously (B) 25-100 mg/kg feed, continuously 80 mg/kg milk replacer (neonatal calves) Free choice in salt at 0.75% total salt mixture
Monensin	2 mg/kg bwt for 20 days (O)	1 mg/kg bwt for 28 days 10-20 ppm in feed, continuously 16-33 g/ton of feed, continuously Intraruminal controlled-release device (weaned beef calves)
Nitrofurazone 10	15 mg/kg bwt for 5-7 days In feed at 0.04% or in water at 0.0133% for 7 days	33 mg/kg bwt for 14 days In feed at 0.04% for 21 days
Salinomycin		10 ppm in feed (O)
Sulfadimethoxine		50 mg/kg bwt for 5 days (O)
Sulfamethazine	110 mg/kg bwt for 5 days 140 mg/kg bwt for 3 days 140 mg/kg bwt once, then 70 mg/kg bwt for 5-7 days	35 mg/kg bwt for 15 days (B) 25 mg/kg bwt for 7 days (O) 55 g/ton of feed (C)
Sulfaquinoxaline	10-20 mg/kg bwt for 5-7 days	
Toltrazuril	20 mg/kg bwt	20 mg/kg bwt once, 10 days after turnout onto pasture

B, Bovine; bwt, body weight; C, caprine; O, ovine.

*Oral administration; dose or regimen may vary among references.

Note: Coccidiostats used in poultry feeds may be toxic to ruminants.

OTHER STRATEGIES FOR MINIMIZING CLINICAL INFECTIONS. Use of growth implants containing estradiol and progesterone can attenuate the effects of high oocyst challenge in dairy calves.²⁹¹ Attempts at developing a conventional vaccine against coccidiosis have been disappointing. Peptide or recombinant vaccines may prove to be efficacious in the future.²⁹² Immunization with a “trickle dose” of oocysts 2 weeks before turnout onto infected pasture may attenuate the effects of natural challenge in calves.²⁹³ Oocysts can survive the hay-making process, so pastures known to be infected with coccidian oocysts should not be used to make hay for susceptible animals.²⁹⁴

■ **Evaluation of Preventive Programs.** Oocysts can be found using standard flotation techniques.²⁸⁴ However, the presence or absence of oocysts does not necessarily correlate with the presence of disease. In any given herd or group a baseline level of oocyst shedding is normal. Because immunity is incomplete, many immune animals shed oocysts. On the other hand, nonimmune animals with low-level infections may shed oocysts but have no clinical signs or need for treatment. Furthermore, because intestinal damage occurs during the prepatent period, animals with clinical coccidiosis may not yet be shedding oocysts. This variation complicates both evaluation of preventive measures and the diagnosis of coccidiosis in clinically affected animals. The presence of oocysts in healthy or sick animals does not necessarily indicate the need for anticoccidial treatment.

Nevertheless, microscopic examination of diarrheic or bloody feces from young animals still remains the most direct and cost-effective method of diagnosis.^{278,279} Examination of fecal samples from several animals is needed to obtain a true estimate of the presence of coccidia within a group. Because pathogenicity of the various species of *Eimeria* varies considerably and the clinical picture is not specific, it is imperative that species identifications be determined.²⁷⁷ This information is then combined with a good history and thorough knowledge of the herd management on the farm in question to guide interpretation of clinical observations and diagnostics.

Herds that require preventive strategies have a history of prior disease and a large proportion of herd members shedding high numbers of oocysts. Efficacy is evaluated on the basis of a decreased prevalence of clinically ill animals.

■ Clinical Management

DIAGNOSIS. Definitive diagnosis may be made at necropsy. Antemortem, young, diarrheic animals passing large numbers of oocysts are not difficult to diagnose. However, as discussed earlier, making a diagnosis on the basis of oocyst counts alone can be misleading.

TREATMENT. Drugs used in the treatment of coccidiosis are listed in Table 49-5. Supportive therapy, when indicated, is primarily directed at replacing fluid losses and supporting the animal until the gut epithelium regenerates.

Nutrition of the Sick Animal

RAYMOND W. SWEENEY AND MERI STRATTON-PHELPS

The influence of nutrition on the recuperation of veterinary patients is often overlooked, although the effects of nutritional status on recuperative ability are well known. Many patients are in a state of protein calorie malnutrition when first presented to the clinician. Early intervention with supplemental calories, protein, and other essential nutrients provides the patient with the dietary resources needed to optimize immune function, promote wound healing, and improve the recovery of the animal.

Multiple research studies have demonstrated that the immune response of an animal is directly related to the nutritional state of the animal.¹⁻⁴ A deficiency of calories, protein, minerals, or vitamins alters the production of inflammatory cytokines, adversely affects leukocyte function, and decreases host resistance to bacterial infections.^{1,2} Clinical studies in hospitalized horses have demonstrated an improved recovery after gastrointestinal surgery in patients supplemented with intravenous nutrition.⁵

Different forms of diet therapy may be employed, depending on the clinical condition of the animal and the ability of the animal to tolerate different types of supplemental nutrition. Large animal patients that have a functional gastrointestinal tract and can tolerate placement of a nasogastric (NG) or esophageal feeding tube are candidates for treatment with liquid enteral nutrition. Glucose can be added to a patient's intravenous fluids to provide an energy source. Parenteral nutrition (PN) is ideal for animals that have gastrointestinal ileus, that have an obstructive lesion in the gastrointestinal tract, or that are recumbent.

ASSESSMENT OF NUTRITIONAL STATUS

Before initiation of dietary therapy, the large animal patient must be examined to determine its nutritional needs. Animals may be anorectic owing to systemic disease, or they may be dysphagic owing to a mechanical (foreign body, abscess, poor dentition) or neurologic (botulism, tetanus, viral encephalitis) disease. Assessment of the nutritional status of the patient should include a measurement of the body weight (BW) and body condition score (BCS) of the animal. BW measurements should be taken at the time that the large animal patient is presented to the clinician and as frequently as possible during hospitalization. If a scale is not available, estimations of BW can be made with a weight tape or by using length and girth measurements (see Chapter 9). When a scale or weight tape cannot be used, the animal's BCS should be used to evaluate the nutritional status of the patient. The BCS system enables the clinician to subjectively assess the endogenous protein and lipid stores in a large animal patient. A list of BCS descriptions for different species is provided in Chapter 9. Changes in weight or BCS are often easily overlooked in day-to-day observations of the patient if a concerted effort is not made to detect them.

Palpation of the animal (ribs, dorsal vertebral processes) is necessary in sheep with a heavy fleece, camelids with long fiber, and horses with a thick winter hair coat. Animals with a low BCS (1 to 3 of 9; 1 to 1.5 of 5) have minimal protein and lipid stores and are at greater risk for developing protein calorie malnutrition after a period of anorexia. Large animal patients with a high BCS (7 to 9 of 9; 3.5 to 5 of 5) that are anorectic may have an increased risk for developing complications (hyperlipemia, hepatic lipidosis) from abnormal lipid metabolism. A clinician should initiate dietary therapy in a large animal patient that loses 3% to 5% of its initial BW or whose BCS diminishes by ≥ 1 grade.

Biochemical tests provide another method to evaluate the nutritional status of the large animal patient. Endogenous protein catabolism is a normal physiologic response to anorexia in animals. To date, few biochemical tests are available to assess protein malnutrition in large animals. Although anemia and hypoproteinemia (hypoalbuminemia) are occasionally seen in cases of malnutrition, they are not specific and frequently are associated with another primary disease process such as parasitism or protein-losing enteropathy. Severe protein malnutrition can result in abnormally low serum urea nitrogen (SUN) concentrations in horses and ruminants. Liver disease also decreases the formation of urea nitrogen and must be ruled out when evaluating the animal. Protein malnutrition can result in an increase in the urinary excretion of 3-methylhistidine, a myofibril amino acid that is not metabolized. Measurement of this metabolite in the future may be a useful tool to monitor protein catabolism in large animal patients.

Underfed horses develop a mild hyperbilirubinemia (unconjugated) that, although not directly related to nutritional status, is readily reversed when food intake resumes.^{6,7} Animals that are in negative energy balance also use endogenous lipid as an energy source. Serum nonesterified fatty acids (NEFAs) and/or triglycerides are expected to rise in these animals. Once nutritional support or refeeding is initiated, these lipid metabolites usually decrease. Pathogenic elevations in serum triglyceride (>500 mg/dL) develop in some equine patients that are anorectic and that have a high daily energy requirement (lactation, pregnancy), insulin resistance (Cushing's syndrome), or renal failure and in predisposed breeds (miniature horses, ponies). Ketone bodies have a glucose-sparing effect in the body and are normally produced from fatty acids and amino acids in animals that are in negative energy balance. Ketonuria develops after the excess production of ketones and can be used to indirectly monitor the severity of caloric malnutrition in ruminants. Hypoglycemia is a common complication in large animal neonates that are malnourished but is an uncommon finding in adults. Both adult and neonatal large animals may develop glucose intolerance and hyperglycemia during periods of systemic illness and may require treatment with

a diet that will not exacerbate the hyperglycemia. Electrolyte and mineral derangements including hypocalcemia, hypomagnesemia, hyponatremia, hypochloremia, hypophosphatemia, and hypokalemia may develop in inappetent systemically ill large animals or during the refeeding process.^{8,9}

NUTRIENT REQUIREMENTS OF LARGE ANIMALS DURING CLINICAL ILLNESS

Although it is generally accepted that sick animals have increased nutritional requirements, these requirements have not been quantified for specific disease conditions. The current trend in critical care nutrition is to provide adequate calories to meet the resting energy requirements of the hospitalized patient and sufficient protein to meet the maintenance requirements. These values can be calculated based on the animal's BW (see Chapter 9) or determined by reference to National Research Council (NRC) tables.¹⁰ For adult horses, the resting digestible energy (DE) requirement is calculated as DE_{rest} (Mcal) = $0.975 + 0.021 \text{ BW(kg)}$, and maintenance crude protein (CP) requirement is calculated as CP (g) = 1.26 BW(kg) .¹⁰ For a 450-kg horse, these would equate to a 10.4-Mcal resting energy requirement and a 567-g crude protein requirement. For foals and calves, resting energy requirement is approximated as DE (Mcal) = 0.07 BW(kg) and digestible protein as DP (g) = 3.5 BW(kg) , which would equate to 3.50 Mcal (3500 kcal) and 175 g of protein for a 50-kg neonate. These values represent starting points for formulating dietary therapy, and adjustment based on clinical response or specific medical conditions may be necessary.

Vitamin and mineral requirements, also available from NRC tables, can usually be met if an enteral diet is formulated with commercial complete feed pellets or pelleted hay. Parenteral solutions can be supplemented with vitamins and minerals. Although B vitamin deficiencies do not occur naturally in horses and cattle, supplementation is probably beneficial in large animals with gastrointestinal diseases that result in the disruption of the normal tract flora that produce B vitamins.

ORAL SUPPLEMENTATION

The animal's feed intake should be monitored during treatment. If the animal is losing condition despite consuming all feed offered, more or higher-quality feed should be provided. If the animal's appetite is poor, the patient should be offered a variety of highly palatable feeds including fresh grass, dried forages, and complete commercial feed pellets. Although sweet feeds are palatable, their use should be limited to a top dressing of other feeds. Ruminants in particular may consume small quantities of fresh feed if it is offered frequently, whereas if the same quantity is offered in one feeding, it may be ignored after a few bites. Many dairy cows can be coaxed into eating hay if it is placed in the back of the pharynx by the clinician, and oropharyngeal stimulation may result in increased voluntary feed consumption. Fresh silage and dried brewer's grain frequently appeal to the hypophagic cow. Many sick horses and ruminants benefit from grazing if grass is available.

A hospital feeding chart can be created to facilitate monitoring of the feed consumed by a hospitalized patient. Use of an inexpensive farm scale is the most accurate way to measure the amount of feed offered to a patient. Feed that is not consumed within a few hours should be weighed and discarded to prevent the accumulation of stale, and possibly fermented malodorous feed. If the animal does not voluntarily consume enough feed to meet its resting energy requirements or its maintenance

protein requirements, or if the animal loses weight or condition, dietary therapy with a liquid diet by intragastric administration should be considered. Dysphagic animals can be managed with a liquid diet that can be fed through a tube as the sole source of nutrition.

LIQUID DIETS FOR HORSES

Adult Horses

Assisted enteral feeding (AEF) with a liquid diet should be used in horses that require nutritional support to maintain their energy and protein intake during a short period (2 to 14 days) of partial or complete anorexia. Horses that are good candidates for AEF do not have gastrointestinal ileus or gastric reflux and are able to tolerate an indwelling NG tube, repeated intubation, or an esophagostomy tube. Horses fed using AEF should be standing. Diet choice will depend on product availability and on the nutrient requirements of the equine patient. Energy, protein, vitamin, and mineral requirements should be calculated for each equine patient to ensure that the appropriate concentration of nutrients is administered. Enteral diets may be administered to provide partial or complete nutrient supplementation to an adult horse.

Liquid diets may be classified into three categories: (1) complete feed blender diets consisting of liquefied or finely ground whole food suspended in water; (2) composition diets containing highly digestible whole protein (usually casein or soy), fats, and carbohydrate; and (3) commercially available liquid enteral diets sold for human use. When commercial liquid enteral diets are chosen, the source of carbohydrate should be examined, and only diets that contain a limited amount of sucrose should be used for horses.

Vital HN* and Osmolyte HN* are human liquid enteral diets that have been administered to adult horses.^{11,12} Ross Laboratories produces a variety of human liquid enteral products, including formulations that contain oat and soy fiber. A partial list of formulas that can be administered to adult horses is provided in Table 50-1. All human formulations are designed for administration through a small-diameter tube and are an option for horses that can tolerate only an 18 Fr feeding tube (Mila NG18100).[†] Most products contain approximately 1 kcal/mL and 4.1 to 4.2 g of protein per 100 kcal. Almost 10.5 L of a human enteral product would be required to meet the stall resting energy requirement of 10.4 Mcal for a 450-kg horse, at an approximate cost of \$120/day. The protein content (approximately 440 g) in 10.5 L of Osmolyte or Vital HN will not meet the requirement of 567 g of protein for a 450-kg horse, and supplemental protein (casein, lactalbumin, whey, soy) may need to be added to each formulation to ensure adequate protein intake. The nutrient composition of a human formulation should be evaluated to ensure that the horse is receiving the most appropriate product. Diets that contain a high (>15%) proportion of calories as fat are contraindicated in horses with hyperlipemia and hepatic lipidosis. The soluble carbohydrates included in a human enteral formulation may not be tolerated by horses that have a compromised gastrointestinal tract or by horses with hyperglycemia. Any commercial human product should be fed starting at approximately 25% of the final maintenance requirement, with the volume gradually increased over 4 to 7 days to the target quantity.

8. Oat hay pellets [†]	1760	8.6	2.2	29.1

*As fed, manufacturer analysis.

[†]As fed, estimated values.

Although they may be inconvenient, complete feed blender diets have the advantage of being inexpensive (\$5 to \$10/day), and the ingredients are usually available. Most products contain 14% to 25% crude fiber (dry matter [DM]) and vary in energy density from 2.6 to 3.1 Mcal/kg of diet. A list of commercial feeds that can be fed as a liquid enteral diet is provided in Table 50-2. From 3.4 to 6.0 kg of diet per day is required to meet the resting energy requirements of a 450-kg horse. In some equine patients, protein supplementation may be required. Some patients may also benefit from vitamin and mineral supplementation. This type of a diet may be prepared either by grinding one quarter to one third of the daily requirement of dry pellets in a blender and suspending the blended product in water, or by soaking the pellets in water before blending to create a slurry. The total amount of water that is added to the preparation should be recorded and added to the daily fluid administration log for the patient. The preparation should be fed three to six times daily to horses that require complete feeding or once or twice daily if only partial supplementation is required. Hay pellets or alfalfa meal can be blended into a liquid enteral diet; however, the nutrient content and quality of pelleted forages is often more variable than those of commercial feeds.

An ingredient-based composition diet can be designed using structural carbohydrate and protein ingredients that are available in the local region. One such diet (Table 50-3) composed primarily of dehydrated cottage cheese, dextrose, and alfalfa meal requires considerable preparation by the clinician.¹³ Corn, canola, or soy oil (113 to 227 mL)

can be added as an energy source. Diets with high concentrations of oil and dextrose should be avoided. Structural carbohydrate should comprise 50% to 75% of the diet DM. The approximate cost for complete supplementation with the homemade equine diet is \$30 to \$40 per day for a 450-kg horse. As indicated in Table 50-3, the homemade diet is introduced gradually over a period of 7 days.

The consistency of any formulation can be adjusted by blending the ingredients with water to ensure that the formulation can be delivered through the NG tube that has been selected for administration. Larger diameter NG tubes (>0.65 cm inner diameter) must be used when fiber is included in the diet. The diet should be tested using the NG tube before the tube is placed in the animal to ensure that the tube will not be clogged with the feed. The total volume of enteral diet should be divided into at least three feedings per day and should be administered slowly enough to ensure that feed does not reflux around the NG tube. No more than 6 to 8 L of total volume should be administered at one time. This volume must be appropriately lowered when treating a pony or miniature horse. Before feeding, the amount of residual fluid in the stomach should be checked. Horses with ≤ 2 L can be fed the meal, but if the volume of gastric fluid is >2 L, the feeding should be delayed for 2 hours. Horses with persistent gastric reflux should not be fed enterally, and instead the clinician should consider treatment with PN. After the horse has been fed, the tube should be flushed with at least 500 mL of water before the tube is capped. Excessive distention of the stomach must be avoided. If the NG tube will remain in place

TABLE 50-3

Suggested Feeding Regimen for a Liquid Diet for a 450-kg Adult Horse^{11*}

Ingredient	Day						
	1	2	3	4	5	6	7
Water (L)	21	21	21	21	21	21	21
Dextrose (g)	300	400	500	600	800	800	900

[†]May substitute edible acid casein—90 mesh, American Casein Company, Burlington, NJ.

[‡]Electrolyte mix ingredients: NaCl, 10 g; NaHCO₃, 15 g; KCl, 75 g; K₂HPO₄, 60 g; CaCl₂·2H₂O, 45 g; MgO, 25 g.

between feedings, a muzzle may be used to prevent the horse from removing the tube. During treatment, horses should be offered palatable feeds to encourage a transition to voluntary food consumption. The equine patient can gradually be weaned from AEF once it is consuming 75% of its DE_{rest} on a daily basis.

All liquid enteral diets may result in a mild, self-limiting diarrhea when fed as the sole source of nutrition, possibly because of lack of dietary fiber or because of fermentation of the highly soluble ingredients in the large colon.^{11,13,14} This may be ameliorated by addition of a fiber source such as alfalfa meal.

Foals

Mare's milk is the ideal supplemental feed for orphan or critically ill foals. Neonatal foals with normal gastrointestinal tract motility can initially be fed a volume sufficient to meet 10% of BW (100 mL/kg BW) each day. The volume should be incrementally increased until the foal is consuming 20% of its BW (200 mL/kg/day). Neonatal foals should be offered milk every 2 hours as long as the feedings are tolerated and should be encouraged to nurse from their dams once they develop a strong suckle reflex. A small-diameter NG feeding tube can be used for milk supplementation until the foal can nurse voluntarily. Foals have minimal endogenous energy stores and require supplemental nutrients within 6 to 12 hours of losing the ability to nurse. Any foal that cannot tolerate enteral feedings should be placed on PN to ensure that its dietary requirements are met.

Orphan foals can be fed 20% of their BW per day using a commercial foal milk replacer (Mare's Match*, Mare's Milk Plus[†], Foal Lac[‡]) if a nurse mare or mare's milk is not available. If a foal milk replacer is not available, goat's milk can be fed as a short-term substitute but is not recommended for long-term use because the nutrient profile is different from that of mare's milk. Because indigestion occurs relatively commonly when using milk substitutes in foals, dietary changes should be instituted gradually over a period of 1 to 2 days at a minimum. If indigestion occurs, both the frequency and volume of feeding should be decreased until the indigestion resolves. Foals that are 2 weeks of age or older can be fed every 4 to 8 hours, with a decreased frequency of feeding as the foal ages. Orphan foals should be fed from a pan or bucket because it forces the foal to actively ingest and swallow the milk and decreases behavioral complications

that can develop when an orphan foal is bottle-fed. If a foal will be bottle-fed, the nipple should be checked to ensure that milk does not freely flow from the nipple. Improper use of a bottle can result in aspiration pneumonia if the foal does not have a normal swallow response.

LIQUID DIETS FOR RUMINANTS

In most cases the most practical and least expensive way to force-feed ruminants is the blender-type or slurry diet. Hypophagic adult cattle may be force-fed a suspension of alfalfa meal and dried brewer's grain (3 to 5 kg each in 20 L of water) two or three times daily. If a ruminal fistula is necessary (e.g., tetanus), the diet may be directed into the rumen. Presumably similar preparations would be suitable for sheep and goats, although published reports are scarce. Administration of ruminal liquor obtained from a healthy donor cow provides a good source of microflora as well as volatile fatty acids as an energy source in hypophagic cows.¹⁵

INTRAVENOUS FEEDING

Intravenous Dextrose

The simplest and least expensive form of intravenous feeding is the supplementation of intravenous crystalloid fluids with dextrose. This represents a short-term solution for boosting caloric intake when a rapid return to normal feed consumption is anticipated. Dextrose can be added to make a final solution with a concentration that ranges from 2.5% to 10%. If the fluids are infused at a rate to meet maintenance fluid requirements (2.2 mL/kg/hr), the patient's renal threshold of glucose (10 mmol/L or 180 mg/dL for adult horses; 12 mmol/L or 216 mg/dL for foals) will usually not be exceeded. The energy provided may be calculated based on 3.4 kcal/g of dextrose. A 450-kg horse treated with fluids supplemented with 2.5% dextrose and infused at a maintenance rate of 1 L/hr (24 L/day) will receive 2040 kcal from the dextrose (close to 20% of the patient's DE_{rest}). Although protein is not provided with the dextrose therapy, the supplemental energy will blunt the catabolism of endogenous lipid and protein stores. Dextrose-supplemented fluids can be administered as the sole source of nutrition for 24 to 48 hours. If a patient consumes <75% of its maintenance protein requirement and/or <75% of its resting energy requirement, supplemental nutrition should be administered. Patients that have complications with glucose regulation may be able to tolerate therapy with a 2.5% solution of dextrose, but if complications with glucose regulation persist, alternative methods of nutritional supplementation should be initiated.

[‡]Pet Ag, Hampshire, IL.

Parenteral Nutrition

Intravenous feeding or PN is a means of providing nutritional support to animals that do not have a functional digestive tract or animals that cannot tolerate placement of an NG tube. Because of the greater expense (approximately \$80/day for foals and \$450/day for adult horses), the need for special infusion supplies, and the risk of complications when compared with enteral feeding, PN should be reserved for cases in which bowel rest is necessary. Possible indications for PN include neonatal diarrhea in cases in which oral feeding exacerbates the diarrhea, postoperative feeding after gastrointestinal surgery, nonsurgical intestinal obstruction or ileus (proximal jejunitis, botulism), dietary supplementation in a laterally recumbent patient, gastrointestinal intolerance in premature neonates, and hypoxic ischemic gastrointestinal syndrome. Because enteral nutrition provides nutrients directly to the enterocytes and promotes both intestinal barrier function and immune system function, a small volume of a liquid enteral diet should be administered whenever possible in a patient receiving PN.

PN formulations are composed of dextrose and lipids as an energy source, and amino acids as a protein and nitrogen source. Compatible vitamin and mineral supplements can be added to the PN formulation. A variety of PN mixtures can be designed to meet the nutritional requirements of a clinically ill large animal patient. Sufficient calories in the PN solution must be provided in the form of carbohydrates and lipids to promote the incorporation of amino acids into protein instead of the catabolism of amino acids for energy. The ideal calorie-to-nitrogen ratio for adult horses is extrapolated from data calculated for critically ill humans, in whom the ideal ratio is 120:1 to 150:1 for healthy individuals, and 80:1 to 90:1 for acutely ill humans.¹⁶ (Glucose provides 3.4 kcal/g, amino acids provide 4 kcal/g, and lipids provide 11 kcal/g; amino acids include 0.16 g of nitrogen per gram.) Animals with systemic inflammatory diseases or severe protein loss and large animal patients recovering from major surgery will probably benefit from a therapeutic enteral or parenteral diet that has a calorie-to-nitrogen ratio that is between 80 and 100, as long as protein supplementation is not contraindicated in the patient. Although PN solutions can be formulated with dextrose alone as the energy source, addition of lipids provides many advantages. Because of the larger size of the molecule and higher energy density on a per-gram basis, replacement of dextrose with lipid lowers the PN osmolarity and/or infusion volume required to meet the energy needs of the patient and reduces the hyperglycemic effect of PN administration. The lipid content of the PN solution is usually targeted as approximately 50% but no more than 80% of the nonprotein calories in the formulation. Animals with hypertriglyceridemia (>500 mg/dL) or hepatic lipidosis that require PN should be treated with a formulation that is restricted in lipid, or that is lipid-free, whereas the concentration of dextrose or the PN administration rate should be restricted in animals with hyperglycemia. If long-term administration (>5 days) is expected, calcium (200 mg/kg/day), phosphorous (110 mg/kg/day), and other micronutrient supplementation of the PN solution should be considered. Commercial multiple vitamin (e.g., MVI-12*) and trace mineral (e.g., Multitrac5†) supplements are available for addition to the PN mixture but may add as much as \$20/day to the cost of the formulation.

All parenteral solutions must be mixed aseptically. A laminar flow hood should be used to prepare the formulation, but if this equipment is not available, the solution can be mixed in a clean room with low traffic such as a surgical

BOX 50-1

Instructions for Compounding a Parenteral Nutrition Solution

1. Compound the solution in a laminar flow hood, if available. Use a clean room in the hospital if a laminar flow hood is not available.
2. Clean the preparation area well, using alcohol as a final preparation on the counter.
3. Wear a gown, mask, and sterile gloves when compounding the parenteral nutrition (PN) solution.
4. Wipe off all injection sites and infusion ports with alcohol before connecting the infusion lines.
5. Use a new transfer set for each PN ingredient.
6. Add the dextrose and amino acid solution to the compounding bag or container.
7. Add the lipid solution *after* the dextrose and amino acid solutions have been mixed together.
8. Gently swirl the solution to mix the ingredients.
9. Add any vitamin or mineral supplements to the solution *after* the macronutrients (dextrose, amino acid, lipid) have been added.
 - a. Ensure that there are no incompatibilities with the supplemental additives.
10. The PN formulation can be stored in the refrigerator for 24 hours, followed by 24 hours of storage at room temperature. Shield the solution from sunlight.

instrument preparation room. Alternate options for PN compounding include human hospitals, human parenteral compounding companies, and the commercial compounding pharmacy CAPS (Central Admixture Pharmacy Services, www.capspharmacy.com). The formulation can be made in a 2- or 3-L all-in-one infusion bag (Vitalmix‡), in a sterile glass container, or in a sterilized carboy. Single-use infusion containers are preferred. Guidelines for PN compounding are listed in Box 50-1.

Parenteral solutions should be administered through a dedicated line in a large-diameter or central vessel (jugular, vena cava) to reduce complications from phlebitis but can be administered in a peripheral vein (lateral thoracic, cephalic) if the osmolarity of the solution is <900 mOsm/L. A multilumen polyurethane catheter§ is ideal for PN infusion because one port can be reserved exclusively for PN infusion while the other port(s) can be used for blood sampling and medication or fluid infusion. In many settings, when this is not feasible, dual infusion ports can be added to a single-lumen Arrow catheter. Patient medications may not be compatible with the PN solutions and should be given through a separate line, or the PN line flushed with saline before and after administration. Correction of electrolyte abnormalities in separate crystalloid supplemental fluids is best because rapid adjustments in the electrolyte supplements can be made without discarding an expensive PN solution.

The PN solution should first be administered at 25% to 33% of the total infusion rate, and if the patient tolerates the PN the rate should be gradually increased over 12 to 36 hours. A fluid administration pump facilitates a constant rate of infusion. During PN therapy the patient should be monitored for hyperglycemia, hypertriglyceridemia, and serum electrolyte abnormalities. Hyperglycemia and hypertriglyceridemia should be managed first by reducing the rate of infusion and then by lowering the concentration of dextrose or lipid in the PN solution. If hyperglycemia is

persistent, treatment with subcutaneous Ultralente insulin (0.2 to 0.3 IU/kg, q12-24h) or regular insulin as a continuous rate infusion (0.005 to 0.01 U/kg/hr) may improve glucose use and permit increased caloric intake without further hyperglycemia. Similarly, heparin (40 IU/kg q12h) may be administered if hyperlipemia persists. At the conclusion of therapy, PN should be gradually discontinued over 18 to 36 hours.

PARENTERAL NUTRITION IN HORSES

Adult Horses

The stall resting digestible energy (DE_{rest}) and maintenance protein requirements, calculated as shown earlier, should be used as guidelines when formulating a PN solution for an adult horse. Although the exact energy requirements during a clinical illness have not been determined for the equine

Parenteral Nutrition Worksheet for Adult Horses

PATIENT INFORMATION

1. Initial body weight (BW) (kg) _____ kg
2. Stall resting energy requirement: DE_{rest} (kcal/day) = $975 + 21$ (BW in kg) _____ kcal
3. Maintenance energy requirement: DE_{maint} (kcal/day) = 33.3 (BW in kg) _____ kcal
4. Protein requirements: Crude protein (g/day) = 1.26 (BW in kg) _____ g
5. Fluid requirements for maintenance: 60 mL/kg/day _____ mL

PARENTERAL NUTRITION FORMULATION

6. Total kcal required per day (estimate between **2** and **3** calculated above) _____ kcal
7. Calculate volume of 10% amino acids required to meet protein requirement (from 4)
Protein (g) \times 1 mL/0.1 g of protein for a 10% amino acid solution* _____ mL
8. Calorie contribution from 10% amino acid solution (from 7)
4 kcal/g protein \times grams of protein in solution _____ kcal
9. Total kcal required/day (from **6**) – total kcal provided by amino acids (from **8**) _____ kcal
The caloric contribution from protein can be omitted from the following calculations, if desired.
10. Determine amount of lipid required to meet 20% to 70% of the remaining energy requirements;
10% lipid solution contains 1 kcal/mL, 20% lipid solution contains 2 kcal/mL
Example: If providing 50% of remaining energy requirements with 10% lipid:
(kcal [from 9] \times 0.5) \times 1 mL/1 kcal (substitute 0.5 mL/1 kcal if using 20% lipid) _____ mL
11. Calculate remaining energy requirements to be provided by 50% dextrose _____

Example

- Providing 50% of calories with dextrose: (kcal [from 9] \times 0.5) \times 1 mL/1.7 kcal _____ mL
12. Add 1 to 2 mL of B vitamin complex per liter _____ mL
 13. Add up to 5 mL of trace minerals per day _____ mL
 14. Determine the total volume of the PN solution (**7** + **10** + **11** + **12** + **13**) _____ mL
 15. Determine the rate of PN infusion for a 24 hour period: mL (from **14**)/24 mL/hr _____
 16. Calculate the calorie:nitrogen ratio for the PN solution _____
Total kcal from PN solution (from **6**)/(total g of protein/6.25) _____
 17. Calculate osmolarity of the solution

10% Amino acid	_____ mL (from 7)	\times 0.840 mOsm/mL =	_____ mOsm	
10% Lipid	_____ mL (from 10)	\times 0.276 mOsm/mL =	_____ mOsm	
50% Dextrose	_____ mL (from 11)	\times 2.550 mOsm/mL =	_____ mOsm	
	+ _____ Total mL			
				+ _____ Total mOsm
PN solution mOsm/L =	Total mOsm/Total mL \times 1000 mL/L			_____ mOsm/L

*An 8.5% amino acid solution with electrolytes contains 0.085 g of protein per milliliter and 1.045 to 1.444 mOsm/mL.

FIG. 50-1 ■ Parenteral nutrition worksheet for adult horses.

species, provision of enough nutrients to meet the stall resting requirements should provide the adult horse with sufficient energy to blunt the catabolic effect of anorexia and illness. Horses with a limited medical budget can be managed with a PN solution that provides a portion of the DE_{rest} energy.

The preferred way to formulate a PN solution is first to meet the calculated protein requirements of the horse with the amino acid solution and then to meet the remaining energy requirements with a combination of dextrose and lipid calories. A formula with approximately 50% of non-protein calories as lipid and 50% as dextrose is recommended. The final composition of the solution can be altered to manage patients with hyperglycemia or hypertriglyceridemia. An example of a worksheet used to facilitate calculations for PN formulation for an adult horse is shown in Fig. 50-1. Alternatively, the clinician can calculate the daily requirements of dextrose, amino acids, and lipids on a dose per BW basis. The formula listed in Table 50-4 provides 2.8, 1.3, and 0.8 g of dextrose, amino acids, and lipids, respectively, per kilogram per day, providing the resting stall DE and maintenance protein requirements with a calorie:nitrogen ratio of 108:1, with 48% of nonprotein calories as lipid and an osmolarity of 1026 mOsm/L. Approximate cost is \$450/day not including administration sets. If the clinician is willing to forgo the benefits of lipid inclusion, the lipid component in Table 50-5 can be replaced with an additional 2.8 g/kg/day of dextrose, at a savings of nearly \$200/day.

A commercial amino acid and dextrose admixture (Clinimix, 5% Aminosyn II, 25% dextrose*) is a convenient alternative that does not require special preparation. However, because these products do not contain lipids, the osmolarity (1539 mOsm/L) is higher than that of the PN solution in Table 50-5. The increased cost of these products may be partially offset by the savings in sterile mixing containers and time costs of PN preparation.

Foals

The nutrient density of PN solutions for foals is higher than that for adult horses. The PN formula in Table 50-5 is designed to provide 10, 3.5, and 2 g of glucose, amino acid, and dextrose, respectively, per kilogram per day. This formula will provide 70 kcal/kg/day at a calorie:nitrogen ratio of 125:1 and an osmolarity of 1139 mOsm/L, with 40%

TABLE 50-5

Parenteral Nutrition Formulation for Foals

Ingredient	Dosage Rate	Volume per Day (50-kg Foal)
50% Dextrose	10 g/kg/day	1000 mL
10% Amino acids	3.5 g/kg/day	1750 mL
10% Lipid	2 g/kg/day	1000 mL
Begin administration at 0.7 mL/kg/hr and gradually increase to target of 3.1 mL/kg/hr (3750 mL/day for a 50-kg foal).		

of the nonprotein calories as lipid. Once the full flow rate is achieved, additional caloric density can be achieved by increasing the proportion of lipid emulsion, and if fluid volume restriction is required, 20% or 30% lipid emulsion can be used instead of 10%. Further increases in caloric intake require increased flow rates.

PARENTERAL NUTRITION IN RUMINANTS

Because of cost, use of PN is usually limited to calves, and little information exists on the use of PN in the adult bovine or the ovine and caprine species. The most common indication for the use of PN in calves is diarrhea, particularly in chronic cases accompanied by weight loss.¹⁷ In such cases, if sufficient milk is fed to meet the calf's nutritional needs, the diarrhea is exacerbated, and PN allows the quantity of milk to be reduced without compromising the nutritional status of the patient. The PN regimen provided for foals in Table 50-5 would also be suitable for calves. However, because amino acids and lipids are the most expensive components of PN, a modified formula based on a 10:2:1 glucose:amino acid:lipid ratio has been used with success.¹⁷ For a 50-kg calf, this would result in administration of 1 L of 50% dextrose, 1 L of 10% amino acids, and 500 mL of 10% lipids daily, at an approximate cost of \$60 per day. Eliminating the lipid emulsion from the formula is an acceptable alternative that will reduce the cost approximately 15%. A multiple B vitamin product may be added to the formula (approximately 1 mL of supplement per liter of PN), but trace minerals are not usually necessary for the short-term administration that is most common in calves.

Catheter-related complications are rare in calves, and a central venous catheter, although preferred, is not required. I (RWS) have had success with 16-gauge, 3/4-inch, Teflon-coated, over-the-needle catheters available from several distributors. These are placed in the jugular vein, sutured or glued to the overlying skin, and left in place for up to 10 days if no signs of phlebitis or sepsis occur.

SPECIAL DIETS

Numerous diseases require specific alterations in the therapeutic ration because of metabolic disturbances that accompany these conditions. Recommendations are discussed in the individual chapters dealing with these diseases and include alterations in dietary protein for hepatic disease and restrictions in the protein and calcium content of the diet for horses with chronic renal failure. A nutritionist can develop therapeutic enteral and parenteral formulations to meet the unique nutritional requirements of individual patients.

Genetic Disorders

ANGELA M. HUGHES

INHERITED DISEASES

Inherited diseases and congenital defects are structural or functional abnormalities that may or may not be obvious at birth. There are a wide range of possible defects, from a single structural change (e.g., leg length) to the involvement of multiple organs or systems (e.g., storage diseases, chromosomal abnormalities), depending on the type and extent of toxic exposure during gestation or genetic mutation. It is important to identify animals with genetic or congenital disorders because of the economic and emotional impact on clients, but many disorders can be difficult to recognize and trace, particularly if they lead to embryonic or fetal death, abortion, dysmaturity, premature birth, or full-term stillbirth.

It is important to remember that not all congenital defects are genetic in origin and making the distinction between conditions caused by an environmental factor and a genetic cause will help clients make appropriate changes to prevent the disorder in the future. To determine the cause of a disorder, it is vital that each case be thoroughly examined. Each case should be subjected to a full, careful description of the disorder, including a complete necropsy. The environment and management conditions should be investigated for potential causative agents, and all available genetic information for the affected animal(s) and unaffected herdmates should be collected, including gender, birth date, and breed. Environmental teratogens affecting large animals include toxic plants, drugs, viruses, and physical agents (e.g., hyperthermia, irradiation). Although it may be difficult to identify inciting teratogens, analysis of affected herds will reveal patterns that follow seasonal or management changes or stressful events.

This chapter focuses on the essential genetic information that veterinarians require to inform their clients about genetic diseases and how to find information on diseases and traits with a genetic component.

GENETIC INFORMATION

The basic blueprint for life in most organisms, the genetic material, is deoxyribonucleic acid (DNA). DNA is composed of two strands of bases: adenine (A), thymine (T), guanine (G), and cytosine (C). These bases align to form complementary base pairings such that A always pairs with T and G always pairs with C. These strands can be completely separated and replicated in preparation for cellular division. Alternatively, these strands can be partially separated, transcribed into ribonucleic acid (RNA), and translated into functional proteins.

The DNA sequence of a mammalian genome is divided into autosomes and a pair of sex chromosomes, X and Y. Each chromosome contains a variety of genes as well as

“filler” DNA that does not code for proteins, but may determine where and to what degree each gene is expressed. Genes on each chromosome code for the various structural and enzymatic proteins required for life. One set of chromosomes, and thus one set of genes, is inherited from each parent. As a result, a mammal generally has two copies, or “alleles,” of any given gene. Simple traits or diseases involving these genes can be inherited in dominant or recessive patterns and involve the autosomes, or sex chromosomes. Unfortunately, not all traits or inherited diseases are simple; many involve multiple genes and interactions between genes and the environment, which can make it difficult to diagnose and understand a complex disease or trait.

Recessive Inheritance

Traits or diseases with a recessive mode of inheritance require two affected copies, or alleles, of the gene to express that trait or disease. These conditions can be *autosomal*, involving genes on the autosomes, or *sex-linked*, caused by genes on either the X or Y chromosome. Generally, autosomal recessive traits or diseases are caused by mutations that render a protein unable to perform its original function. When an animal inherits the affected allele from both parents, it is *homozygous* for the gene and is unable to make functional copies of that specific protein. *Heterozygous* individuals inherit only one copy of the affected allele, and they have a “backup” copy of the normal or wild-type allele to provide the functional protein. These heterozygous individuals are carriers of the trait or disease allele and can produce affected offspring if bred to another heterozygous or homozygous affected individual.

The hallmarks of autosomal recessive traits include that all offspring of two affected parents are affected and approximately equal numbers of males and females are affected. Unaffected carrier parents can produce affected offspring, and thus the trait or disease can skip generations. Additionally, mating an affected individual to a noncarrier (homozygous normal) produces all offspring that appear normal but carry the affected allele. Breeding two carrier individuals results in approximately 25% normal, 50% carrier, and 25% affected offspring.

An example of an autosomal recessive trait is spider lamb syndrome, or hereditary chondrodysplasia. Lambs affected with this syndrome display several skeletal abnormalities, including disproportionately long “spider” legs, curvature of the spine, facial deformities, rib and sternum deformities, lack of body fat, and muscular atrophy. The causative mutation is a single base-pair substitution, from a T to an A, altering a highly conserved amino acid in the fibroblast growth factor receptor 3 (FGFR-3) gene, which prevents the receptor from functioning to limit endochondral ossification and thus bone growth.¹

Dominant Inheritance

Traits or diseases with a dominant mode of inheritance only require one affected allele to express the trait or disease, also known as the affected *phenotype*, and there is no distinguishable difference in the affected phenotype of a heterozygote and homozygote. Again, the genes that are responsible for these traits or diseases can be on the autosomes or sex chromosomes. Dominant traits or diseases may be caused by mutations that enable the mutant protein to have an altered function or structure. Alternatively, a single, functional copy of a gene may not be enough to achieve normal levels of function (“haploinsufficient”), resulting in the need for two normal copies of the gene to achieve a normal phenotype.

The main feature of an autosomal dominant trait or disorder is that affected individuals must have at least one affected parent (unless it is a new mutation), and thus the disorder does not skip generations. There is no gender bias with an autosomal dominant trait, and approximately half the offspring of a heterozygous affected individual will be affected.

An example of an autosomal dominant disease is myotonia in goats. When startled or making sudden, forceful movements, these goats can develop severe, acute muscle stiffness causing immobility and sometimes falling over, resulting in descriptions such as “fainting,” “nervous,” “stiff-legged,” or “epileptic” goats. A single nucleotide change was identified that substituted a proline for a conserved alanine residue in a chloride channel in the muscle fibers. This alteration in the chloride channel causes a diminished channel-open probability at voltages near the resting membrane potential of skeletal muscle, resulting in decreased chloride conductance and a significantly decreased electrical threshold for firing action potentials. Ultimately, this altered chloride channel allows conduction of repetitive impulses that result in sustained muscle fiber contraction and stiffness.²

Co-dominant Inheritance

The co-dominant (or semidominant) pattern of inheritance is distinguished by the fact that homozygotes can be differentiated from heterozygotes based on clinical features. A well-known example of a co-dominant disease is hyperkalemic periodic paralysis (HYPP) in quarter horses. In HYPP the voltage-gated sodium channels in the muscle fibers have a mutation that increases sodium permeability across the skeletal muscle cell membrane, resulting in increased muscle mass, but also drooling, prolapse of the nictitating membrane (“third eyelid”), respiratory stridor, and weakness. Homozygous HYPP horses experience more frequent and severe clinical signs of disease than heterozygous horses.³ Thus, it is important to counsel breeders to avoid producing homozygous affected horses by not mating two heterozygous horses, because 25% of their offspring would be expected to be homozygous affected, and 50% of the offspring would be heterozygotes. Breeding a heterozygous horse to an unaffected horse will also result in approximately 50% of the offspring being heterozygous and no possibility of producing a homozygous affected foal.

Sex-Linked Traits

Sex-linked traits and diseases involve genes located on either the X or the Y chromosome. Males are particularly susceptible to these conditions because they have only one each of the X and Y chromosomes. Thus, if they have a mutant allele for one of the genes on either of these chromosomes, they will express the affected phenotype because they do not have a “backup” copy. They have only one copy of the X and Y chromosomes, so they are *hemizygous*.

Females generally are less likely to demonstrate sex-linked recessive traits or diseases because they have two copies of the X chromosome. However, because of random X inactivation in each cell during fetal development, some females may express an affected phenotype. To achieve this, the X inactivation must be skewed such that the unaffected chromosome is inactivated more often than the X chromosome carrying the affected allele. In rare cases in which the inactivation is significantly skewed, females may be mildly to severely affected, depending on the level of expression for the affected chromosome.

Key characteristics of X-linked recessive traits are that the trait appears with much greater frequency in males than females, half the sons of carrier females will be affected, and half the daughters of carrier females will also be carriers. Hemophilia A, characterized by a strong tendency to bleed resulting from mutations in the clotting factor VIII gene on the X chromosome, is an example of an X-linked recessive disorder.

X-linked dominant traits are characterized by the following: affected offspring must have at least one affected parent, the disorder does not skip generations, and an affected male mated to normal females will transmit the mutation to all his daughters but not to his sons.

There are very few Y-linked diseases recognized in any mammalian species because of the small number of genes on the Y chromosome. Additionally, the majority of the genes contained on the Y chromosome are involved in male fertility; thus mutations in these genes generally render the animal sterile, resulting in no transmission of the mutations to future generations.

Polygenic Traits

In addition to the single-gene traits and diseases, numerous conditions are the result of two or more genes and may also involve genetic and environmental interactions. Some of these polygenic traits are economically important, such as milk quality and yield in dairy cows. For milk quality, a large number of genes may be contributing a small portion to the overall milk production of an animal.⁴ Teasing out the details of a complex polygenic system is difficult; however, research is ongoing to identify the exact genes involved and the role each gene plays for many economically important traits and diseases.

Penetrance and Expressivity

For many simple traits, there is an obvious difference between the two phenotypes that can be translated to the alleles involved, or *genotype*, with 100% certainty. A good example of this is albinism, which is considered to be 100% penetrant, with *penetrance* defined as the percentage of individuals with a given genotype who actually show the phenotype associated with that genotype. Influences such as modifying genes or environmental interactions can alter the expression of certain genes such that the exact genotype is not expressed in the outward phenotype. Alternatively, the function of a gene may be subtle, making it difficult to measure distinctions adequately between genotypes. Genotypes that may not be expressed in every individual are considered to be “incompletely penetrant.”

Another measure of genetic expression is the concept of *expressivity*. Modifier genes and environmental influences can affect the degree to which a genotype is expressed. For example, “variable expressivity” may be involved in pigment intensity when two individuals have the same genotype at the gene responsible for red pigmentation, but one has clearly darker red hairs than the other.

Incomplete penetrance and variable expressivity can greatly complicate analysis of genetic traits and diseases. These factors can also make breeding decisions more difficult because it may not be possible to classify an animal's genotype based solely on a phenotype. In these more ambiguous cases, genetic testing will play a vital role in the unequivocal determination of genotypes, allowing appropriate and informed breeding decisions.

POSITIVE AND NEGATIVE SELECTION

Breeders can improve their breeding stock by selecting for or against specific traits and diseases. These processes are known as *positive* and *negative* selection, respectively. A breeder may choose to breed an animal because it has desirable genes or qualities (positive selection). Alternatively, they may choose not to breed an animal that has been shown, either through genetic or breeding tests, to carry an undesirable trait or disease (negative selection). Ultimately, both scenarios will achieve the goal of improved breeding stock.

CHROMOSOMAL ABNORMALITIES

Occasionally, problems arise during mitosis, meiosis, or fertilization, resulting in chromosomal, or *karyotype*, abnormalities. Many karyotypic abnormalities have been identified in all large animal species, but not every chromosomal abnormality has been associated with an overt disease phenotype.^{5,6} Some examples of common chromosomal abnormalities include the absence of an X chromosome, called XO Turner's syndrome, which results in female infertility. An additional X chromosome in XXY Klinefelter's syndrome causes underdeveloped males with underdeveloped male sexual behavior. In addition to abnormal numbers of sex chromosomes, two chromosomes can unite into a single chromosome, called a "Robertsonian translocation," leading to reduced reproductive capacity in some species and early embryonic death in cattle. Because of possible chromosomal abnormalities, several countries have instituted mandatory karyotyping of some breeding cattle. Additionally, clinicians should consider karyotyping any animal that presents for reduced fertility or has multiple abnormalities.

BREEDING SCHEMES: TEST MATINGS

As a result of numerous advances in the field of genetics, the genetic causes of many diseases and traits are known and can be tested before using an animal in a breeding program. Additionally, more DNA-based tests are expected as research continues. However, clients may be interested in testing for a disease or trait that does not have a known genetic cause. For these situations, sires can be tested using breeding trials, as described in Table 51-1. For example, if a sire is bred to carrier females for a disease of concern, he would have to produce 10 normal offspring to ascertain that he is not a carrier with 95% confidence, 16 normal offspring to have 99% confidence, and 24 normal offspring to have 99.9% confidence that he is not a carrier for the disease of concern.

The time required to complete test matings can be significantly shortened using superovulated affected females, insemination, and embryo transfer (two per recipient) followed by early cesarean section at 60 days and examination of the offspring for the genetic defect(s) of concern.

OBTAINING GENETIC INFORMATION

Because of the ever-increasing wealth of genetic information, the most complete and current information can be

TABLE 51-1

<http://www.vgl.ucdavis.edu/research/equine/>

found using online resources. It is recommended that clinicians use websites produced by reputable institutions to obtain the most accurate and referenced information available (Box 51-1).

Alternatively, clinicians are encouraged to contact the Veterinary Genetics services available at many veterinary schools if they are unable to locate the information they require.

RECOMMENDATIONS FOR BREEDING PROGRAMS

When a genetic disease has been identified, it is recommended that parentage be verified by DNA analysis and the extended pedigree be confirmed. Additionally, a pathologist should make appropriate examinations of tissues for an accurate diagnosis, and a certified statement detailing the condition should be written by a veterinarian or other third-party witness. The final decision with regard to the status of a particular animal should be withheld until all reasonable doubt has been removed; for bulls, this is usually at least two thoroughly documented cases or a positive genetic test, if available. The artificial insemination (AI) organization and breed registry should be informed of the status of each animal because disease information is important in future breeding decisions. Many AI organizations list any undesirable recessive alleles in their advertising, and some also remove carrier animals from service.

Depending on the value of the animal in question, a breeder may choose to remove the animal from the breeding program at the first sign of a potential genetic problem. In these cases, documentation of the abnormal conditions should still be conducted for completeness and for comparison with other cases that may be found in the future.

Genetic Tests for Large Animals

DANIKA BANNASCH

Genetic testing based on deoxyribonucleic acid (DNA) involves the analysis of an animal's DNA to determine the individual's genotype for an inherited disorder, trait, or anonymous marker. Genetic testing can be used for positive or negative selection in a population, depending on whether it is being used to identify a disease (negative) or a trait (positive). Genetic testing can also be used for permanent individual identification and parentage determination. Many breed registries require parentage verification to ensure the accuracy of their pedigrees.

Using genetic testing results for selection requires an understanding of the mode of inheritance of the disease or trait. Most often, a genetic test will be performed for a recessive disorder to determine if an animal is a carrier. Carriers are asymptomatic but have the potential to produce diseased progeny. Because they have no outward manifestation of disease, a genetic test is extremely valuable for managing their breeding appropriately. Carrier animals can be bred to noncarriers if needed to retain valuable characteristics while not producing diseased offspring. In the case of positive selection for a trait of interest, carrier animals may have higher breeding values because they can produce a trait if bred to other carriers or to animals with the trait. Genetic tests may also be used for dominant disorders if the disease/trait has a late age of onset or if it is inherited in a co-dominant manner. DNA testing for traits that are controlled by more than one locus (polygenic) may also be used for selection for economically important traits. In these cases, one particular genotype may confer a slight advantage over another and therefore, in a large population, can have a significant effect on production.

Box 52-1 defines key genetic terms; see also Chapter 51.

INDIVIDUAL IDENTIFICATION AND PARENTAGE TESTING

Researchers use genetic markers distributed along all the chromosomes as tools to identify regions associated with diseases or traits. The markers are composed of small nucleotide repeats and are called *microsatellite* markers or *short tandem repeats* (STRs). These markers have a feature that makes them extremely useful to geneticists; the markers have been chosen to be "polymorphic" (show differences) between individuals. In other words, individual animals will have different lengths of the nucleotide repeats for each of these markers. The high level of polymorphism of this type of marker makes them useful for "mapping" (identifying the chromosomal location of diseases and traits).

The microsatellite markers are assayed by polymerase chain reaction (PCR) amplification using fluorescent-labeled primers. Primers are short (~20 base pairs), single-strand lengths of DNA that are complementary to a specific region

of the genome. PCR is the amplification of a section of DNA contained between two primers designed to complement the unique sequence flanking the STR. The PCR products are then resolved by electrophoresis based on their length. Figure 52-1 shows a single microsatellite marker in three different animals. This marker is polymorphic and would be a useful marker for individual identification or parentage. Because the markers show differences between individuals, a collection of these markers can be used as a form of identification of an animal. High statistical significance can be obtained with as few as 10 markers, depending on the species and breed. The DNA type of an animal will not change over its lifetime and can therefore be used as a form of permanent identification.

Many purebred registries require parentage verification for registration purposes. To accomplish parentage verification, a DNA sample must be available from both parents

BOX 52-1

Definitions of Genetic Terms

- Allele** One of the variant forms of a gene at a particular locus, or location, on a chromosome.
- Base pairs** Two bases that form a "rung of the DNA ladder." A DNA nucleotide is made of a molecule of sugar, a molecule of phosphoric acid, and a molecule called a "base." The bases are the "letters" that spell out the genetic code. In DNA the code letters are A, T, G, and C, which stand for the chemicals adenine, thymine, guanine, and cytosine, respectively.
- Genotype** Genetic makeup, either at a single locus or at all loci.
- Linked** Association of genes and markers that lie near each other on a chromosome; linked genes and markers tend to be inherited together.
- Locus** Place on a chromosome where a specific gene is located; a type of "address" for the gene.
- Marker** Segment of DNA with an identifiable physical location on a chromosome, the inheritance of which can be followed. A marker can be a gene or some section of DNA with no known function. Also known as a *genetic marker*.
- Microsatellite** Repetitive stretches of short sequences of DNA used as genetic markers to track inheritance in families.
- Phenotype** Observable traits or characteristics of an animal (e.g., coat color, weight, presence or absence of a disease).
- Recombination** Genetic transmission process by which the combinations of alleles observed at different loci in two parental individuals become shuffled in offspring individuals.
- Splicing** Ribonucleic acid (RNA) splicing removes introns and joins exons in a primary transcript.

FIG. 52-1 ■ Microsatellite markers are visualized after polymerase chain reaction (PCR) by running the fluorescent-labeled PCR product (*shown in black*) through capillary electrophoresis, which separates the products based on size relative to an internal size standard (*shown in gray*). Each panel (A, B, and C) shows the results for a different animal. Size (base pairs of DNA) is resolved along the x axis, and the y axis shows the fluorescence intensity.

as well as the offspring. DNA samples are taken in the form of hair, blood, or buccal swabs (depending on the species and registry) and submitted at the time registration is requested. Each animal inherits one copy of each marker from its sire and one copy from its dam, so the markers can also be used to verify parentage. The most useful marker has a high polymorphism rate because that type of marker will be most likely to show differences not only between the sire and the dam, but also between the two copies (alleles) of the

marker. A set of polymorphic markers (~10 to 20) is used to verify parentage to ensure a high probability that the parentage is correct. Table 52-1 shows the allele sizes for a set of markers in a parentage case. For marker A the offspring inherited a 122 and a 126 allele. The 122 came from its dam, so the 126 came from the sire. Because sire 1 does not have a 126 allele, it has been excluded. In this example, sire 1 is excluded as the sire of the offspring, and sire 2 is verified on the basis of the results for all three markers.

TABLE 52-1

Parentage Verification Using Microsatellite Markers

Individuals	Allele Sizes for Four Markers			
	A	B	C	D
Dam	122/124	110	131/133	80/82
Offspring	122/126	110/112	133	82/86
Sire 1	128	112/114	131	84
Sire 2	126	112/114	131	86/90

DISEASE TESTING

Clinicians can use DNA testing in disease diagnosis or to determine an animal's potential for producing diseased progeny. Generally, disease diagnosis is based on clinical signs and other diagnostic tests, but occasionally DNA testing is used, in particular for later-onset diseases or diseases for which diagnosis by traditional methods is difficult or invasive. To offer a genetic test, the gene responsible must be known. Ideally, the actual mutation that causes the disease has been identified. Rather than knowing the exact gene or mutation, only a region of a chromosome may have been implicated in a particular disease. DNA tests can be divided into two categories: mutation tests and linked-marker or haplotype tests. *Mutation* tests are based on an actual mutation that causes disease, whereas the *linked-marker* or *haplotype* test is based on the region of the chromosome that is known to cause disease, but not necessarily the actual mutation. Usually, haplotype tests are offered instead of a mutation test because the mutation has not yet been identified.

Mutations that cause disease appear in many different forms. A change of a single base pair from one base to another can cause a disease either by changing an amino acid ("missense" mutation), truncating the amino acid chain ("nonsense" mutation), or altering expression or proper splicing. For example, missense mutations have been shown to cause lethal white foal syndrome in the American Paint horse.¹⁻³ Insertions or deletions of a single base pair (bp) can cause mutations in the coding sequence by altering the translational frame, which ultimately causes protein truncation. An 11-bp deletion in the myostatin gene causes a frameshift mutation and protein truncation in Belgian blue and Piedmontese cattle with the double-muscle phenotype.⁴⁻⁶ Large deletions or insertions that remove hundreds and thousands of base pairs can also cause disease. For example, the polled intersexuality mutation in goats is caused by an 11.7-kilobase deletion that removes a regulatory element that controls the expression of two genes.⁷ This endless array of possible changes in the DNA that result in disease makes each individual DNA-based genetic test different.

The basis for DNA testing is PCR. Primers can be designed specifically to amplify either the disease-causing allele or the normal allele. Alternatively, the PCR product can be digested with a restriction enzyme that cleaves the DNA at a particular sequence of bases. A restriction enzyme is chosen that shows a different cleavage pattern between the mutant and the normal version of the PCR product. Direct sequencing of a section of DNA can also be used to determine the animal's genotype. Many different methods are available to assay changes in DNA that lead to disease. Each company that offers a test may choose a different type of assay for the same mutation.

If the exact mutation that causes the disease has not been discovered, a linked-marker test can be used. A "linked marker" is a microsatellite marker similar to those

previously described for individual identification and parentage analysis. The marker is "linked" along the chromosome to the disease gene. It can be used as a proxy for the actual mutation; the associated error rate can be decreased by using a set of markers that flank the gene causing the disease. When a set of markers is used, the test is called a "haplotype" test. Because the test does not directly test for the mutation, an error is still possible. Figure 52-2 shows a pedigree that is segregating a disease allele and a marker. In panel A the disease allele is in linkage phase with the marker allele 132. In this family the 132 allele is correlated to the disease locus. Panel B shows a family in which the linkage phase is different. In this family the sire has a 138 allele associated with the disease allele. Therefore, his affected son would be called a "carrier" and one of his daughters that is a carrier would be called "normal" based on this linked marker. Linked markers can be used in families with affected individuals to test for the presence

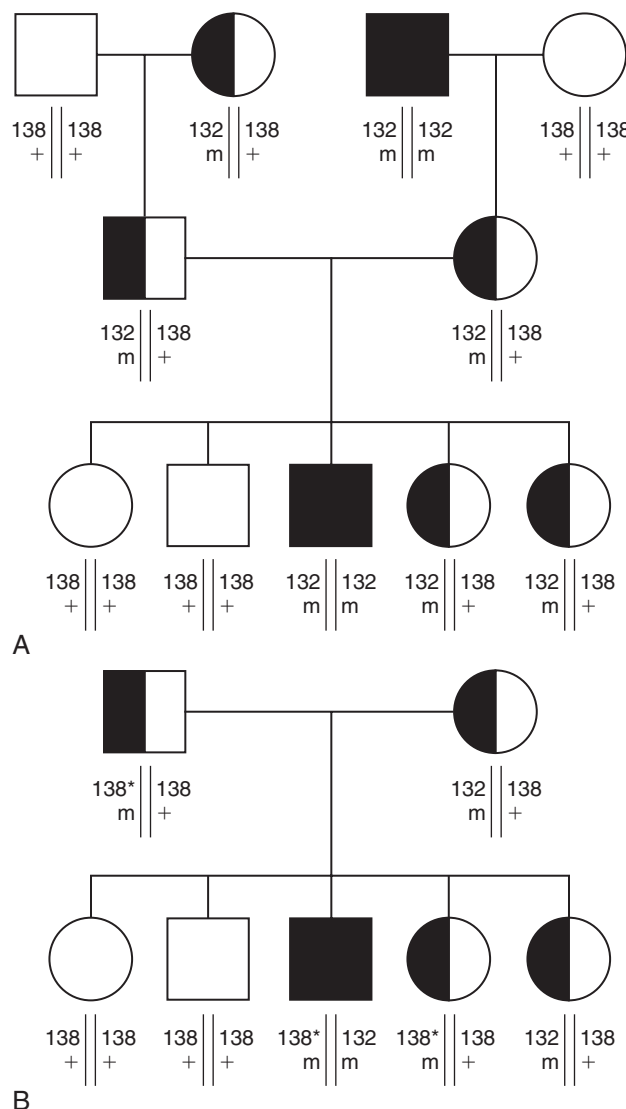

FIG. 52-2 ■ In this pedigree, squares are males and circles are females. Filled symbols represent affected individuals, half-filled symbols represent carriers, and open symbols represent normal animals. The allele sizes for a marker linked to the disease locus are given below each symbol. For clarity, the genotype at the disease locus is also written below each symbol as *m* for the mutant allele and *+* for the normal allele. Panels A and B are two different families. The asterisk marks the allele in different linkage phase in family B.

or absence of the disease allele in other family members. The problem arises when a linked-marker test is used to test individual animals. The linkage phase is assumed based on research done in one family, but may not be true for every animal in the breed.

There are limits to all genetic testing. In mutation tests the specific mutation being assayed is the only factor being evaluated. An animal may have a different mutation in that gene or a mutation in a different gene that causes the same phenotype (phenocopy). It is therefore correct to state that an animal has been “DNA tested negative” for this specific mutation rather than “DNA tested clear” of the disease. Linked-marker tests have these same sources of error, as well as additional sources. Recombination events between the markers and the disease gene can lead to false-positive and false-negative results. The use of multiple markers that flank the gene of interest (haplotype test) can increase the probability that a recombination event will be identified. If one is identified, the laboratory will know that the test is not valid in this individual. The

second source of error with either a linked-marker or a haplotype test occurs when there is an ancestral recombination event that changes the linkage phase of the alleles. The result is that the laboratory would interpret an animal’s genotype at the disease locus incorrectly, based on the linked markers.

No association or committee evaluates quality control of DNA tests that are available in animals. Most tests are published in the scientific literature not as tests but as articles describing the discovery of the mutation. Because some cases involve patent issues, some tests are offered before publication. Much of the research done to identify the mutations involved in the tests is performed at universities and funded by granting agencies that have both financial and intellectual interest in patenting the tests. Companies then license the rights to offer the tests. Because the companies that have a license for each test can change, company names are not listed in this chapter. Rather, searching on the Internet for the test name will give veterinarians access to the companies offering the tests. Tables 52-2, 52-3, and

52-4 list available genetic tests for horses, cattle, and sheep and goats, respectively. Only tests published in peer-reviewed journals are listed. Additional tests available in cattle for various forms of the milk proteins also are not listed in Table 52-3. The breeds of cattle are not listed because rapid changes in testing mean that tests are always being validated for new breeds. It is therefore recommended that a search be performed for the availability of a test for a particular breed each time the need arises.

The diseases or traits that are tested can be divided into two categories: those that have straightforward Mendelian inheritance patterns (recessive, dominant, and sex-linked) and those that are more complicated because many genes are involved with conferring the phenotype (polygenic). *Quantitative trait loci* (QTL) are the genes that contribute to

a polygenic disease. In cattle a vast number of QTL have been placed in specific regions of chromosome for quantitative traits such as dairy form, milk production, and fertility.⁸ Selection for these traits can be done with DNA testing (see Table 52-3). Because so many different QTL exist, however, selection can be challenging, and trade-offs need to be made.

Genetic testing relies on advances made in the field of genomics. Veterinarians and owners are fortunate that both cattle and horses were chosen as economically important species for whole-genome sequencing. A Hereford bull and a thoroughbred mare have both been sequenced, and studies describing the results should be available soon. The number of disease-based or trait-based tests available in the future will increase as the information in the genome sequence is translated.

Immunologic Disorders

EQUINE IMMUNODEFICIENCY DISEASES

DEBRA C. SELLON

MELISSA T. HINES

JILL R. JOHNSON

The environment in which domestic animals live with regard to exposure to pathogens is challenging and often life threatening. Complex defense mechanisms have developed to protect the host from outside challenges, particularly the pathogenic effects of microorganisms. It is important to understand that diseases, particularly infectious diseases, can result from failure of the host's normal defense mechanisms, as well as from overwhelming challenge from the outside. When animals are plagued by repeated or chronic infections, the clinician should always determine whether host factors are involved.

The analysis of immunodeficiency diseases depends on an understanding of the normal immune response. The development of protective immunity is a result of the orchestration of numerous cell types and soluble serum factors (Fig. 53-1). Both *innate* (nonspecific) and *adaptive* (specific) mechanisms play a role.

Two major populations of lymphocytes are involved in immune responses, T cells and B cells. Classically, T cells are associated with cell-mediated immune responses that protect against fungal, protozoal, intracellular bacterial, and many viral infections. B cells are associated with humoral immunity. T cells originate from stem cells, which probably develop in the fetal liver. These cells must undergo a maturation process in the thymus before becoming fully functional. T cells comprise about 70% to 80% of peripheral blood lymphocytes and populate the periarteriolar regions of the spleen and the paracortical regions of lymph nodes. As with T cells, B cells originate from stem cells in the fetal liver. The site of B-cell maturation varies with species and includes several different organs, such as the bursa of Fabricius in birds and the bone marrow and certain Peyer's patches in mammals. Of peripheral blood lymphocytes, 15% to 30% are B cells. B cells populate germinal centers of spleen and lymph nodes.^{1,2}

T lymphocytes are important in regulating the immune response, and both humoral and cellular immune responses depend on input from T cells. Initially characterized as either helper T (Th) cells or cytotoxic/suppressor T (Tc) cells based on their primary function, T cells have subsequently been differentiated on the basis of cell surface antigens, with Th cells expressing the CD4 antigen and Tc cells expressing CD8.^{3,4} Further work has shown that the function of these cells is complex, and that the pattern of cytokine expression is important in regulation of the immune response. Based on their

cytokine expression, CD4⁺ cells have been further subdivided into distinct subsets, Th1 and Th2 cells (Fig. 53-2). Although there is some species variation, Th1 cells generally produce interferon- γ and interleukin-2 (IL-2) and are involved primarily in the generation of cell-mediated immune responses, whereas Th2 cells produce IL-4, IL-5, and IL-13 and are involved in humoral responses. In mice, either protection from disease or development of lesions can be associated with the particular type of Th cell response, and the clinical relevance of this is currently being investigated in a number of equine diseases.

The second major class of lymphocytes is B lymphocytes, which produce immunoglobulins and are the precursors of plasma cells. Several classes of immunoglobulins are produced by B cells. There is some variation among species, but the major classes are IgG (IgG1 and IgG2), IgM, IgA, IgE, and in horses, IgG(T). Immunoglobulins provide a defense against extracellular bacterial and certain viral infections.

The innate immune system, which is nonspecific in nature, includes natural killer cells, phagocytic cells, neutrophils, eosinophils, basophils, and nonimmunoglobulin serum and cellular factors such as complement and interferon. These components play a distinct role in host defenses and work with T and B cells to produce an effective protective response.

A deficiency of functional T cells, B cells, nonspecific components, or any combination predisposes animals to infections that may result in death. Immune deficiencies can be classified according to (1) the site of defect in the host defense system and (2) whether the mechanism is primary or secondary.^{1,5-7} In a *primary* disorder there is an inherent abnormality in the immune system that has a proven or suspected genetic basis, whereas in a *secondary* disorder the host's initially normal ability to respond immunologically is altered. Some factors that can produce secondary immunodeficiencies include irradiation, neoplasia, toxicities, malnutrition, and certain microbial infections.^{1,6,7} Physiologic stress, such as that caused by pregnancy, lactation, and exercise, can also induce transient immunosuppression.^{6,8} Both primary and secondary immunodeficiencies can affect various components of the immune system, and by careful dissection of the immune response, the site of the defect can often be identified.

General clinical features associated with immunodeficiencies include the following^{1,5-7}:

- Onset of infections during the first 6 weeks of life.
- Repeated infections that respond poorly to standard therapy.
- Increased susceptibility to organisms with low pathogenicity.
- Infection with organisms rarely observed in immunocompetent individuals.
- Systemic illness after administration of attenuated live vaccines.

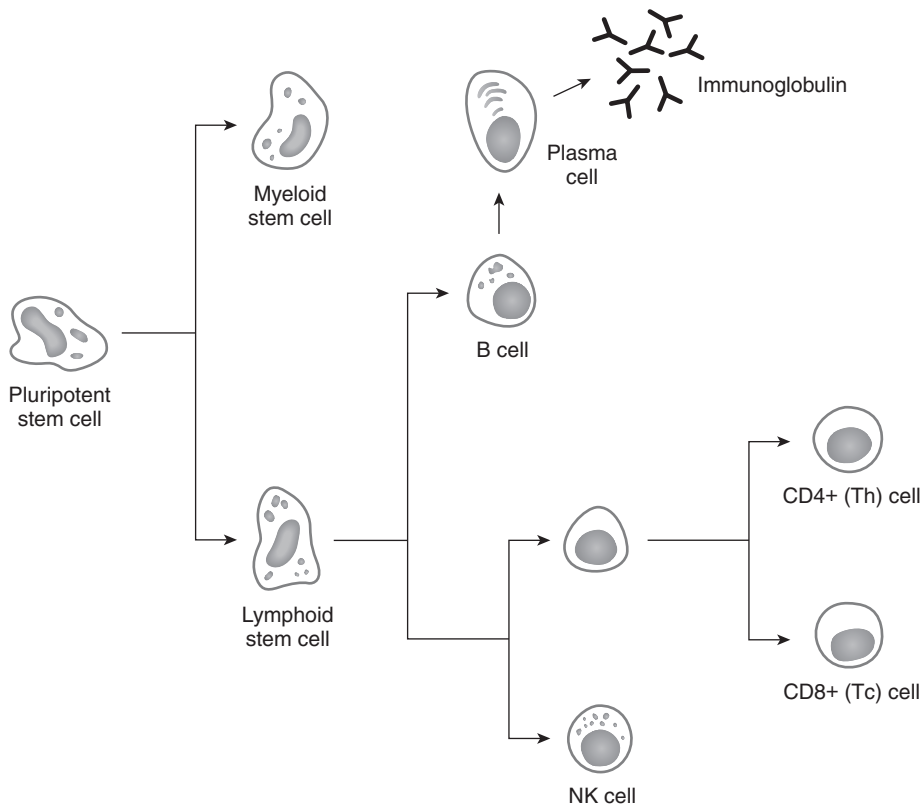

FIG. 53-1 ■ Ontogeny of the immune response. Failures at any site in the maturation process can result in manifestation of immune deficiencies.

FIG. 53-2 ■ CD4+ T cells can be subdivided into Th1 and Th2 on the basis of their cytokine profiles. Preliminary data suggest that the pathogenesis of certain diseases is associated with the particular type of Th response.

- Failure to respond to vaccination.
 - Persistent marked abnormalities in leukocyte numbers.
- Laboratory or special in vivo testing is necessary to confirm the presence of an immunodeficiency. Such testing is also important in differentiating the various immunodeficiency syndromes because clinically the presenting signs are nonspecific. In general, tests to evaluate the immune system either quantify the component or measure the functional capacity.

The enumeration of lymphocytes, and in some cases, specific lymphocyte types, can be useful in the diagnosis of immunodeficiencies. Currently, specific subsets of lymphocytes are most often identified using antibodies to cell surface markers and flow cytometry.^{3,4,9} In normal horses, about 20% of circulating lymphocytes are B cells, and about 62% are CD4+ T cells and 18% CD8+ T cells.^{9,10} B cells can also be enumerated in blood and lymphoid tissue using fluorescent-labeled antibody to detect surface

immunoglobulin and erythrocyte-antigen-complement rosetting techniques to detect complement receptors. Erythrocyte rosetting assays and fluoresceinated peanut agglutinin surface labeling tests have been used to enumerate T cells in peripheral blood and lymphoid tissue.

The primary clinical tests of B-cell function are quantitation of immunoglobulins and measurement of specific antibody responses. Numerous methods are available to quantitate or semiquantitate immunoglobulin levels. Semiquantitative tests are useful for some conditions, such as failure of passive transfer (FPT) after colostrum ingestion; however, they do not provide information on specific immunoglobulin classes. Some tests are species specific, whereas others can be used to detect immunoglobulins of several species. Precipitation of immunoglobulins with specific salt concentrations tends not to be species specific, although the tests may work better in some species than others. These tests include zinc sulfate and sodium sulfite precipitation and glutaraldehyde coagulation (see p. 1679).^{11,12} Commercial tests based on these principles are available. * Serum electrophoresis can also be used in all species to quantitate γ -globulins, which are primarily immunoglobulins. Several species-specific tests based on antigen-antibody reactions that use latex bead agglutination[†] or enzyme immunoassay[‡] as the marker systems are also commercially available. These tests are semiquantitative and are primarily marketed for detection of FPT after colostrum ingestion.

Radial immunodiffusion (RID) quantitates immunoglobulins of specific classes using a precipitation reaction between antigen and antibody directed against one species-specific, class-specific immunoglobulin to be quantitated. This is an accurate method for quantitating specific classes of immunoglobulin such as IgG and IgM. RID kits are commercially available for some immunoglobulin classes for domestic animals.[§] These tests require incubation for 18 to 24 hours, which is their greatest drawback for clinical use. Test reagents are prepared for use in a single species; however, some cross-reactivity does exist among species. Test reagents designed for use in another species (e.g., human) have been shown to be useful¹³; however, they must be standardized and calibrated for the species in which they are to be used.

Production of antibody in response to immunization with specific antigens is another way B-cell function can be evaluated, although functioning T cells are also required for this response. The only requirement to assess antibody production is an *in vitro* test to detect specific antibody. Serologic measurement of antibody titers before and after vaccination with commercially available vaccines is one approach. Killed infectious bovine rhinotracheitis (IBR) and bovine viral diarrhoea (BVD) vaccines in cattle and influenza or rhinopneumonitis vaccines in horses are readily available, and responses are easily tested. Another approach is to look for the presence of naturally occurring antibodies that are produced without immunization (e.g., antibodies that cross-react with sheep red blood cells in horses), although the assays for these antibodies may not be readily available. Other foreign "nonvaccine" antigens can also be used if an assay is available for the detection of antibody.

One clinical *in vivo* test of T-cell function is intradermal skin testing with the plant lectin, phytohemagglutinin (PHA), which identifies delayed-type hypersensitivity

(DTH) responses. PHA is capable of eliciting a DTH response without requirement of prior sensitization, which is required with some other antigens, such as dinitrochlorobenzene. To perform this test, the thickness of a skin fold is measured before injection. A 50- μ g dose of PHA* in 0.5 ml of phosphate-buffered saline (PBS) is injected intradermally, and the same volume of PBS is injected at a control site at least 10 cm (4 inches) away from the site. Twenty-four hours later the skin thickness is measured. A 1-mm to 3-mm increase in skin thickness at the test site should normally occur. An increase of 0.6 mm or less indicates a defect in cell-mediated immunity.¹⁴

Other tests for B- and T-cell function are available primarily on a research basis. *In vitro* lymphocyte blastogenesis with pokeweed mitogen requires both B- and T-cell function for normal responses, whereas lipopolysaccharide requires predominantly a B-cell response. Blastogenesis with PHA and concanavalin A assess primarily T-cell function.

A variety of assays for phagocytosis and killing by neutrophils and macrophages have been developed.¹⁵⁻¹⁷ Recently, flow cytometric analyses of phagocytic function have been described, as well as methods for the quantitation of complement, interferon, and various lymphokines. However, these procedures are currently available only in selected research facilities.

From a practical standpoint, only a limited number of tests are available, and most are crude indicators of immune response and therefore detect only severe deviations from normal. Nevertheless, a number of immunodeficiency syndromes have been characterized in domestic animals. As methods improve, so will veterinarians' ability to define immune disorders more precisely.

FAILURE OF PASSIVE TRANSFER

■ **Definition and Etiology.** Normal foals are immunocompetent at birth (i.e., they are capable of mounting an immune response). However, they are immunologically naive in that they have had no exposure to foreign antigens and have therefore not yet mounted any type of protective immune response or accumulated significant levels of immunoglobulins. Although foals are capable of producing antibody, they are essentially devoid of immunoglobulin at birth, with the exception of small amounts of IgM normally produced *in utero*. Because they are "starting from scratch," foals are indeed more susceptible to infectious agents during the early neonatal period. Foals begin producing immunoglobulins immediately on exposure to antigens after birth, and immunoglobulins produced by the foal are detectable within 1 to 2 weeks of life and reach significant levels by 2 months.

Under normal circumstances, temporary protection against infection for the first 1 to 2 months is provided to the foal in the form of passively transferred antibody (Fig. 53-3). Because of the diffuse epitheliochorial nature of the equine placenta, no transplacental transfer of immunoglobulins occurs in horses. Instead, ingestion and absorption of immunoglobulin-rich colostrum are the sole means of passive transfer in foals. In a properly functioning system, maternal antibodies wane as levels of autologous antibodies increase, and thus the neonate is never left totally unprotected (Fig. 53-4).

Failure of the foal to ingest or absorb sufficient quantities of colostrum, primarily as defined by absorption of IgG, is termed *failure of passive transfer* (FPT). *Complete* FPT is defined as a foal with a serum IgG concentration of less

FIG. 53-3 ■ The duration of protection provided by maternal immunoglobulins varies with the class of immunoglobulin and the quantity ingested during the first 24 hours of life.

FIG. 53-4 ■ Maternal immunoglobulin wanes, whereas the production of autologous immunoglobulin increases during the first several months of life. The combined total amount of immunoglobulin ideally remains above the level considered minimum for maintenance of good health.

than 400 mg/dL at 24 hours of age. *Partial FPT* is defined as a foal with a serum IgG concentration of 400 to 800 mg/dL at 24 hours of age. The reported incidence of complete or partial FPT in foals varies from 3% to 37.8%.¹⁸⁻²⁵

Immunoglobulins are not produced locally in the mammary gland, but rather are selectively concentrated from the mare's sera into colostrum in response to hormonal changes that occur in the last 2 weeks of pregnancy. Most immunoglobulin in equine colostrum is IgG or IgG(T), with smaller quantities of IgM and IgA. At birth the neonate has specialized enterocytes in the gastrointestinal (GI) tract that are able to absorb large molecules such as immunoglobulins intact by pinocytosis. Absorbed proteins pass through the intercellular spaces and lacteals into the systemic circulation via the lymph. The window of gut absorptive capacity for immunoglobulins is narrow, lasting from birth until about 18 to 24 hours. Maximal absorptive efficiency occurs immediately after birth, declining to only 22% efficiency at 3 hours after birth and less than 1% by 20 hours.^{26,27} The decline in immunoglobulin absorption is accompanied by transient proteinuria that peaks at 6 to 12 hours of age and declines by 24 to 36 hours of age. This proteinuria most likely reflects absorption and excretion of low-molecular-weight milk proteins.²⁸

Diminished immunoglobulin absorption over the first 12-24 hours of life is the result of shedding of specialized enterocytes capable of pinocytosis and replacement by more mature cells that are incapable of absorbing immunoglobulins.^{26,27,29} It has been hypothesized that delayed ingestion of macromolecules may prolong the duration of intestinal permeability to immunoglobulins. In one study, however, the type of fluid administered to foals before the ingestion of colostrum did not influence subsequent IgG absorption, suggesting that the process of gut closure is not mediated by a finite capacity for the uptake of macromolecules.³⁰

The half-life for maternal antibodies in the foal's circulation varies between 20 and 30 days.³¹⁻³³ Concentrations decline as a result of normal protein catabolism, gradual dilution in an increasing plasma volume as the foal grows, and transfer of functional antibody into the GI tract. Most maternal antibodies are present in only negligible concentrations by 6 months of age, although antibodies to some infectious agents have been detected for up to 12 months after birth. As passive antibody concentrations decline, autogenous antibody production begins. There is a nadir in serum immunoglobulin concentrations in colostrum-fed foals at approximately 1 to 2 months of age, followed by gradually increasing concentrations until adult levels are reached at 5 to 10 months.^{2,34} Serum immunoglobulin concentrations are similar in colostrum-fed and colostrum-deprived foals by 3 to 4 months of age.

In addition to antibody, other colostrum factors may be important for optimal immune protection of foals. For example, colostrum influences cell-mediated immunity and activates granulocytes. Colostrum contains many constituents of innate immunity and immunomodulating agents, such as complement, cytokines, and trace elements, that have a local protective effect in the neonatal digestive tract.^{35,36}

In foals, FPT may occur because of ingestion of poor-quality colostrum with a low immunoglobulin content, failure to ingest a sufficient quantity of colostrum, or failure to absorb colostrum immunoglobulins from the GI tract.^{29,37} Colostrum may have an insufficient quantity of immunoglobulin because of prelactation (lactation before parturition), premature foaling, a defect in the mare's ability to concentrate immunoglobulin in the colostrum, ingestion of endophyte-contaminated fescue grass or hay, or other factors. Mares most likely to produce colostrum with low immunoglobulin content are those older than 15 years of age, those that foal early in the year, and standardbred mares.

Foals that are orphaned or rejected at birth, too weak to stand, or unable or lack the desire to suckle are unlikely to ingest sufficient colostrum to prevent FPT. Malabsorption is occasionally incriminated as a cause of FPT in foals that are observed to suckle adequate quantities of good-quality colostrum. This most often happens in premature or dysmature foals, possibly as a result of immature GI function, but may also occur in otherwise healthy and vigorous full-term foals.³⁸ Glucocorticoids enhance the maturation of small-intestinal epithelial cells and thus their loss of absorptive capacity, leading to speculation that endogenous corticosteroids released secondary to stress at parturition may impair immunoglobulin absorption in foals.^{39,40} However, administration of adrenocorticotrophic hormone (ACTH) failed to affect absorption in experimental foals, and stress has not been a consistent historic finding in foals with FPT caused by presumptive impaired immunoglobulin absorption.^{22,41}

■ **Clinical Signs and Differential Diagnoses.** The association between FPT and infection has been investigated in

numerous studies.^{18-20,24,25} Although the results have varied somewhat, FPT is generally considered a risk factor for infectious disease. By itself, FPT produces no clinical signs of disease and cannot be detected by physical examination. Clinical presentations that strongly suggest an underlying problem with FPT include onset of bacterial infections within the first 2 weeks of life, particularly septicemia, septic arthritis, pneumonia, and enteritis. Other immunodeficiencies or simply exposure to potent pathogens cannot be ruled out solely on the basis of the time of onset; however, even with other forms of immunodeficiency, clinical signs of infection usually do not show up for several weeks if passive transfer is adequate.

■ **Clinical Pathology.** FPT is diagnosed by the demonstration of low serum concentrations of IgG in the foal as early as 6 to 12 hours after birth and probably for as long as several weeks after birth (Table 53-1). The level of IgG considered adequate for protection against infectious disease is poorly defined and probably varies considerably with the environment. A serum IgG concentration greater than 800 mg/dL is considered adequate for most foals. However, levels of 400 mg/dL may be sufficient in healthy foals housed in clean environments. In contrast, an IgG concentration of 400 to 800 mg/dL in a foal at high risk for sepsis because of its environment or other factors indicates the need for treatment. Importantly, these figures only address total immunoglobulin content and not specific antibody titers, which also play a critical role in determining resistance to particular pathogens.

In healthy foals that nurse within 2 hours of birth, serum IgG concentrations become detectable at approximately 6 hours of age and peak at approximately 18 hours. Routine determination of serum IgG concentrations in apparently healthy foals is usually recommended at 18 to 24 hours of age. Foals considered to be at high risk for FPT and sepsis may be assessed as early as 6 to 12 hours of age.^{35,42}

Methods available for IgG quantitation include single radial immunodiffusion, zinc sulfate turbidity, latex agglutination, glutaraldehyde coagulation, turbidometric immunoassay, and enzyme immunoassay.^{11,35,43-47} Single radial immunodiffusion is considered the most quantitatively accurate diagnostic test of those widely available to practitioners. However, this test is more expensive than some other screening tests, and results are not available for at least 24 hours, making it impractical when a critically ill foal needs rapid diagnosis and treatment. Total serum protein is not a reliable indicator of FPT in foals (unlike calves) because of the wide variation in total serum protein in cases of adequate transfer.

No consistent changes in the hemogram and biochemical panel are seen in foals with FPT; however, a range of abnormalities related to secondary infection (e.g., neutrophilia, neutropenia), hyperfibrinogenemia, and hypoglycemia may be present. The presence and severity of these changes depend on the organisms and systems involved.

■ **Necropsy Findings.** No specific necropsy findings are indicative of FPT. Necropsy findings reflect the site and severity of secondary infectious problems that have developed. Lymphoid tissue is normally developed, unless secondary infections have caused lymphoid necrosis or atrophy.

■ **Treatment and Prognosis.** Treatment of FPT depends on the degree of FPT, the environment in which the foal is exposed, the foal's age at diagnosis, and the presence of secondary infectious problems. Treatment is aimed at minimizing exposure to pathogens, supplying immunoglobulins, and managing secondary infections, if present.

If FPT can be anticipated within hours of birth because of premature lactation, low-specific gravity colostrum, or a weak or orphaned foal, treatment can include the provision of an alternative source of colostrum or antibody orally. Foals with complete colostrum deprivation require approximately 1.5 g IgG/kg body weight to achieve a peak serum IgG concentration of more than 800 mg/dL. In a 45-kg foal, administration of 1 to 3 L of colostrum with a specific gravity greater than 1.060, divided into multiple hourly feedings over the first 6 to 8 hours of life, is desirable. Mares that donate colostrum for feeding should be healthy, checked for blood type, negative for anti-red blood cell (RBC) alloantibodies (especially anti-A and anti-Q) and appropriately vaccinated during the last 4 to 6 weeks of gestation.

If equine donor colostrum is not available, bovine colostrum, a commercial colostrum substitute, or equine plasma may be administered orally to the foal.⁴⁸⁻⁵⁵ Because bovine colostrum is often more readily available than equine colostrum, it may be substituted in emergency situations when equine colostrum is not available. Bovine colostrum is relatively well absorbed in the foal, but bovine immunoglobulins have a much shorter half-life in foals and do not contain antibodies specifically directed against equine pathogens. It is certainly better than no colostrum and, on the basis of a small experimental study, may be used without creating adverse reactions.⁴⁸⁻⁵⁰ Approximately 2 to 4 L should be administered orally; many foals develop transient mild diarrhea.

TABLE 53-1

Normal Serum Immunoglobulin Concentrations (mg/dL) in Horses

Age	Breed	IgG	IgG(T)	IgM
Newborn, presuckle	Arabian	1-10	ND	5-15
1-20 days	Arabian	814 ± 583	142 ± 88	28 ± 11
21-40 days	Arabian	480 ± 293	126 ± 41	30 ± 10
41-60 days	Arabian	264 ± 193	96 ± 33	42 ± 12
61-80 days	Arabian	252 ± 128	75 ± 17	36 ± 12
81-140 days	Arabian	248 ± 92	162 ± 126	39 ± 15
3-5 months	Mixed	380 ± 188	211 ± 148	61 ± 22
10-15 months	Arabian/thoroughbred	790	728	48
Adult	Shetland	1334 ± 350	821 ± 301	120 ± 13

From Riggs MW: Evaluation of foals for immune deficiency disorders, *Vet Clin North Am Equine Pract* 3:515, 1987.
ND, Not determined.

Lyophilized equine IgG* is available as an equine colostrum substitute. A minimum of 50 to 70 g of IgG is recommended for treatment of the average 45-kg foal that receives no colostrum, but in one study this dose failed to increase serum IgG concentration to over 450 mg/dL in colostrum-deprived foals.⁵⁵ A concentrated equine serum product† is also available for use in foals with FPT.⁵⁶ Again, however, in one study it failed to increase serum IgG concentrations in colostrum-deprived foals to adequate levels, probably because of the relatively low total IgG dose administered.⁵¹ If the product contains 25 to 30 g of IgG per 300-mL bottle, approximately three bottles may be required to increase the serum IgG concentration of a 45-kg colostrum-deprived foal to greater than 400 mg/dL.⁵¹

If no other sources of immunoglobulin are available for a foal, oral administration of equine plasma or serum may be considered. This is an expensive source of oral immunoglobulin, however, and approximately 2 to 4 L are required to treat a colostrum-deprived 45-kg foal.

If the foal is over 6 hours old, the absorption of colostrum antibody is significantly decreased, although a locally protective effect of the colostrum may still be present in the intestinal tract. If the foal is over 12 hours old, it is unlikely that sufficient colostrum will be absorbed; therefore, immunoglobulin levels should be rechecked at 24 hours and intravenous (IV) plasma transfusion given, if indicated by persistently low serum immunoglobulin levels.

Some animals with FPT, particularly partial FPT, do well without treatment if they are systemically healthy, are not heavily exposed to pathogens, and have no preexisting infections. FPT itself is not necessarily fatal. If plasma transfusions are not administered, owners should be made aware of the risks, and these foals should be maintained in an environment with minimal exposure to potential pathogens. Foals with other risk factors for septicemia (e.g., prematurity, dysmaturity, placentitis) should receive IV plasma transfusions if they have blood IgG concentrations of less than 800 mg/dL at 12 to 24 hours of age.

If the decision is made to supplement plasma parentally, equine plasma for transfusions is commercially available‡ or can be collected and processed locally. Commercial sources are convenient, save time, have been screened for anti-RBC antibody, are free of diseases such as equine infectious anemia, and originate from animals with known immunoglobulin levels. The major disadvantage is that plasma may not contain antibody specific for the pathogens from the particular environment to which the foal is exposed.

Use of a local donor is desirable in that it presumably has antibody specific to the environmental pathogens to which the foal has been exposed. If a local donor is to be selected, several criteria should be met. First, the horse should be healthy, and results of agar gel immunodiffusion for equine infectious anemia should be negative. Second, no anti-RBC antibody should be detectable in the horse's serum. The donor's plasma should be screened for lysins and agglutinins by a blood-typing laboratory against a panel of cells representing all known blood groups. If plasma evaluated in this way is not available, the presence of anti-RBC antibody in donor plasma can be crudely evaluated with a minor crossmatch for agglutination using

donor plasma and recipient blood cells. Lytic antibodies require an external source of complement for activity *in vitro* and may not be detected using this test.

Ideally, a third criterion is selection of a horse that is negative for blood group factors Aa and Qa. Even though there are dozens of blood group factors, Aa and Qa have been associated with the great majority of cases of neonatal isothermolysis (NI).⁵⁷⁻⁵⁹ If plasma is collected and separated by sedimentation, it is inevitable that some RBC contamination be present. If Aa-positive (Aa+) RBCs are given to an animal that is Aa negative (Aa-), or if Qa+ RBCs are given to an animal that is Qa-, the recipients could become sensitized to these antigens. This sensitization would probably not have any immediate consequences for the recipient foal, because the foal's cells would not be affected by the antibodies, but it has potentially sensitized any Aa- and Qa- females for production of an NI foal later (see p. 1685). To avoid these potential complications, the ideal donor should be Aa- and Qa- and possess no anti-RBC antibody in its serum. It is desirable to have identified this type of donor to avoid the need for immediate crossmatching in every case of plasma transfusion.

The volume of plasma needed to correct the measured IgG deficit in a foal can theoretically be calculated on the basis of the blood volume of the foal and the concentration of IgG in the foal's serum and in the donor plasma; however, these calculations do not reliably predict the actual levels of IgG achieved after transfusion.^{35,60} A 20-mL volume of plasma per kilogram of body weight administered intravenously routinely only raises serum IgG levels 200 to 300 mg/dL, and often two to three times this amount is needed to bring serum IgG levels into the range considered minimum for protection (e.g., 400 to 800 mg/dL).^{35,61} If the foal is already clinically ill, additional plasma will often be required to raise IgG levels an equivalent amount.^{35,44} In a newborn foal (estimated 50 kg) with complete FPT, between 2 and 4 L of plasma is frequently needed.

Plasma should be administered through an IV catheter placed aseptically in one jugular vein. Frozen plasma is thawed and warmed slowly to room temperature in a warm water bath. Microwave thawing or thawing with very high temperatures is not recommended because this may denature important plasma proteins. An appropriate in-line blood filter should be used for IV administration of any blood product to remove fibrin clumps and other debris. Initial infusion rates should be slow (0.5 mL/kg over 10 to 20 minutes) to monitor for adverse reactions. Muscle fasciculations, piloerection, increased heart or respiratory rate, fever, respiratory distress, abdominal pain, blanching of mucous membranes, and collapse are indicative of transfusion reactions. In the absence of these or other adverse effects, the remainder of the transfusion may be administered at rates up to 40 mL/kg/hr. Slower infusion rates are recommended for foals that are systemically ill. If other IV fluid therapy is being administered concurrently, slower infusion rates are also indicated to diminish the likelihood of inadvertent fluid overload.

Serum IgG concentrations in the foal should be rechecked 12 to 24 hours after plasma transfusion to confirm that the desired increase has been achieved. The delay from transfusion to IgG assessment is necessary to allow for distribution of immunoglobulin into extravascular spaces. Healthy foals transfused with plasma at 1 day of age experienced a 30% decrease in serum IgG concentrations by 7 days of age.⁶² This decline might be even more dramatic in septic foals with increased vascular permeability, increased catabolism, and increased demand for utilization in immune responses.

Although several equine serum-derived products are marketed for IV administration in the treatment of foals with FPT, these products have been associated with significant adverse reactions in some foals. Administration of high-quality equine plasma is preferred for treatment of foals with FPT.

■ **Prevention and Control.** Evaluation of colostrum immunoglobulin content has proved to be valuable in predicting the occurrence of FPT and assessing the neonate's risk for FPT.^{35,63} Colostrum with high immunoglobulin concentration tends to be sticky, yellow, and thick, but these subjective criteria are unreliable in assessing colostrum quality. The quantity of immunoglobulin in colostrum may be more accurately estimated by single radial immunodiffusion (RID), refractometry, glutaraldehyde coagulation, or specific gravity.⁶² Because 18 hours are required to read the results of RID, it is more practical in a field situation to assess specific gravity with a refractometer, glutaraldehyde coagulation test or colostrometer. Sugar refractometry using a hand-held Brix 0-50% sugar refractometer is a simple and cost-efficient stall-side screening test for assessing colostrum quality.^{64,65} A Brix reading of 20% to 30% correlates with adequate colostrum quality; a reading greater than 30% indicates good-quality colostrum.⁶⁶ A commercial kit based on glutaraldehyde coagulation of immunoglobulins* is available for screening of colostrum quality. Using a colostrometer,[†] colostrum specific gravity should be a minimum of 1.060, corresponding to an IgG concentration of greater than 3000 mg/dL; levels of 6000 mg/dL or higher are desirable. Approximately 75% of foals that ingest colostrum with a specific gravity less than 1.060 will have serum IgG concentrations under 400 mg/dL; when colostrum specific gravity is greater than 1.060, foals usually attain serum IgG concentrations above 500 mg/dL.⁶³

Some of the causes of FPT can be alleviated or recognized for early intervention by careful management. These include identification of mares that drip colostrum before parturition, attendance at foaling to ensure that foals suckle within several hours of birth or are supplemented artificially with colostrum, and screening of high-risk foals with doubtful nursing histories. Routine screening of foals at 18 to 24 hours of age allows early identification of FPT and potentially allows for therapy before the onset of infections. Although signs of septicemia secondary to FPT are often first observed on day 3 to 4 of life, a bacteremia may already be present at 24 hours of age or earlier.^{66,67}

A colostrum bank can be established by collecting small amounts of colostrum from lactating mares (e.g., 200 to 250 mL) within the first 3 to 6 hours after foaling. This is only about 10% of the total colostrum produced by the average mare in the first 20 hours after parturition and therefore does not adversely affect the foal suckling the donor mare. Although the volumes are quite variable, mares produce about 300 mL of colostrum per hour and about 5 L during the first 18 hours. Colostrum can be stored frozen for at least 1 year at standard freezer temperatures, approximately -20°C (-4°F). Although frozen immunoglobulins are stable for much longer, the overall quality of the colostrum may deteriorate. Ideally, banked colostrum should be screened for the presence of anti-RBC antibodies as advised for plasma. Colostrum typically has low titers of agglutinins, which are probably not of significance unless present at dilutions of 1/8 or greater.

SEVERE COMBINED IMMUNODEFICIENCY

■ **Definition and Etiology.** Severe combined immunodeficiency (SCID) is a lethal, inherited condition in which both T-cell and B-cell function is absent.⁶⁸ Affected foals have a stem cell defect that prevents maturation of T and B cells, resulting in a complete inability to produce antigen-specific immune responses. The condition primarily affects Arabians and part Arabians, although sporadic cases have been described in other breeds.^{68,69} In horses of Arabian breeding, the condition is transmitted as an autosomal recessive trait.⁷⁰ Carriers of the gene are asymptomatic but can now be detected by genetic testing.⁷¹

■ **Clinical Signs and Differential Diagnoses.** Foals that are homozygous for the defective SCID gene are clinically affected. These foals generally appear physically normal at birth, but the absence of both specific humoral and cellular immune responses renders them susceptible to infections once colostrum protection wanes.⁶⁸ Affected foals typically develop infectious diseases between birth and 2 months of age and die before 5 months of age. The age of onset of infectious disease depends to some degree on the adequacy of passive transfer and the environmental challenge by organisms. The infections in affected animals are nonspecific and are caused by a variety of bacterial, viral, parasitic, and fungal agents, some of which rarely affect animals that are not immunocompromised.^{68,72,73} Many body systems may be involved, but pneumonia is a particularly common feature. *Pneumocystis carinii* pneumonia and adenoviral pneumonia are found often in SCID foals and rarely in other foals.

■ **Clinical Pathology.** A consistent finding on the hemogram is an absolute lymphopenia, which is consistently less than 1000 lymphocytes/ μL and often much lower. The total white blood cell (WBC) count may be low, normal, or elevated, depending on the neutrophilic response; thus it is imperative that the absolute number of lymphocytes be determined. Infected and other compromised foals, as well as some normal foals, have low lymphocyte counts during the first few days of life; therefore, the clinician should establish persistent lymphopenia before considering a diagnosis of SCID.^{68,74}

Foals affected with SCID are unable to produce immunoglobulins. Therefore, levels of autologous serum immunoglobulin for age are abnormally low. However, quantitative immunoglobulin tests do not distinguish between autologously produced and maternal-origin immunoglobulin. Thus the degree of colostrum transfer and the age of the foal must be considered when interpreting the serum immunoglobulin values (see Table 53-1). Some IgM is normally produced in utero by the foal, and some IgM should be present in presuckle serum.⁷⁵ Although not pathognomonic, the absence of IgM in presuckle serum is a feature of SCID. The presence of colostrum antibody of maternal origin may mask low levels of autologous IgG and IgM, particularly early in life. The levels of maternal IgM in colostrum are lower than IgG, and the half-life of IgM is shorter (Table 53-2). Most maternal IgM received from colostrum is metabolized by about 3 weeks of age, whereas the age at which maternal IgG is gone is much more variable and may actually be months, depending on the original amount absorbed. The absence of serum IgM after 3 weeks of age is not pathognomonic but is consistent with SCID.

Foals affected with SCID do not respond to intradermal phytohemagglutinin (see p. 1667) by increasing skin thickness as do normal foals, nor do they respond to DTH stimulators, such as dinitrochlorobenzene.⁷⁶ *In vitro* tests such as blastogenesis are depressed with all mitogens.^{77,78}

TABLE 53-2

Approximate Half-Life (in Days) of Immunoglobulin Classes in Large Animals

Species	IgG	IgM	IgA	IgG(T)
Equine	11.5-23	4-5	NA	20
Bovine	G1: 17	2.8	4.8	—
	G2: 22			
Sheep	G1: 14.5	1.8	4.1	—
	G2: 10.6			
Goat	G1: 13.2-17.2	NA	NA	—

From Perryman L: Personal communication, 1988.
NA, Not available.

The definitive diagnosis of SCID in foals of Arabian breeding is based on demonstrating that the foal is homozygous for the defective SCID gene.^{71,79} Blood or cheek swabs may be submitted to VetGen for DNA testing to determine if a horse is clear, heterozygous, or homozygous for the gene defect. Before the advent of genetic testing, the criteria required to confirm a diagnosis of SCID included (1) persistent lymphopenia (<1000/ μ L), (2) absence of serum IgM in presuckle samples or samples collected after 3 weeks of age, and (3) thymic hypoplasia and characteristic histopathologic changes in lymphoid tissue.^{80,81}

■ **Pathophysiology.** Foals with SCID lack activity of the enzyme DNA-dependent protein kinase (DNA-PK) resulting from a mutation in the gene encoding the catalytic subunit.^{79,82,83} The mutation results in a five-base-pair deletion in the gene on equine chromosome 9. Without functional DNA-PK, lymphocyte precursors are unable to complete gene rearrangement events that lead to the expression of antigen-specific receptors on lymphocyte surfaces. As a result, there is an absence of mature, functional T and B lymphocytes. Interferon- γ (EqIFN- γ), which is produced by lymphocytes, is deficient.⁸⁴

Neutrophils, monocytes, and natural killer (NK) cells appear to be fully functional.^{85,86} Complement levels are normal.⁷⁸ Although these nonspecific protective mechanisms appear to be intact, the absence of both cell-mediated and antibody-mediated immunity leaves the foal vulnerable to even innocuous infectious agents.

■ **Epidemiology.** SCID has been reported in Arabians in the United States, Canada, Australia, and Great Britain.^{68,87,88} It is believed that the trait originated in a horse in Great Britain and was subsequently imported into the United States. The distribution of this disease provides a significant example of the *founder effect* in population genetics.

The prevalence of SCID at one time was estimated to be 2% to 3% of Arabian foals born in the United States. From this, it was predicted that the numbers of SCID carriers at that time could be as high as 25% of the U.S. Arabian horse population. A 1998 study of 250 randomly selected Arabian horses in the United States found the frequency of SCID gene carriers to be 8.4%.⁸⁸ Based on this finding, it was predicted that 0.18% of Arabian foals would be affected with SCID, assuming a random breeding population.

■ **Necropsy Findings.** It is imperative to evaluate lymphoid tissues grossly and histologically in cases of suspected immunodeficiencies. In SCID the thymus is small and has a fatty appearance on gross examination.⁸⁰ It is frequently difficult to locate, and mediastinal tissue often must be collected "blindly" for subsequent histologic evaluation and

identification of thymic remnants. Histologically, the thymus is largely replaced with adipose tissue, with only islands of lymphoid cells and partially formed Hassall's corpuscles present. The gross appearance of spleen and lymph nodes may not be dramatically abnormal; however, they have very abnormal microscopic appearances, including absence of germinal centers and periarteriolar lymphocytic sheaths in the spleen, as well as absence of germinal centers with scarcity of lymphocytes in other areas of lymph nodes.

Bronchopneumonia is a common finding in SCID. Infectious lesions in other systems are also frequently found, including colitis and hepatitis.

■ **Treatment and Prognosis.** Affected foals invariably die by about 5 months of age, despite intensive conventional therapy (e.g., antimicrobials, plasma, isolation).

There is no practical method of curing affected foals at this time. Successful bone marrow transplants have been performed between histocompatible full siblings in a research setting, but this option remains impractical.⁸⁹

■ **Prevention and Control.** Production of an affected foal identifies both sire and dam as carriers of the SCID gene.⁷⁰ Mating of two carriers of an autosomal recessive trait such as SCID is expected to result in one in four foals affected with SCID, one in four completely normal and not a carrier, and two in four asymptomatic carriers of the SCID trait. Mating of a carrier and a normal (noncarrier) does not produce any affected foals, but half the offspring would be expected to be carriers.

The disease can be controlled in horses of Arabian breeding by avoiding the production of affected foals, which has been simplified now that carriers can be identified by genetic testing. Mares and stallions intended for breeding should be tested to determine whether they are free or heterozygous for the defective SCID gene. Under no circumstances should two heterozygotes be mated to each other. If an owner decides to continue breeding a heterozygote, the breeding partner should be confirmed homozygous normal. All foals from such matings should be tested to determine if they are clear of or heterozygous for the defective gene (50/50 probability). Homozygous normal foals may be selected for future breeding purposes, whereas heterozygous foals should be managed for nonreproductive pursuits.

SELECTIVE IgM DEFICIENCY

■ **Definition and Etiology.** Selective IgM deficiency is an immunologic disorder characterized by absent or decreased serum IgM levels with normal or elevated levels of other immunoglobulin classes. Three presentations of the disorder have been described in horses.⁹⁰⁻⁹³ The most common involves foals that have severe infectious pneumonia, arthritis, or enteritis, resulting in death before 10 months of age. The second involves foals with a history of repeated episodes of infections that respond to antimicrobial therapy but that recur when treatment is stopped. These foals tend to do poorly and are stunted, although they may survive for 1 to 2 years. The third involves older horses that are usually 2 to 5 years of age at initial diagnosis. These horses do not necessarily have problems with recurrent infections, but about half ultimately have lymphosarcoma.⁹⁴

It is not known whether the IgM deficiencies reported in foals are primary or secondary. The levels of IgM present before the onset of infections have not been measured. The occurrence of multiple cases within groups of related horses suggests a genetic basis. However, breeding trials have been inconclusive to date with regard to the heritability of

this condition. In humans, both primary and secondary selective IgM deficiencies are known. Secondary cases are often associated with neoplasia, immunologic diseases such as Wiskott-Aldrich syndrome, and gluten-sensitive enteropathies.

■ **Clinical Signs and Differential Diagnoses.** Foals with selective IgM deficiency tend to have frequent *Klebsiella* infections of the respiratory tract, although enteritis and septic arthritis may also be complicating infections. The age of onset of clinical signs may be slightly later than in foals with SCID and certainly later than in foals with FPT.

Older horses with IgM deficiency should be carefully evaluated for lymphoid neoplasia, including palpation of peripheral and internal lymph nodes. Weight loss, depression, and other nonspecific signs frequently accompany lymphosarcoma (see Chapter 37).

■ **Clinical Pathology.** The only significant immunologic abnormality is a low or absent serum IgM. IgM levels are more than 2 standard deviations below the age-specific mean IgM level (see Table 53-1). Other classes of immunoglobulin are generally within normal limits or elevated for age. It is advisable to document that IgM levels are persistently depressed rather than to base a diagnosis on a single sample, because IgM levels may sporadically decrease in seriously ill foals but return to normal with recovery. Lymphocyte counts and other *in vitro* immunologic tests are generally normal, and these features serve to differentiate selective IgM deficiency from other immunodeficiency conditions. In one horse with selective IgM deficiency, however, lymphocytes failed to respond to the B-cell mitogen lipopolysaccharide (LPS), whereas response to the T-cell mitogens concanavalin A (ConA) and phytohemagglutinin (PHA) was normal.⁹³ The hemogram and biochemical profile may reflect infection or inflammation, depending on the underlying infectious process (e.g., neutrophilia, hyperfibrinogenemia, anemia) and the organ system involved, but no diagnostically specific changes occur.

■ **Pathophysiology.** Whether IgM is low because of decreased production, hypercatabolism, or loss is not known. In one case with lymphosarcoma, suppressor activity was identified in the neoplastic cells, suggesting that the low IgM may be a result of suppression of B-cell function by neoplastic cells. Selective IgM deficiency has been most frequently reported in Arabians and quarter horses, although it affects other breeds as well.

■ **Necropsy Findings.** Lymphoid tissue in affected foals is grossly and histologically normal. Pneumonia is usually present and is frequently caused by *Klebsiella* infection. Other findings reflect secondary infections.

■ **Treatment and Prognosis.** Selective IgM deficiency has an unfavorable prognosis. Most horses eventually succumb to infection despite appropriate antimicrobial therapy. Plasma therapy may provide short-term benefit, but only small amounts of IgM are contained in transfused whole plasma, and the half-life of transfused IgM is probably quite short. No concentrated IgM preparations are commercially available for parenteral use. Relief, at best, can be considered only temporary. However, the outcome of these cases seems less certain than with SCID foals, and a rare case recovers. If persistently low IgM levels can be documented, a poor to grave prognosis can be expected.

■ **Prevention and Control.** Because some cases of selective IgM deficiency might be hereditary, it may be advisable to avoid repeating the mating that produced the affected foal. However, no firm recommendations can be made.

TRANSIENT HYPOGAMMAGLOBULINEMIA

■ **Definition and Etiology.** Transient hypogammaglobulinemia is a rare disorder characterized by the delayed onset of immunoglobulin synthesis by the neonate.^{5,95} Foals normally begin to produce significant amounts of immunoglobulins at birth, when they are first exposed to environmental antigens (see Fig. 53-4). Assuming adequate passive transfer, maternal antibody fills the void from birth until the foal has produced sufficient autologous antibody for protection (e.g., first 1 to 2 months). In transient hypogammaglobulinemia the onset of autologous production is delayed for unknown reasons and may not begin for as long as 3 months. As maternal immunoglobulins wane, for a time the production of autologous antibody is insufficient to be protective, making the foal highly susceptible to infections.

The disorder has been described in an Arabian and a thoroughbred foal, but the low number of reported cases may not accurately reflect the prevalence. To make a diagnosis, serial samples are required to document decreasing maternal immunoglobulin and subsequent increasing autologous immunoglobulin. Many cases probably occur that are not followed this closely.

■ **Clinical Signs and Differential Diagnoses.** As with other immunodeficiency disorders, recurrent episodes of bacterial and viral infections are characteristic of transient hypogammaglobulinemia.

■ **Clinical Pathology.** The cardinal feature is low immunoglobulin levels.^{5,23,95} At approximately 2 to 4 months of age, the concentrations of all classes of immunoglobulin, particularly IgG and IgG(T), are substantially below the means when age-matched. At this stage, maternal antibody will have waned, but the foal should have produced significant quantities of autologous antibody, regardless of whether passive transfer occurred. Affected foals have normal cell-mediated responses *in vitro* and *in vivo* and appear to be able to respond to immunization with some antigens. Normal numbers of B cells are present in blood and lymph nodes.

Differentiation between FPT and transient hypogammaglobulinemia is based on the age of the patient at evaluation. Transient hypogammaglobulinemia must be differentiated from agammaglobulinemia. Both disorders have normal lymphocyte counts and responses to PHA skin testing and show waning levels of maternal IgG and IgG(T) if followed serially. However, transient hypogammaglobulinemia cases usually have low but detectable levels of IgM and IgA, whereas agammaglobulinemia cases usually have no detectable levels. Differentiation between the two may require serial sampling to show that immunoglobulin production does ultimately increase in the patient with transient hypogammaglobulinemia.

■ **Necropsy Findings.** No specific gross or microscopic lymphoid changes have been associated with transient hypogammaglobulinemia. Necropsy findings reflect the secondary infectious processes that have affected the foal.

■ **Treatment and Prognosis.** The goal of therapy is to minimize infections until the foal's immune system begins to function properly. Treatment should include antimicrobial

therapy and plasma transfusions. Bacterial infections may be manageable with antibiotics alone, but the effects of viral infections may be more difficult to manage and may be helped by plasma transfusions.

AGAMMAGLOBULINEMIA

■ **Definition and Etiology.** Agammaglobulinemia is a rare primary immunodeficiency disorder of horses. It is characterized by complete B-cell dysfunction with an intact cell-mediated response. This condition has been observed only in males, suggesting the possibility of an X-linked disorder. It has been described in thoroughbreds, quarter horses, and standardbreds.^{23,96-98} Agammaglobulinemia in a young boy was the first immunodeficiency disorder described in any species, and in human patients it is now known to be inherited as an X-linked trait.⁹⁹

Horses with agammaglobulinemia illustrate the significant contribution of T and B lymphocytes to the maintenance of good health. Horses with defects in both B-cell and T-cell functions (e.g., SCID) seldom survive to 5 months of age, whereas the cases with a pure B-cell defect such as agammaglobulinemia have survived between 1 and 2 years. Recently, agammaglobulinemia with a lack of circulating B cells was diagnosed in a Pinto gelding that did not exhibit recurrent pyogenic infections until 3 years of age. Although it could not be established whether the immunodeficiency was primary or secondary, an underlying disease process was not identified.*

■ **Clinical Signs and Differential Diagnoses.** No outward physical signs suggest agammaglobulinemia other than the opportunistic infections that develop. Frequently, recurrent infections of the respiratory tract or joints with extracellular bacteria have been reported. Dermatitis, enteritis, and laminitis have also been associated with this disease.

■ **Clinical Pathology.** Total peripheral blood lymphocyte counts are within the normal range. However, there is a lack of circulating B cells with normal numbers of T cells. Neutrophil counts may be normal, low, or high, depending on the response to infection. No specific changes are noted in the biochemical profile. Serum levels of IgM, IgA, IgG(T), and IgG are persistently low or absent. Depending on the age at evaluation, maternal antibody may be present, but its decline is evident if sampled serially. The continued presence of low levels of immunoglobulin in these foals may be explained by the prolonged catabolism of antibody or by some residual B-cell activity, as in human patients with sex-linked agammaglobulinemia.^{23,96-99}

Specific antibody responses are depressed, both for antigens to which horses naturally tend to produce antibodies, such as sheep RBCs, and for antigens administered by planned immunization, such as vaccines. Cell-mediated tests are essentially normal, including blastogenesis and DTH skin testing. Total hemolytic complement activity is also normal.

■ **Pathophysiology.** The molecular basis of agammaglobulinemia in horses is unknown, but a defect at the stem cell level that blocks early B-cell differentiation is suspected because all classes of immunoglobulin are affected. In human patients a mutation in BTK, a gene encoding tyrosine kinase, accounts for the disease. Assessment of the BTK gene in horses may help in understanding this disorder.

■ **Necropsy Findings.** Gross lymphoid changes in lymph nodes, spleen, and thymus have been observed. Lymph nodes are small. The thymus may be small and difficult to locate. Lymphoid tissue taken from the mediastinal region where the thymus should be found lacks the defined lobular structure of normal thymus. The spleen grossly may be small and contracted. Microscopically, lymph nodes are devoid of germinal centers and follicles. The spleen has no germinal centers, periarteriolar lymphocytic sheaths, or plasma cells.

The thymus does not show recognizable epithelial structure and lacks defined nodules.^{23,98} Why cell-mediated functions are normal while the architecture of the thymus is so abnormal remains unexplained.

■ **Treatment and Prognosis.** In the absence of production of autologous antibody, affected horses respond poorly to infections over the long term. Antimicrobial therapy and administration of plasma may temporarily control infections; however, the long-term prognosis is poor.

FELL PONY SYNDROME: ANEMIA, IMMUNODEFICIENCY, AND PERIPHERAL GANGLIONOPATHY

■ **Definition and Etiology.** A congenital fatal syndrome characterized primarily by severe anemia and immunodeficiency has been identified in Fell Pony foals.¹⁰⁰ In addition, peripheral ganglionopathy has been reported in some cases. Both genders are affected. The exact nature of the defect is as yet unknown, but an intrinsic genetic disorder transmitted by a single autosomal recessive gene is suspected.¹⁰¹ The Fell Pony is considered an endangered breed by the Rare Breeds Survival Trust, with an estimated 5000 animals worldwide. Originally described in Fell Ponies in the United Kingdom, Fell Pony syndrome has also been found in the Netherlands and North America.¹⁰⁰⁻¹⁰²

■ **Clinical Signs.** Affected Fell Pony foals typically develop signs of decreased suckling, diarrhea, cough, and chewing motions beginning at 2 to 3 weeks of age.¹⁰⁰⁻¹⁰² The foals progressively lose condition and develop pale mucous membranes. The condition is generally fatal by 4 to 12 weeks of age. Opportunistic infections such as cryptosporidial enteritis, adenoviral pancreatitis, and adenoviral bronchopneumonia are frequently observed in affected foals and suggest an underlying immunodeficiency.

■ **Clinical Pathology.** Foals develop severe normocytic to macrocytic anemia associated with small numbers of erythroid precursor cells in the bone marrow.¹⁰⁰⁻¹⁰² Myeloid/erythroid ratios in the bone marrow have ranged from 21:1 to 62:1. Although total circulating lymphocyte counts are variable, lymphopenia is described in some cases. Numbers of both CD4⁺ and CD8⁺ T lymphocytes are normal, but numbers of B cells are decreased.^{103,104} Consistent with this B-cell lymphopenia, serum immunoglobulin concentrations are often decreased once concentrations of maternal antibodies have declined.¹⁰²⁻¹⁰⁴ Because maternally derived concentrations of IgM and IgA generally do not persist as long as IgG, concentrations of these antibodies are more likely to reflect production by the foal. The responses of lymphocytes to in vitro stimulation with mitogens have been variable.¹⁰⁵

At this time, no definitive test is available for the diagnosis of Fell Pony syndrome, and diagnosis is based on the

*VetGen, Ann Arbor, MI; 800-4-VetGen; <http://www.vetgen.com>.

signalment, history, clinical signs, and laboratory findings, including anemia, B-cell lymphopenia, and low concentrations of IgM after 4 weeks of age.

■ **Pathophysiology.** The precise nature of the immune defect is unknown, and thus far the characteristics identified do not conform to any known immunodeficiencies in other species. In addition to the decrease in circulating B cells, immunohistochemical staining reveals decreased B cells in the bone marrow, lymph nodes, and primary follicles of the spleen. Although analyses of cellular immunity and phagocytic activity have not revealed any consistent abnormalities, the severity of disease has led to speculation that multiple arms of the immune system are affected. The anemia is associated with severe erythroid hypoplasia of the bone marrow.

■ **Necropsy Findings.** The absence of secondary lymphoid follicles and lack of plasma cells on histologic examination is characteristic of the condition. There is also marked erythroid hypoplasia in the bone marrow. In some cases, peripheral ganglionopathy is seen, characterized by neuronal chromatolysis and nuclear pyknosis of the trigeminal, cranial mesenteric, or dorsal root ganglia. Other common necropsy findings include abnormalities associated with infections characteristic of immunodeficiency, particularly infections with *Cryptosporidium parvum* and adenoviral infections of the pancreas and bronchial tree.

■ **Treatment and Prognosis.** Affected foals respond poorly to treatment for infections and anemia.¹⁰⁰⁻¹⁰² They generally die by 12 weeks of age.

COMMON VARIABLE IMMUNODEFICIENCY

■ **Definition and Etiology.** Common variable immunodeficiency (CVID), a heterologous syndrome of immunodeficiency, has been described in four horses.^{106,107} It has also been suspected in additional horses with varying immunologic deficits.¹⁰⁸⁻¹¹⁰ CVID was initially defined in human patients, and although the syndrome is highly variable, recurrent bacterial infections and hypogammaglobulinemia are common characteristics.^{111,112} CVID has also been reported in miniature dachshunds with *Pneumocystis carinii* pneumonia.¹¹³

■ **Clinical Findings.** Information on CVID in horses is limited because of the small number of cases. The syndrome has been identified in various breeds and both genders and is characterized by a late onset, with horses ranging in age from 6 to 14 years.^{106,107} In human patients the disorder affects both men and women and can develop at any age, although the onset is most frequently seen during the second or third decade of life.^{111,112}

Recurrent bacterial infection is common in CVID. Three horses with CVID diagnosed with presumptive bacterial meningitis were successfully managed medically with antibiotic therapy without immunoglobulin replacement therapy.¹⁰⁷ Another horse with CVID presented with infection of the guttural pouch and cholangiohepatitis and was ultimately euthanized because of deterioration in the horse's condition.¹⁰⁶ The clinical spectrum of CVID in human patients is broad, and as expected, clinical disease is more severe in patients with more marked immunologic abnormalities.^{111,112}

■ **Immunologic Findings.** Common features of CVID in affected people include recurrent bacterial infections and

agammaglobulinemia or hypogammaglobulinemia, particularly involving IgM and IgG.^{111,112} The humoral response to vaccination is generally impaired. B-cell maturation may be arrested at various stages, and B-cell numbers may be normal or decreased. T-cell abnormalities may also be present. As in human patients, immunologic abnormalities identified in affected horses include hypogammaglobulinemia and failure to respond to immunization.^{106,107} The type and severity of the hypogammaglobulinemia vary; IgM deficiency is common. Affected horses have an abnormal lymphocyte distribution characterized primarily by B-cell lymphopenia. The lymphocyte response to mitogens varies but generally is decreased. Phagocytosis, oxidative burst activity, and serum opsonization capacity were normal in three horses tested.

The variable immunologic abnormalities associated with CVID make it difficult to define cases, and it has been suggested that additional cases of recurrent bacterial infections and immune abnormalities may represent variations of CVID. An adult Paso Fino mare with proliferative interstitial pneumonia and *Pneumocystis carinii* infection was found to have a complete lack of IgM, low concentrations of IgG, and decreased numbers of immune cells expressing major histocompatibility complex (MHC) class II cell surface antigens.¹⁰⁸ In another case, a 3-year-old quarter horse with chronic diarrhea and bacterial pneumonia was diagnosed with an acquired B-lymphocyte deficiency associated with deficiencies in serum IgG, IgA, and IgM and a concurrent decrease in T-cell function.¹⁰⁹ Additional cases with hypogammaglobulinemia and other immunologic abnormalities may fit the description of CVID.^{93,110,114}

UNCLASSIFIED AND SECONDARY IMMUNODEFICIENCIES

Many equine patients with evidence of immunologic defects cannot be placed in a currently recognized immunodeficiency category. These animals form a diverse group that may seem to have little in common except the propensity to develop infections. Attempts to further classify these cases have been hampered by the lack of specific, practical tests that precisely define the immunologic defect. As newer testing methods are developed, this group will eventually be defined. Numerous immunodeficiency syndromes are described in humans, the counterparts of which can be reasonably assumed to exist in horses. As previously discussed, some of the previously unclassified immunodeficiencies characterized primarily by hypogammaglobulinemia are now suspected to be a form of CVID.^{93,107-110,114} Also, a CD4⁺ and CD8⁺ T-lymphocytopenia has been described in a filly with *Pneumocystis carinii* pneumonia.¹¹⁵

Numerous endogenous and exogenous factors can cause secondary immunodeficiency or suppression.⁷ These include malnutrition, specific nutrient deficiencies or excesses, microbial and parasitic agents, corticosteroids and other hormones or drugs, and neoplasia. In addition, factors such as age and pregnancy can influence the immune system. Stress, such as that associated with exercise or transport, may also have immunomodulatory effects. To complicate the issue, many of these factors can induce either suppression or stimulation under appropriate circumstances; thus their presence alone is not adequate to confirm immune compromise. In general, the effects of these factors on the immune system can be assessed by the same tests used to classify primary immunodeficiencies. Distinguishing the role of these factors from more subtle types of primary immunodeficiency is difficult.

Adult Acquired Immunodeficiency

A 7-year-old Appaloosa gelding with no history of prior illness became lethargic, anorexic, and dyspneic.¹¹⁴ *Rhodococcus equi* septicemia was diagnosed on the basis of blood cultures. Immunologic evaluation of the patient revealed lymphopenia, low IgM and IgA concentrations, marginally low IgG concentrations, low *R. equi* antibody titer, negligible response to lymphocyte stimulation, histologic depletion of the lymphoid tissue, and failure to respond to antigenic stimulation. Marked thrombocytopenia was also present. These abnormalities suggested suppression of both humoral and cell-mediated arms of the immune system. The age of the horse, absence of previous history of illness, and histopathologic findings suggestive of atrophy of lymphoid tissue indicated the immunodeficiency was acquired. No underlying cause was identified for the immunodeficiency; specifically, no neoplasms were identified at necropsy, and there was no history of exposure to immunosuppressive toxins. This may represent CVID.

Infectious Disease

Secondary immune suppression can result from a variety of infectious or inflammatory diseases. Many viral, fungal, and bacterial infections transiently suppress specific and nonspecific immune responses, predisposing to secondary bacterial infections.¹¹⁶ Severe endotoxemia or septicemia may suppress neutrophil numbers and bactericidal function.

Perinatal Equine Herpesvirus Type 1 Infection

Infection of the fetus with equine herpesvirus type 1 (EHV-1, rhinopneumonitis) late in gestation has been associated with postnatal development of interstitial pneumonia, lymphopenia, marked necrosis and atrophy of the thymus and splenic lymphoid tissue, and increased susceptibility to bacterial infections.¹¹⁷ Affected foals may be either weak or normal at birth. Despite apparently adequate passive transfer of maternal antibody, affected foals contract a variety of infectious bacterial diseases, including colibacillosis, streptococcal septicemia, salmonellosis, and Tyzzer's disease. EHV-1 is isolated from nasal passages of about 30% of the cases. The spleen and thymus are grossly small at necropsy. Bilateral adrenocortical hyperplasia is noted in most foals. Histologically, splenic periarteriolar lymphocytic sheaths are depleted of lymphocytes, and no lymphoid follicles are detectable. Thymic alterations vary from extreme diminutions of thymocyte numbers to complete necrosis of thymic lymphocytes with disappearance of Hassall's corpuscles and disruption of the epithelial matrix. Lymph nodes also show lymphoid necrosis.

An immunodeficiency secondary to the marked lymphoid damage induced by the virus is credited with allowing secondary bacterial infections to become established. Immunization of broodmares against EHV-1 would seem to be the most appropriate approach to prevention.

Immunodeficiency Associated with Oral Candidiasis and Bacterial Septicemia

■ **Definition and Etiology.** A group of foals with laboratory or histologic evidence of immunodeficiency that did not fit into any recognized category of primary immunodeficiency have been described with oral candidiasis and bacterial septicemia.¹¹⁸ The foals shared no consistent pattern of in vitro immunologic abnormalities, but all had the

clinical features of oral candidiasis and bacterial septicemia. This syndrome has some similarities to mucocutaneous candidiasis in people, which has been associated with several different subtle T-cell defects. Not all human cases are thought to result from a single immunodeficiency disorder. Candidiasis does not occur in the presence of B-cell defects alone, or in the absence of T-cell defects.

■ **Clinical Signs.** Most affected foals with oral candidiasis were about 4 months of age at onset, although several were less than 2 weeks old.¹¹⁸ Oral lesions ranged from discrete, focal, white, plaquelike lesions on the margins of the tongue to a generalized, thick, white, pseudomembranous coating covering the tongue and gingival mucosa. Most foals exhibited bruxism, ptyalism, fever, and depression. Other significant clinical problems included pneumonia, septic arthritis, and diarrhea. This syndrome should be distinguished from the glossitis caused by *Candida* infection seen in inappetent or debilitated neonatal foals, which is fairly common and generally resolves with amelioration of the primary disease.¹¹⁹

■ **Clinical Pathology.** Serum IgG and IgM levels were variable, but most of the older foals also had low or marginal IgG or IgM for their age.¹¹⁸ The younger foals all had FPT and low IgG levels. Some horses showed a transient lymphopenia, but lymphocyte counts were generally within normal limits. Almost all cases had other abnormalities, including depressed blastogenesis, suggesting a cellular defect distinct from previously described immunodeficiency cases that involved only immunoglobulin production.

■ **Necropsy Findings.** Thymic tissue was difficult to locate grossly at necropsy.¹¹⁸ Mediastinal tissue collected in the thymic region was confirmed to be thymus microscopically in only one of six cases. Histologically splenic lymphoid depletion was present. Evidence of disseminated bacterial infections included pulmonary abscesses, enteritis, septic arthritis, and focal hepatitis. *Candida* species were identified in tissues histologically or with culture in all cases. A variety of bacterial organisms were associated with the septicemias and secondary infections. Organisms usually considered minor pathogens, such as *Acinetobacter* and adenovirus, were identified in some cases.

■ **Treatment and Prognosis.** Affected foals did not respond to extensive parenteral antibiotic, topical antimycotic, or plasma transfusion therapy. Because antibiotic administration can predispose animals to secondary candidiasis, the role that antibiotic therapy may have played in the development of the oral lesions was considered. In light of the high frequency of antibiotic use in foals in the general population and the uncommon occurrence of oral candidiasis, additional factors such as an underlying immune defect are deemed likely. Whatever the cause, the prognosis for foals with oral candidiasis and associated bacterial septicemia is guarded to poor.

Neoplasia

Neoplastic disease can impair cell-mediated and humoral immune responses as a result of an abnormal bone marrow environment, altered patterns of cytokine production or release, or impaired proliferative responses (anergy). In horses, immunodeficiency has most often been described in association with lymphosarcoma or plasma cell myeloma.

LYMPHOSARCOMA. Immunodeficiency has been identified in some cases of equine lymphosarcoma. The immunologic abnormality most often described is a decrease in the concentrations of serum immunoglobulins, especially IgM.^{94,120-123} In addition, decreased lymphocyte blastogenesis in response to mitogens has been reported. Some horses with lymphosarcoma have been diagnosed with concurrent bacterial infections, which may be related to immunosuppression.^{122,123} A horse with myelomonocytic leukemia was found to have pulmonary aspergillosis.¹²⁴

PLASMA CELL MYELOMA. Plasma cell myelomas have been diagnosed in horses of several breeds.¹²⁵ Although reports of the condition are limited, there appears to be no gender predilection. Horses have ranged in age from 3 months to 22 years (median, 11 years) at diagnosis. Common clinical signs include weight loss, anorexia, fever, pneumonia, and limb edema. As a malignancy of plasma cells or lymphocytoid plasma cells, plasma cell myelomas typically produce large quantities of a homogenous immunoglobulin or immunoglobulin fragment, resulting in a monoclonal gammopathy. In both equine and human cases of myeloma, the predominant serum globulins are generally subclasses of IgG.^{125,126} Hyperglobulinemia is a characteristic but not invariable finding. Monoclonal gammopathies in the horse have also been reported with lymphoma and benign disorders.^{127,128} Both equine and human patients with plasma cell myelomas have an increased susceptibility to bacterial infections, probably as a result of a secondary immunodeficiency.^{125,126,129} The concentrations of normal polyclonal immunoglobulins are generally decreased in myeloma patients as a result of several mechanisms, including decreased synthesis and accelerated catabolism of antibody and suppressed clonal expansion of B cells.^{125,126,129} Decreased numbers of neutrophils, which may also be dysfunctional, and defective complement activation may also contribute to the impaired immune function.

Corticosteroid-Induced Immunosuppression

Increased concentrations of corticosteroids can result in varying degrees of immunosuppression. The increase in corticosteroids may be associated with stress or disease, most often pituitary pars intermedia dysfunction. In addition, corticosteroid treatment is the most common iatrogenic cause of immunosuppression. Increased concentrations of corticosteroids may exacerbate preexisting infectious diseases or decrease resistance to environmental pathogens.^{130,131}

Corticosteroids have a number of effects on the immune system, many of which are dose dependent. They may suppress macrophage phagocytic function by impairing the killing of ingested microorganisms, decreasing secretion of monokines, and inhibiting antigen processing and presentation. Corticosteroids suppress cell-mediated immunity through induction of a T-cell lymphopenia, suppression of proliferation in response to mitogen stimulation, altered cytokine production, and decreased antigen presentation. Humoral immunity may be affected through impaired T-cell responses, enhanced catabolism of immunoglobulins, and decreased antigen presentation.^{132,133}

Exercise

Exercise can clearly act as a stressor that may significantly alter the immune response.^{134,135} However, defining the precise effects of exercise on the equine immune system and susceptibility to disease has been difficult because of the complexity of the immune system, host factors (e.g., age, level of fitness), and the variable nature of exercise.¹³⁴⁻¹³⁶

In general, it appears that exercise may have both positive and negative effects on the immune response.¹³⁴⁻¹⁴⁰ Suppressive effects, such as a decline in the ratio of CD4⁺ to CD8⁺ T cells, decreased lymphoproliferative responses, and suppression of the innate immune system, have been associated with strenuous high-intensity exercise, prolonged exhaustive exercise, or overtraining. In contrast, moderate exercise tends to have beneficial effects on the host defense mechanisms.

Data in horses directly linking exercise-induced immunosuppression and increased susceptibility to infectious disease are limited. However, the potential immunosuppressive effects of exercise need to be recognized. In one study, unconditioned ponies vaccinated with a killed influenza vaccine and subjected to 5 days of strenuous exercise had an increased susceptibility to clinical influenza after challenge exposure compared with rested ponies.¹⁴¹ However, ponies with exercise-induced immunosuppression responded to the administration of an intranasal modified-live equine influenza vaccine and were protected from challenge.¹⁴² In a study of influenza infection in trained horses, moderate exercise led to increased signs of clinical disease, but the duration of disease was unaffected.¹⁴³

Age

Age has been shown to affect immune function in multiple species. The increased vulnerability of foals to respiratory tract infections, especially with specific pathogens such as *Rhodococcus equi*, is thought to reflect an innate immunodeficiency.¹⁴⁴ Although foals are immunocompetent at birth, it is likely that their immune responses differ from those of adults.¹⁴⁴⁻¹⁴⁶ Recently it has been shown that newborn foals have a diminished ability to express the interferon-gamma (IFN- γ) gene and produce IFN- γ protein.¹⁴⁶ This ability increases steadily, reaching adult levels with the first year of life. These findings suggest that foals have an inherent inability to mount a Th1 immune response, which may contribute to their susceptibility to intracellular pathogens.

Aging may also be associated with a relative immunodeficiency. Data in horses are limited, but older horses have been shown to have lower proliferative responses to mitogens and antibody titers than younger horses.¹³⁶⁻¹⁴⁷ However, older horses were more resistant to exercise-induced immune suppression than younger horses. The high prevalence of pituitary pars intermedia dysfunction in older horses is thought to be a risk factor for infectious disease, possibly because of elevated steroid concentrations.

RUMINANT IMMUNODEFICIENCY DISEASES

GEORGE M. BARRINGTON

STEVEN M. PARISH

FAILURE OF PASSIVE TRANSFER

■ **Definition and Etiology.** At birth, ruminants leave the sterile uterus and are exposed to an environment laden with pathogens. Although capable of mounting a measurable immune response at birth or even earlier, neonates are best characterized as being “immunonaive.” A neonate’s ability to mount a protective immune response is hindered by the immaturity of the immune system and the delay between initiation of response and effective protection. Unless adequate maternal immunologic assistance is provided,

neonates have an increased likelihood of succumbing to infectious diseases such as septicemia, diarrhea, enteritis, omphalitis, arthritis, and respiratory conditions.

Neonatal ruminants are protected against disease from infectious agents through passive transfer of maternal immunity by consumption of colostrum. The concept of failure of passive transfer (FPT) has largely been used to describe a neonate that does not absorb adequate levels of immunoglobulin. Immunoglobulins are a significant component of colostrum and have been the most studied constituent of colostrum. However, colostrum is a complex fluid that, in addition to immunoglobulins, contains high numbers of immune cells, immunoreactive substances such as cytokines, and nutritional elements.¹⁴⁸

Successful passive transfer of immunity can be defined as the timely ingestion and absorption of an adequate mass of colostral immunoglobulins (primarily IgG1 in calves), and possibly other colostral components as well. Successful passive transfer has been quantitatively defined as calves that have attained greater than 10 mg/mL serum IgG1 by 48 hours of age.¹⁴⁹ The levels of serum immunoglobulins defining successful passive transfer are simply guidelines derived from statistical analysis of large populations. Numerous factors interact with the level of passively acquired immunoglobulin to determine the occurrence of disease, including management, environment, hygiene, infection pressure, virulence of infectious organisms, and antibody specificity. Although neonates with FPT are at increased risk for disease, having low serum immunoglobulin does not necessarily guarantee disease if the neonate resides in a clean environment or does not interact with highly virulent organisms. Alternatively, neonates with adequate passive transfer can readily develop disease if exposed to an environment with a high pathogen load or highly virulent organisms.

■ **Mechanism of Passive Transfer.** Two distinct processes must occur for adequate passive transfer of maternal immunoglobulins through colostrum. The first process, *colostrumogenesis*, is the transport of immunoglobulin from maternal serum into colostrum during the last 4 to 6 weeks of gestation and is largely controlled by lactogenic hormones.¹⁵⁰⁻¹⁵² Studies in cattle have demonstrated that the mechanism of immunoglobulin transfer involves an active, IgG1-specific, receptor-mediated process.¹⁵³

The second process involves the transport of colostral IgG1 from the gut lumen into the neonate's system. This process is not selective for specific immunoglobulin isotypes and does not appear to differentiate between most macromolecules. Specific receptors for immunoglobulins are absent in the calf's gut; rather, transport occurs through nonselective pinocytosis. Absorption is initiated by the presence of macromolecules but declines over the first 24 hours of life¹⁵⁴; absorption is finite and decreases regardless of macromolecules being present.^{155,156} The absorptive process also appears to be saturable; efficiency of immunoglobulin absorption decreases with increasing immunoglobulin concentration in the colostrum being fed.¹⁵⁷ Presumably, because all macromolecules compete for the same absorptive process, the mass of immunoglobulin absorbed by the calf would be inversely proportional to the concentration of nonimmunoglobulin macromolecules present in the gut lumen.

■ **Epidemiology.** The percentage in calves with FPT at 24 hours of age varies from 15% to 68%.¹⁵⁸ Similar findings have been recorded in other neonatal ruminants. In one report comparing FPT in beef calves and dairy calves, rates

of 5% and 39% were reported, respectively.¹⁵⁹ Several interrelated factors account for the varying incidence of FPT, including the formation of colostrum with an adequate immunoglobulin concentration, ingestion of an adequate mass of immunoglobulin, and absorption of immunoglobulin in a timely manner.

Formation of Colostrum with Adequate IgG1 Concentration. The mass of immunoglobulin presented to the neonate for absorption depends on the colostral immunoglobulin concentration and volume of colostrum available. The volume of colostrum produced by the cow is usually not a limiting factor.¹⁶⁰ However, colostrums have varying immunoglobulin concentration; IgG1 concentration in beef cow colostrum is two to three times greater than that of dairy cow colostrum.¹⁶¹⁻¹⁶⁴ Significant differences exist not only among different breeds but also among cattle within a specific breed.¹⁶⁵ Lactation number also influences IgG1 concentration in colostrum, although this variation is less than between cows or breeds.

Colostrum with low immunoglobulin concentration, resulting in ingestion of an inadequate mass of immunoglobulin, is a primary cause of FPT in dairy calves.¹⁶¹ In contrast, FPT in beef calves is unlikely to result from low colostral IgG1 concentration.

Ingestion of Adequate Mass of IgG1. Depending on the environment and pathogen load to which they are exposed, calves must ingest an adequate mass of IgG1 to obtain protective immunity. Although the actual mass of immunoglobulin needed for protection depends on many factors, studies suggest that for a 45-kg calf to attain a serum IgG1 concentration greater than 10 mg/mL, it must consume approximately 100 g of IgG1 in the first hours of life.¹⁶⁶ Consumption of 100 g colostral IgG1 ultimately depends on colostral volume and IgG1 concentration. A calf provided colostrum with 35 mg/mL IgG1 would need to consume approximately 3 L in the first 12 to 24 hours, whereas a calf provided colostrum with 100 mg/mL IgG1 must consume only 1 L. An accepted recommendation for attaining adequate passive transfer in dairy calves is to administer 4 L of colostrum in the first 12 hours of life.¹⁶⁶

Concentration of colostral immunoglobulin is rarely a significant factor leading to FPT in beef calves. Instead, factors such as mis-mothering, poor udder conformation, and environmental stresses are more significant in preventing beef calves from ingesting the colostrum. Other factors that may affect passive transfer in beef calves have been reviewed.¹⁶⁷ There is little evidence to suggest a direct effect on passive transfer when beef cows are fed protein- or energy-restricted diets. Dystocia does not appear to affect passive transfer of immunoglobulins as long as the calf receives an appropriate mass of immunoglobulin in a timely manner.

Young age of the dam is a risk factor for FPT, likely because of lower colostral immunoglobulin concentration in heifer colostrum (beef and dairy) and poorer mothering ability.

Timely Absorption of IgG1 by Gut. Cessation of absorption of colostral immunoglobulins (closure) occurs at approximately 24 hours of age.^{154,168} If colostrum is completely withheld, closure will still occur by 30 hours of age.^{155,156} Closure is minimally affected by stresses such as dystocia or cold environmental temperatures, although extremely high environmental temperature has been associated with reduced immunoglobulin absorption in calves.^{154,169} In a study comparing three different feeding methods of colostrum to dairy calves, FPT was more prevalent with sucking than artificial feeding methods, presumably because of inadequate colostrum volumes ingested by calves.¹⁶⁶ That is,

dairy calves consuming relatively low IgG1 concentration colostrum did not consume adequate volumes of colostrum to obtain 100 g of IgG1 in a timely manner. When artificial feeding methods are used, inadequate immunoglobulin concentration in the colostrum is the most important factor resulting in FPT, even when calves are fed in a timely manner.

Mothing. Mothing has been associated with increased efficiency of absorption of colostrum immunoglobulins. This may simply be a result of the dam's presence or may be related to the effect of the neonate physically suckling the dam.¹⁵⁴

■ **Clinical Signs and Laboratory Findings.** Although not diagnosed by physical examination, FPT is typically suspected based on physical findings. Young ruminants devoid of passive immunity are highly susceptible to bacterial septicemia.^{158,170} Clinical signs of bacteremia include central nervous system (CNS) depression, weakness, injected scleral vessels, rapid or labored respiration, diarrhea, and anorexia. Fever may or may not be present. Septic arthritis, meningitis, and panophthalmitis frequently develop in many neonates with FPT that survive the initial challenge of bacteremia. Diarrhea can also result from a number of dietary and infectious agents in neonatal ruminants with normal serum immunoglobulin levels.¹⁷¹ Historical information of clinical disease may lead to a high degree of suspicion that FPT is present.

There are no consistent changes in the hemogram or biochemical panel of a neonatal ruminant with FPT. Abnormal laboratory findings usually reflect secondary processes involving sepsis, stress, or starvation. Laboratory evaluation is necessary to assess the degree of passive transfer.

■ **Measurement of Passive Transfer.** Several methods are available to measure passive transfer of immunity either directly or indirectly. The greatest degree of accuracy is obtained if the tests are performed during the first week of life, and most tests are optimized when serum samples are collected between 24 and 48 hours of age. After this period, neonates begin to synthesize significant amounts of immunoglobulins, although a tentative decision can still be made as to the degree of passive transfer that occurred after birth. Any question about the status of passive transfer in a newborn should trigger laboratory evaluation of the animal so that corrective measures can be undertaken.

Single radial immunodiffusion (RID) quantitatively measures serum IgG1 and is considered the standard in cattle. The semiquantitative methods for estimating passive transfer (zinc sulfate turbidity, sodium sulfite precipitation, glutaraldehyde coagulation, total serum solids) are based on the fact that IgG1 normally accounts for the majority of passively transferred proteins in colostrum. Measurement of serum γ -glutamyltransferase (GGT) is based on the findings that mammary secretory alveolar epithelial cells can secrete large amounts of GGT during colostrumogenesis and that GGT is readily absorbed by the neonate before gut closure.

Single Radial Immunodiffusion. Quantification of each immunoglobulin class that is transferred can be determined using specific, commercially available antisera. Forty-eight-hour serum concentrations of less than 1000, 80, and 22 mg/dL for IgG, IgM, and IgA, respectively, are consistent with FPT.¹⁶⁰

Zinc Sulfate Turbidity. Specific concentrations of zinc sulfate precipitate immunoglobulins.^{149,172} Historically, a defined volume of serum (0.1 mL) is added to zinc sulfate solution (6 mL) containing 208 mg of $ZnSO_4 \cdot 7H_2O$ per

liter, and the solution is allowed to incubate at room temperature for 1 hour. The turbidity of the solution is then evaluated visually or with spectrophotometric methods.¹⁴⁹ A decrease in or an absence of turbidity (precipitation) indicates failure of immunoglobulin absorption.

A study by Tyler et al.¹⁷³ suggests that the zinc sulfate test using a 208-mg/L solution has an inappropriately high endpoint, with a specificity of only 0.52. The poor predictive value of this method results in a significant misclassification of calves with adequate passive transfer as having FPT. A follow-up study suggests that higher zinc sulfate concentrations in the test solution provide a more accurate assessment of passive transfer. As zinc sulfate concentrations are increased from 200 to 400 mg/L, sensitivity decreases from 100 to 82.6, and specificity increases from 25.5 to 90.6, respectively. The concentration of zinc sulfate test solution chosen therefore depends on the goal of the test. Choosing a test solution with higher sensitivity (e.g., 250 mg/L zinc sulfate) is likely warranted when testing individual calves with high economic value. In herd-monitoring programs, however, the choice of a test solution with higher specificity (e.g., 350 to 400 mg/L zinc sulfate) will maximize the proportion of calves correctly classified.

Sodium Sulfite Precipitation. This test is similar to the zinc sulfate turbidity test and is also a precipitation test for immunoglobulins, primarily IgG1, with the results recorded visually.¹⁷⁴ The reagents are commercially available. * Historically, three concentrations of $Na_2SO_3^-$ anhydrous (14%, 16%, and 18%) are used in the test. Serum (0.1 mL) is added to each concentration of sodium sulfite (1.9 mL), and these are allowed to incubate for 1 hour. Turbidity in only the 18% sample indicates transfer of less than 500 mg/dL immunoglobulin, turbidity in both the 16% and the 18% sample indicates 500 to 1500 mg/dL of transfer, and turbidity in all samples indicates greater than 1500 mg/dL transfer.

Similar to the zinc sulfate turbidity assay, the endpoint for the sodium sulfite precipitation assay is likely set too high.¹⁷³ The preferred test endpoint appears to be a 1+ test result. A 1+ result equates to observing turbidity in the 18% test solution, with no turbidity in either the 16% or the 14% test solution. Tyler et al.¹⁷³ demonstrated the lowest serum IgG1 concentration (measured by RID) observed in calves with a 1+ test result was 645 mg/dL (range, 645 to 2450 mg/dL), indicating at least partial successful passive transfer of immunoglobulin. Therefore, it is recommended that the sodium sulfite test be used as a single-dilution assay procedure whereby calves with 1+ test results (precipitation in only the 18% test solution) are classified as having "adequate" passive transfer.

Glutaraldehyde Coagulation Test. This test is based on 10% glutaraldehyde reagent coagulating serum immunoglobulins in concentrations greater than 600 mg/dL. When performed on serum, the glutaraldehyde coagulation test is an accurate predictor of passive transfer status.¹⁷⁵⁻¹⁷⁸ However, if whole blood is used in a similar assay, the sensitivity and specificity of the assay are deemed to be inadequate for routine diagnostic use.¹⁷⁹

Refractometer (Total Serum Solids). Quantification of total serum solids as an indicator of passive transfer of immunity assumes that the increase in serum proteins over that of presuckle newborn ruminants is caused by the absorption of immunoglobulin.¹⁸⁰ In the absence of dehydration, serum protein concentration greater than 5.0 g/dL has historically

*Bova-S, VMRD, Pullman, WA; ICN Immunobiologicals, Lisle, IL; Bethyl Laboratories, Montgomery, TX.

been associated with successful passive transfer, and values less than 4.5 g/dL are consistent with FPT. Values between 4.5 and 5 g/dL are deemed questionable.

In a study of 242 calves, use of a 5.0-g/dL threshold resulted in a highly specific (0.96) but insensitive (0.59) test, whereas a 5.5-g/dL threshold resulted in a highly sensitive (0.94) but relatively nonspecific (0.76) test.¹⁷³ The choice of threshold (5.0 or 5.5 g/dL) depends on the prevalence of passive transfer in the herd being tested and the costs associated with false-positive and false-negative results. Using regression analysis to predict serum IgG1 concentration as a function of serum protein concentrations (with a goal of 10 mg/mL IgG1), the optimal threshold value for serum concentration is calculated to be 5.2 g/dL.¹⁷³

γ -Glutamyltransferase. GGT is present in colostrum at levels about 300 times higher than that normally found in serum. GGT is absorbed by the calf during the period of immunoglobulin absorption, and calf serum levels can be used as an indication of immunoglobulin absorption. Levels of GGT are maximal in the calf on the first or second day after birth.^{181,182} Parish et al.¹⁸³ used a regression formula to set age-adjusted thresholds for serum GGT activity in order to define passive transfer status in dairy calves.¹⁸³ Using serum IgG1 concentration of 10 mg/mL as an acceptable goal for passive transfer of immunoglobulins, calves at 1 day, 4 days, and 7 days of age should have serum GGT activities greater than 200, 100, and 75 IU/L, respectively. Calves in the first 2 weeks of life with serum GGT levels less than 50 IU/L can be classified as having FPT.

■ **Prevention.** The intake and absorption of adequate amounts of quality colostrum are key to the survivability of young ruminants. Documented natural sucking or force-feeding of colostrum in the first 6 hours of life helps to ensure adequate transfer. It is generally thought that a neonate should consume between 6% and 10% of its body weight as colostrum in the first 24 hours of life. Most calves consume approximately 2 L (40 to 50 mL/kg) of colostrum at the first feeding. In force-feeding practices, 2 L typically has been advocated as the proper amount for initial intake. However, the variance in colostrum quality suggests that a greater volume should be fed at the initial feeding.¹⁵⁴ As stated earlier, to attain adequate passive transfer in dairy calves, the current recommendation is to administer approximately 4 L of colostrum in the first 12 hours of life.¹⁶⁶ In herds or flocks where neonatal disease is a problem, levels of passive transfer should be determined, and force-feeding of all newborn animals should be instituted to ensure adequate transfer.

Whole-colostrum specific gravity can be reasonably measured with a colostrometer.¹⁸⁴ A specific gravity less than 1.050 is associated with colostrum that has low immunoglobulin concentration. This device can eliminate 50% of the low-immunoglobulin colostrums and predict high immunoglobulin concentrations.¹⁵⁴ At colostrum temperatures other than 20° C (68° F), less accuracy is achieved.¹⁸⁵ Colostrum should contain greater than 6000 mg/dL total immunoglobulin. To ensure that all neonates receive adequate amounts of colostrum, producers should be encouraged to maintain a bank of frozen colostrum. Colostrum from first milkings is preferred because immunoglobulin concentrations decrease with successive milkings.

Immunoglobulins are generally unaltered by freezing, and only small amounts are inactivated by thawing. Thawing frozen colostrum in warm water is quickly accomplished for individual calf feeding. Microwave ovens have been used to thaw frozen colostrum without adverse effects.¹⁸⁶

Pooling or mixing colostrum from several cows is a common practice to ensure adequate immunoglobulin concentrations. This practice is advocated to circumvent the problem of low-concentration colostrum from being fed. However, calves that receive pooled colostrum acquire substantially lower serum immunoglobulin levels than calves fed equivalent volumes of homologous colostrum from their own dam.¹⁶⁰ This appears to relate to the fact that colostrums used in pooling frequently come from cows with high volumes of colostrum that tend to have lower immunoglobulin levels.¹⁸⁷

Many commercially available colostrum substitutes can be used either to supplement available colostrum or to provide a source of immunoglobulins for calves when colostrum is not available. It is important to note the amount of immunoglobulin present in these products and administer enough product to ensure passive transfer. With some products, it may not be possible or practical to administer enough colostrum substitute to obtain 100 g IgG1. Furthermore, the antibody specificity of the immunoglobulins present in these products may be unknown.

Bovine colostrum is frequently used to supplement or replace homologous sources of colostrum in nonbovine ruminants. Neonatal lambs and kids are frequently supplemented in this way.^{188,189} The immunoglobulins are absorbed at rates similar to homologous colostrum. The half-life of bovine IgG1 in lambs is approximately 14 days,¹⁸⁹ which is similar to the 13.7 days reported for ovine IgG1 in lambs¹⁹⁰ (see Table 53-2). Occasionally, anemia has been reported in lambs and kids fed bovine colostrums as a result of immune complex attachment to erythrocytes, causing their removal from circulation.¹⁹¹⁻¹⁹³ The effectiveness of bovine or caprine colostrum in other species is unknown, but the practice appears to be widespread and has been used in a wild animal park successfully hand-raising neonatal exotic ruminants.

■ **Treatment.** FPT in an otherwise normal neonate can be treated with plasma administered at 20 to 40 mL/kg intravenously (or intraperitoneally if IV administration is not possible or practical). Whole blood can also be used, although the dose should be increased to account for the presence of RBCs. Similar approaches are indicated in animals with clinical disease, but the results are often less rewarding. Continued oral colostrum supplementation of neonates with FPT beyond the period of closure may also provide some local immune protection in the gut.¹⁶⁰ Some clinicians have advised oral supplementation with plasma after gut closure, but this practice is questionable in light of the cost of obtaining plasma, and plasma contains only about 15 mg/mL IgG1, significantly less than average colostrum.

LETHAL TRAIT A46

Lethal trait A46 is a primary immunodeficiency that is found in black, pied Danish cattle of Friesian descent.¹⁹⁴ It is an autosomal recessive trait in which the calves appear normal at birth but develop skin disease at 2 to 8 weeks of age. Skin lesions are characterized by exanthema, alopecia, and hyperparakeratosis, with initial lesions occurring around the head, neck, and flexor surfaces of the legs and later involving the entire animal. Death within 4 months is often associated with bronchopneumonia and diarrhea. These animals do respond normally to humoral antigens but show deficits in cellular immunity. At necropsy the calves show marked lymphoid regression involving the thymus, spleen, lymph nodes, and gut-associated lymphoid tissues in the thymic-dependent regions. The condition is responsive to oral zinc oxide therapy, which suggests an

underlying problem in zinc metabolism. Daily oral dosages of up to 1 g zinc oxide have been used to establish normal function.¹⁹⁴ The primary immunologic defect is found in T lymphocytes. Because of a defect in a recessive gene, these animals apparently have an unusually high metabolic requirement for zinc ions to sustain normal T-lymphocyte development and function.

SELECTIVE IgG2 DEFICIENCY

A primary IgG2 deficiency has been described in the red Danish milk breed of cattle involving a primary, partial to complete deficit in IgG2.^{195,196} These animals appear to be more susceptible to gangrenous mastitis and pyogenic infections such as bronchopneumonia, peritonitis, and abomasoenteritis.¹⁹⁷ A transient IgG2 deficiency has also been reported in neonatal lambs.¹⁹⁶ Lambs that ingested colostrum had delayed onset of IgG2 synthesis until 5 to 6 weeks of age, with no adverse consequences.

CHÉDIAK-HIGASHI SYNDROME

Chédiak-Higashi syndrome is an inherited disorder that affects neutrophil and monocyte function in Hereford cattle, mink, cats, mice, killer whales, and humans.^{198,199} Clinically, these patients are recognized by partial albinism that affects the skin and eyes, coagulation difficulties, and an increased susceptibility to bacterial infections. Large cytoplasmic granules are seen within neutrophils. The increased susceptibility to pyogenic infections is related to decreased neutrophil killing of ingested organisms caused by a defect in hexose monophosphate shunt activity and defective degranulation.

BOVINE LEUKOCYTE ADHESION DEFICIENCY

Bovine leukocyte adhesion deficiency (BLAD) is an autosomal recessive disorder of Holstein calves characterized clinically by chronic bacterial infections and premature death.²⁰⁰⁻²⁰² Leukocytes of affected calves lack surface glycoproteins, termed β -2 integrins. A mutation of the gene encoding bovine CD18 causes this disorder. The gene defect is termed the D128G allele mutation.

Heterozygous carriers are clinically normal; however bulls and cows with this mutation may produce homozygous calves that manifest the deficiency. All calves with BLAD can be traced to a single male ancestor that must be present in both the sire and dam pedigree. In the United States, approximately 14% of sires and almost 6% of Holstein calves are affected with BLAD.

Homozygous calves have chronic, recurrent bacterial infections. Consistent clinical findings include fever, bronchopneumonia, stomatitis, gingivitis, recurrent or chronic diarrhea, peripheral lymphadenopathy, vasculitis, and dermatitis.^{203,204} Calves appear normal at birth, but clinical signs are often present within the first few weeks of life. Affected calves usually die within the first year of life. Those surviving past 1 year of age have persistent ill-thrift. Hematologic abnormalities include mature neutrophilia ($>40,000/\mu\text{L}$) without significant left shifts, lymphocytosis, and monocytosis. Abnormal serum biochemical findings include hypoalbuminemia; hyperglobulinemia; and low serum creatinine, urea nitrogen, and glucose concentrations.

Diagnostic tests are available to detect heterozygous carriers and identify homozygous affected calves. Information regarding testing is available from the Holstein Association of America, Brattleboro, VT.

VIRAL- AND BACTERIAL-INDUCED IMMUNODEFICIENCY

Decreased function of B and T lymphocytes has been associated with bovine viral diarrhea (BVD) infection in calves developing chronic BVD syndrome.²⁰⁵ Depression of cellular, but not humoral, immunity is seen in cattle infected with Johne's disease (*Mycobacterium avium* subsp. *paratuberculosis*), with failure to develop or delayed-type hypersensitivity (DTH) reactions in vivo and in vitro.²⁰⁶ It is associated with a humoral-suppressive factor.

COMBINED IMMUNODEFICIENCY

Genetic failure of development of both T and B cell lines results in a severely compromised, immunodeficient animal. As passively acquired maternal antibody wanes, infections tend to develop. One possible case of combined immunodeficiency was reported in a 6-week-old Angus calf that had an absence of serum IgM, low serum IgG, absolute lymphopenia, and an absence of lymphoid tissue at necropsy. The calf died of bronchopneumonia and disseminated fungal infection.²⁰⁷

PREGNANCY-ASSOCIATED IMMUNODEFICIENCY

JAMES F. EVERMANN

The areas of immunology pertaining to pregnancy, fetal survival, and postpartum periods have continued to expand over the past decade.^{208,209} Additional input from the fields of epidemiology and evidence-based medicine has increased our understanding of the delicate balance that occurs at the maternal-fetal interface.²¹⁰ In its broadest context, the immune system of the pregnant animal becomes compromised as the fetus matures.²¹¹ Although transitory, this immunodeficient state also apparently extends into the postpartum period for up to 4 weeks.²¹²

Mechanisms

The cellular mechanisms responsible for the immunosuppression during pregnancy and postpartum involve (1) a shift of T-helper (Th) cells from a Th1 to a Th2 response and (2) a decrease in neutrophil functions.^{213,214} The T-cell populations are affected by progesterone, prostaglandin $F_{2\alpha}$, and α -fetoprotein.²¹¹ The Th1 cells are important effectors of the cell-mediated immune (CMI) response and interact with T-cytotoxic (Tc) cells. Tc cells are the main defense against foreign antigens, which include viral, intracellular bacterial, and protozoal pathogens. With the onset of pregnancy, the hormonal factors cause macrophages to release predominantly Th2-stimulating cytokines, which contribute to the overall dominance of humoral immunity during pregnancy and immediately postpartum. This phenomenon of the Th-cell populations is referred to as the "Th1-Th2 shift of pregnancy" and is generally regarded as a contributing factor to maternal tolerance of the fetus by suppressing the antifetal CMI response.²⁰⁹

The second key cell population affected during pregnancy and postpartum is the neutrophil.²¹² The point of maximum immunosuppression occurs when glucocorticoid levels are acutely elevated in the periparturient cow.²¹⁵ Neutrophil dysfunction, as well as the effects on the Th-cell population, is considered temporary during this period. Nonetheless, with impaired neutrophil response, the animal is then vulnerable to increased bacterial infections because of compromised bactericidal functions.²¹²

Outcome

This temporary immunodeficiency allows for fetal survival but may also result in an increased susceptibility to exterior environmental infection with viruses, bacteria, and fungi. Intracellular infections, such as with viruses and protozoans, which may have been acquired early during postnatal development, may become exacerbated during pregnancy because of the suppressive effects on the Th1 cells.²¹¹ This results in a decreased CMI response. The CMI effector cells (Tc cells) function normally to control virtually all the viral infections, such as infectious bovine rhinotracheitis virus and BVD virus.^{211,216} Intracellular bacterial infections, such as *Brucella abortus*, become more pathogenic during pregnancy. In addition to the effects on T-cell functions, macrophage function is also compromised, allowing for opportunistic bacteria and *Chlamydia* species (usually confined to external mucosal surfaces) to become systemic. Concurrent with the immunosuppression that accompanies pregnancy, there is an increased shedding of infectious microorganisms²¹¹ (Figure 53-5). This is considered to be an extension of impaired Tc-cell function. Although the pregnant animal may appear clinically normal, her altered immune response results in an increased shedding of gastrointestinal (GI) viruses such as coronavirus and rotavirus^{211,217} and bacteria (*Mycobacterium avium* subsp. *paratuberculosis*, *Escherichia coli*), usually during the periparturient period.^{218,219} This increased shedding of infectious microorganisms is an important factor in the management of animals through this period. The suppression of neutrophil functions during later stages of pregnancy and immediately postpartum are the subject of active investigation.^{215,220}

The reduced neutrophil function and its association with periparturient immune suppression are significant problems, especially for the transition dairy cow.²¹⁵ This immunosuppression is directly associated with increased postpartum metritis and increased susceptibility to mastitis. As noted with the immunosuppression during pregnancy, this periparturient stage can be aggravated by both preexisting infections (e.g., bovine herpesvirus type 4)²²¹ and environmental bacterial pathogens (e.g., *Staphylococcus aureus*, *Klebsiella* species).²²²

Management

Although the immunosuppressive periods during pregnancy and up to 4 weeks postpartum are well recognized, current understanding of the cellular processes is still

FIG. 53-5 ■ Proposed relationships among shedding of infectious microorganisms during periods of nonpregnant, pregnant, postpartum, and relative immune competence. (Modified from Evermann JF: Immunology of bovine pregnancy: vulnerability to infectious disease, *Bovine Proc* 26:101, 1994.)

somewhat rudimentary. However, clinicians and owners can proceed with control measures that accomplish two primary goals: maximize reproductive performance and ensure successful neonatal survival.^{210,223,224} Over the years, we have emphasized the importance of effective vaccination programs before breeding, clean birthing areas, and good hygiene for the lactating animal.^{210,222} These measures, in conjunction with good colostrum management, allow owners to compensate for the temporary immunosuppressive states encountered during and immediately after pregnancy.

DISEASES CAUSED BY ALLOGENEIC INCOMPATIBILITIES

JILL JOHNSON

STEVEN M. PARISH

The surfaces of cells are covered with molecular structures, the presence or absence of which is determined by genes. Some of these molecules have limited heterogeneity within a species, and all members of the species share identical forms (monomorphic). In other cases a spectrum of minor structural variations or polymorphisms of a particular molecule occur within the population, so that some members of the species will have one form of the molecule, whereas others will have another. If the structural variations are such that the immune system of one individual can recognize the differences in the molecules from another individual, these are known as *alloantigens*. Antibodies produced against these antigens are *alloantibodies*. Examples of alloantigens include red blood cell (RBC, erythrocyte) antigens and lymphocyte antigens.

In nature, because few situations arise in which tissues are exchanged, there are relatively few naturally occurring diseases that involve allogeneic incompatibilities. Neonatal isoerythrolysis (NI) and neonatal alloimmune thrombocytopenia (NAIT) are two examples of such naturally occurring diseases. Blood transfusion reactions and organ transplant rejection are examples of iatrogenic diseases associated with allogeneic incompatibilities.

The same alloantibodies that mediate disease are also useful in vitro as reagents to detect the presence of alloantigens and serve as the basis for blood typing.

BLOOD TYPING AND DNA PROFILING

The blood type of an individual is actually a composite list of genetic markers that have been detected in the individual's blood. Several types of genetic markers have been used in blood typing, including RBC alloantigens, electrophoretic markers, and lymphocyte alloantigens. Polymorphisms of the DNA itself have emerged as useful genetic markers and have essentially replaced other genetic tests for parentage verification.

Red Blood Cell Antigens

Seven independent RBC groups or systems have been internationally defined in horses under the auspices of the International Society for Animal Genetics²²⁵⁻²²⁸ (Tables 53-3 and 53-4). These systems are named A, C, D, K, P, Q, and U. Additional systems are recognized by individual laboratories. Each system corresponds to a particular gene for which two or more alleles exist. Some blood groups are relatively simple and contain only two alleles, whereas other systems may have over two dozen different alleles.

*Most common factors involved in neonatal isoerythrolysis (NI).

†Previously reported to cause NI in at least one case.

The blood group genes produce surface molecules that contain antigenic sites known as *factors*. More than 30 different factors have been identified. Each factor is associated with only one system, although the same factor may be associated with more than one allele within the system. The factors are named with an uppercase letter to denote the system and a lowercase letter to designate the factor within that system. Groups of factors that are produced by a single allele are called *phenogroups*.

The presence of RBC antigens is detected primarily by either agglutination or complement-mediated lysis of test cells by antibodies directed against specific erythrocyte alloantigens. Antigens in some systems are detected with antiglobulin tests.

Eleven blood groups have been identified in cattle²²⁹ (Table 53-5); groups B and J have the greatest clinical relevance. The B system is a very complex system, with more than 60 different antigens.²³⁰ This complexity has been used to advantage for individual animal identification and parentage studies in the past, but it makes it difficult to match donor and recipient blood for transfusions.

The J antigen is a lipid that is found in body fluid and that is adsorbed to erythrocytes; thus it is not a true erythrocyte antigen. Newborn calves do not have this antigen but

usually acquire it during the first 6 months of life. After acquiring it, some groups of cattle have high amounts of J antigen both in the serum and adsorbed to erythrocytes, whereas other groups have very small amounts found only on RBCs. These latter groups, often referred to as J-negative, may actually have anti-J antibodies and develop transfusion reactions when transfused with blood from J-positive donors.²²⁵

Seven blood groups have been identified in sheep (see Table 53-3). The B system is analogous to the B system in cattle and is extremely polymorphic, with more than 52 different alleles. The R system is similar to the J system in cattle in that the antigens are soluble and are passively adsorbed to erythrocytes.²²⁹ The M-L system is involved in the genetically determined RBC potassium polymorphism found in sheep.²³¹

Blood groups of goats appear to be very similar to those of sheep, and many of the reagents used for typing sheep blood have been used to type goats' blood. Reagents used to detect antigens of the J system of cattle have been used to detect differences in a similar system in goats.²³²

The biologic function of red blood cell antigens is not known for any system in any species with the exception of the M-L blood group system in sheep, which is involved in active potassium transport across red blood cell membranes.

Electrophoretic Markers

Many plasma and intracellular proteins have polymorphic forms. These variants have subtle biochemical differences, which for the most part do not alter the major characteristics of the molecules, but which can be detected using electrophoretic methods. Technically, these are not alloantigens because the differences are not detected immunologically. The various forms of the molecules are detected on the basis of their different rates of migration in electrophoresis. The specific form(s) of any particular protein that an individual possesses are determined genetically, and those used in blood typing are usually expressed co-dominantly. Currently, no diseases are clearly associated with the presence or absence of particular alleles of polymorphic proteins; however, they are useful genetic markers for identification and parentage studies and were typically included in the blood type^{227,232-234} (Table 53-6). Electrophoretic markers

were used extensively in horses because RBC antigens did not provide the same degree of discrimination among individuals in this species as they do, for example, in cattle. The current application is limited to legacy parentage verification when parental DNA is not available for testing.

Lymphocyte Antigens

Three systems of equine lymphocyte alloantigens have been described: ELA, ELY 1, and ELY 2.²³⁵⁻²³⁹ ELA is the major histocompatibility complex (MHC) of the horse. ELA is a complex system that includes several genes, each of which is polymorphic (e.g., has many different alleles). Because the MHC regulates the interactions of many cells in the immune response, disease susceptibility or resistance could be associated with ELA. An association between a particular ELA allele and equine sarcoid has been described.^{240,241} ELY 1 and ELY 2 have limited polymorphism and appear to be two allele systems.

The MHC of cattle is called BoLA, for bovine lymphocyte antigen. In sheep the MHC is called OLA, for ovine lymphocyte antigen, and is also known as SH-LA. In goats the comparable system is GLA.²⁴²

DNA POLYMORPHISMS

A variety of approaches have been developed for detecting genetic variation using DNA. Certainly, DNA sequencing is the most sensitive approach; however, this remains too costly for routine testing outside of research laboratories. Other approaches have been developed to detect DNA variants. Genetic variation of DNA can be detected among individuals on the basis of differences in length for a section of DNA or even for differences in base composition at specific sites. DNA length variants are usually referred to as minisatellite or microsatellite markers. *Minisatellite* DNA markers are based on sequences, often 15 to 100 bases long, that may be repeated hundreds of times on a chromosome. The number of repetitions can vary dramatically between individuals and can be readily detectable in Southern blot assays. These tests were originally referred to as "DNA fingerprinting." Although powerful, these tests are costly and time-consuming.

More recently, another type of DNA length variant has been discovered. *Microsatellite* DNA markers are short

repetitions of nucleotides, usually ranging from one to nine bases long, which may be repeated 15 to 40 times. As with minisatellites, the number of repetitions may vary between chromosomes. The development of the polymerase chain reaction (PCR) has opened the door to easy, inexpensive detection of microsatellite and other types of markers. PCR is a method for amplifying short (<3000 bases) pieces of DNA, allowing a particular gene to be easily studied. The amplification products can be separated by electrophoresis and length variants readily detected. More than 100,000 of these markers are thought to exist in each species. These markers form an important core for development of genetic maps in diverse species. The markers currently form the basis for most parentage analysis.

Variation recognizable as a change in a single base of DNA is more subtle but can be detected through a variety of techniques. DNA sequence variation is often detectable using *restriction enzymes*, which are isolated from bacteria and will cleave DNA when the sequence is specific for the enzyme. For example, the method to detect the gene defect causing hyperkalemic periodic paralysis (HYPP) in horses is based on PCR amplification of the gene and then detection of sequence differences that occur between the normal and mutant gene using restriction enzyme digestion of the DNA. Other approaches to identifying DNA sequence differences include single-strand conformational polymorphism (SSCP), allele-specific PCR amplification, and ligase chain reaction.

Testing based on DNA has essentially replaced blood typing for purposes of parentage analysis. Furthermore, DNA-based techniques are also being used to develop gene maps for many species of domestic animals. These gene maps can be used to identify genes that play a role in performance, production, and disease.

BLOOD-TYPING AND DNA-GENOTYPING APPLICATIONS

To determine an animal's blood type or DNA genotype, a battery of tests are run on the blood or tissue to check for the presence or absence of each recognized allele in each of several genetic systems. Each system is controlled by a separate autosomal gene. These genes are inherited independently of one another.^{228,239} Most genetic markers used in blood typing are expressed co-dominantly, which means that the alleles on both chromosomes are expressed. This often allows determination of *genotype* (the actual genes present) from the *phenotype* (the antigens actually detected). Some systems have *null alleles* (with no detectable products) that do not directly allow inference of genotype (e.g., C, K, and U blood group systems in horses). An individual can have only two of the possible different alleles for any given gene (one on each chromosome of a pair).

Blood typing based on RBC antigens and electrophoretic markers has been used for animal identification and pedigree analysis, but currently, RBC typing is used primarily for prediction of potential for NI and crossmatching for blood transfusion.

The use of genetic markers for parentage verification is based on exclusion (i.e., markers are tested until a discrepancy is found). If no discrepancy is observed after a statistically acceptable amount of testing, the probability of a match is determined.

Because genetic testing is a composite mosaic of a large number of different, largely independent genetic markers, the odds of two individuals sharing exactly the same pattern of markers, whether RBC antigens, electrophoretic markers, or DNA polymorphisms, is remote. Thus, once an animal's genetic type is on record, it can be a powerful identifier of

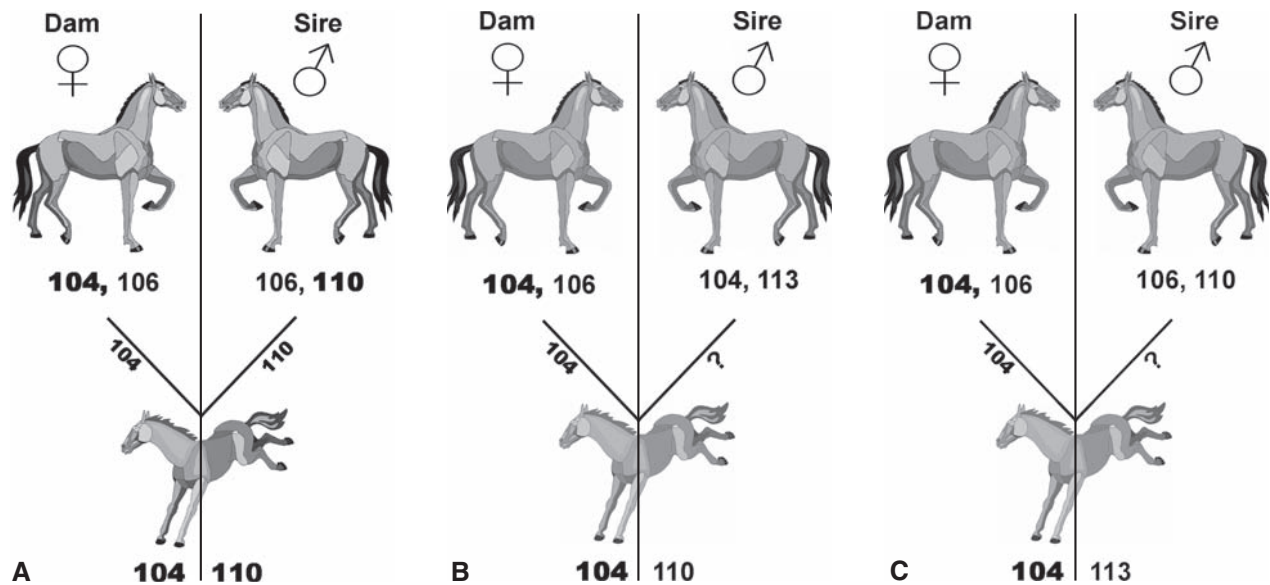

FIG. 53-6 ■ A, The sire of this foal cannot be excluded as the sire of the foal based on the results for DNA marker VHL20. B, The sire of this foal is excluded by a type I exclusion. The foal possesses an allele for the DNA marker VHL20 not present on either parent. Assuming that the dam of the foal is known to be correct and therefore would have contributed the 104 allele to the foal, the sire must be incorrectly stated. C, The sire of this foal is excluded by type I and type II exclusion. The foal possesses an allele not present on either parent and also does not possess either allele expressed by the putative sire.

an individual animal. In this sense it is an unalterable form of identification that is present from birth to death.

Because the presence or absence of markers is genetically determined and because the markers contributed by both parents are expressed in a co-dominant fashion (unless "blank" alleles exist), these markers can be used to support or refute parentage claims. Blood typing and DNA profiling cannot prove that one horse is the parent of another; however, in certain cases it can exclude with certainty a stated parent as the true parent. Two types of parentage exclusions can occur, type I and type II²⁴³ (Fig. 53-6). With type I the foal possesses a dominant or co-dominant marker that is not present in either parent. This means that at least one of the stated parents is incorrect. If one parent (usually the dam) is known with certainty on the basis of circumstances other than genetic type, the error lies with the other stated parent. With type II exclusions, the foal does not possess either of the dominant or co-dominant markers of a stated parent. Because a foal must inherit one of the two markers expressed by each parent, exclusion can be made if neither of the two markers present on the stated parent is detected in the foal. In parentage cases, each genetic system is evaluated for type I and type II exclusions. A parent can be excluded on the basis of an inconsistency in even one system. For this reason, the more systems used, the better genetic typing becomes as a tool for solution of parentage disputes. The calculated effectiveness of blood typing for detecting incorrect paternity using 20 internationally defined systems in horses is as high as 96%.^{227,233,244} With DNA genotyping, effectiveness is as high as 99.998%.²⁴⁵⁻²⁴⁷

Box 53-1 lists laboratories in North America that provide DNA genotyping.

NEONATAL ISOERYTHROLYSIS

Equine

■ **Definition and Etiology.** Neonatal isoerythrolysis (NI) is a condition characterized by the destruction of RBCs in the circulation of a foal by alloantibodies of maternal origin absorbed from colostrum.^{226,248,249}

Production of alloantibodies can be stimulated in mares several ways, including transfusion, exposure to blood from

the foal during parturition, or as a result of placental pathology during gestation. Incompatibilities of at least some blood groups between the dam and foal are the rule rather than the exception, and yet the incidence of sensitization of the dam and occurrence of NI is relatively low. In thoroughbreds the prevalence is about 1% and in standardbreds about 2%.²⁵⁰ The prevalence in mules (donkey sire, horse dam) has been reported to be as high as 10%.²²⁶ Most blood groups are not strongly antigenic under the conditions of exposure through previous parturition or placental leakage. Several blood group factors, however, are particularly immunogenic, and antibodies against these antigens have been reported to cause almost all cases of NI. These include factor Aa in the A system and factor Qa in the Q system. In mules a unique donkey RBC antigen named *donkey factor* has been associated with NI.²⁵¹ Antibodies to these antigens develop after the exposure of the mare to RBCs and are not naturally occurring antibodies. In humans the absence of certain RBC antigens results in the production of natural antibodies against that antigen, presumably because of exposure to cross-reacting antigens in the diet. This does not occur in horses (with a few exceptions) and has not been associated with NI. Ca-negative (Ca-) horses frequently make anti-Ca antibody of low titer without known RBC exposure. However, anti-Ca antibody is generally not associated with NI, and mares with anti-Ca antibody actually appear less likely to develop certain antibodies responsible for NI.

For NI to occur, several conditions must be present (Figs. 53-7 and 53-8). First, the dam must be negative for the antigen in question. Because most cases of NI in horses are associated with either anti-Aa or anti-Qa antibodies, mares that are Aa- or Qa- or both are considered at risk. All horses appear to lack donkey factor; thus all mule pregnancies are considered at risk. Second, the mare must become sensitized and produce antibody to the offending antigen. Sensitization can result from exposure during a previous pregnancy, blood transfusion, or transplacental contamination with fetal RBCs earlier in the current pregnancy (rare). Third, the foal from the current pregnancy must have inherited from its sire the antigen(s) to which the mare has been sensitized. When these conditions are met, there is a significant potential that maternal antibody directed against the foal's RBC antigens will appear in the

colostrum and, if subsequently ingested and absorbed by the foal, could cause loss of RBCs. The higher the anti-RBC titer is at foaling, the higher the risk. The highest titers are likely to be produced in a previously sensitized mare that is reexposed to the same RBC antigens shortly before parturition.

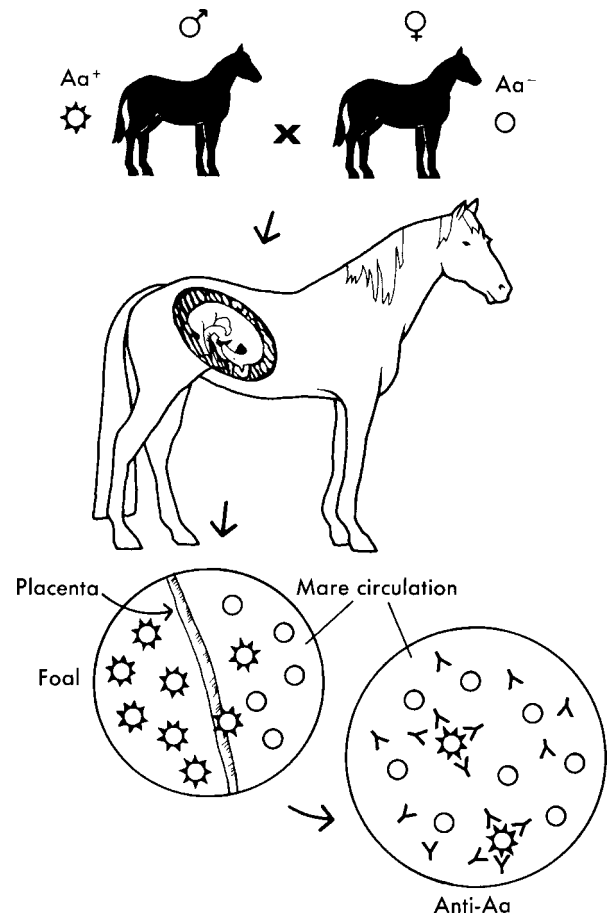

FIG. 53-7 ■ Entrance of RBCs of paternal antigen type into maternal circulation stimulates the production of alloantibody in the mare's serum.

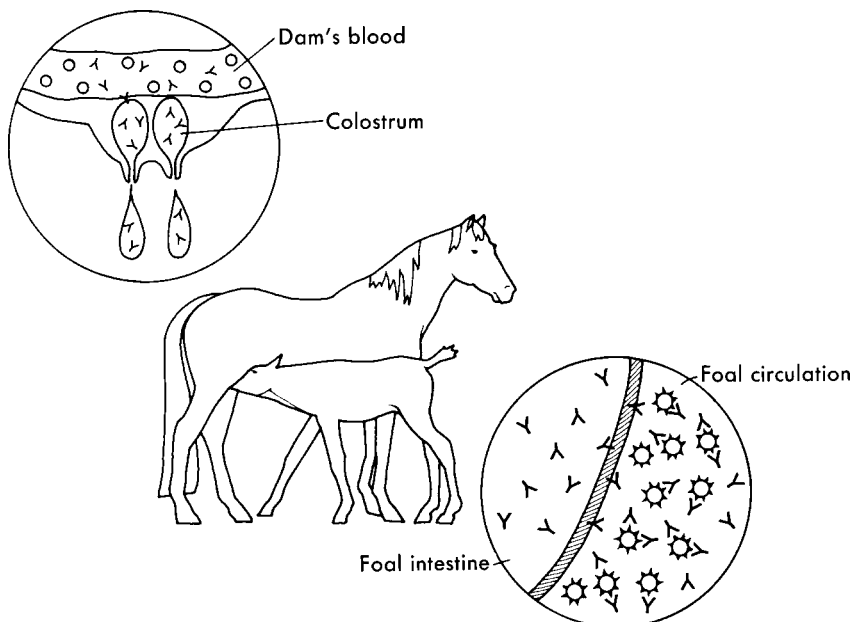

FIG. 53-8 ■ Alloantibody in the mare's serum is concentrated in colostrum at the end of gestation. Through passive transfer, the foal absorbs immunoglobulins, including these alloantibodies. The antibodies attach to RBCs and cause either their premature removal from circulation or intravascular lysis.

■ **Clinical Signs and Differential Diagnoses.** Foals are born healthy and usually begin to develop signs of NI at 24 to 36 hours of age, after suckling. Progressive lethargy and weakness are early signs. In acute cases, mucous membranes show initial pallor that is followed by icterus. In severe cases, hemoglobinemia and hemoglobinuria may be pronounced. In peracute cases, death may precede the development of icterus. Breathing becomes rapid and shallow, followed by labored breathing as the disease progresses. The foals may yawn repeatedly. Heart rate is elevated. Seizure-like activity may occur as the anemia becomes more severe.

■ **Clinical Pathology.** Affected foals are anemic. All indicators of RBC concentration (packed cell volume [PCV], hemoglobin, RBC count) show significant decreases. PCV values often decline to between 10% and 20%, and values as low as 5% have been observed. Hemoglobinemia and hemoglobinuria may be present. Bilirubin (mainly unconjugated) levels will be increased as a result of accelerated RBC destruction. Total bilirubin levels may be close to 20 mg/dL in severe cases. Affected foals, especially mule foals, may also be thrombocytopenic.²²⁸

Demonstration of significant amounts of antibody in the colostrum (or serum from the mare) that are directed against the RBC antigens expressed by the foal provides a definitive diagnosis of NI. These antibodies are most often demonstrated by lytic and agglutinating tests. Lytic tests are believed to be more reliable indicators of the presence of offending antibody.²⁵² The presence of antibodies attached to the foal's RBCs can also be demonstrated with a direct antiglobulin test (Coombs' test). The presence of antibodies in the mare's serum that attach to RBCs can be demonstrated with an indirect antiglobulin test.²²⁶

■ **Pathophysiology.** In mares sensitized to RBC antigens, most often Aa or Qa, alloantibodies are concentrated in the colostrum late in gestation. These antibodies are passed to the foal through passive transfer. If the foal's RBCs carry the antigen that the antibody recognizes, the cells become antibody coated. Subsequently, they are removed prematurely by the reticuloendothelial system or lysed intravascularly by complement. A distinction has been made between antibodies that are lysins as opposed to agglutinins; however, this distinction is based on in vitro testing and may be somewhat artificial. Under appropriate laboratory conditions, offending antibodies may exhibit both abilities.²⁵⁰ However, with conventional agglutination tests, some alloantibodies capable of producing NI may go undetected.²³⁴

■ **Epidemiology.** The percentages of mares at risk for sensitization against the common offending antigens (Aa and Qa) vary among breeds, depending on the frequency in the population of each gene involved (Table 53-7). Increased numbers of mares at risk in a breed does not necessarily translate into higher numbers of NI cases. A corresponding number of stallions lack the factors in question and are therefore unable to sire foals with the offending antigen.²⁴⁹ Virtually all mule pregnancies are incompatible with regard to donkey factor.²⁵¹

Although more common in multiparous mares, NI can occur with the first pregnancy.

■ **Necropsy Findings.** Pale tissues with or without icterus and splenomegaly are characteristic necropsy findings in foals dying of NI. Lesions associated with RBC destruction

TABLE 53-7

Estimated Percentage of Mares in Selected Breeds "At Risk" for Producing Foal with Neonatal Isoerythrolysis*

Breed	At Risk for Aa	At Risk for Qa
Thoroughbred	2%	16%
Standardbred, pacer	22%	†
Standardbred, trotter	3%	†
Saddlebred	25%	88%
Quarter horse	25%	68%
Arabian	3%	72%

Data from Bailey E, Conboy HS, McCarthy PF: Neonatal isoerythrolysis of foals: an update on testing, *Proc Am Assoc Equine Pract* 33:341, 1987.

*Based on the lack of all alleles, including factors Aa or Qa.

†All mares lack factor Qa and are technically "at risk," but all stallions in this breed also lack the factor.

and anemia, such as nephrosis and centrilobular hepatic necrosis, may also be present.

■ **Treatment and Prognosis.** In most cases, by the time NI is recognized clinically (e.g., when the foal is about 24 hours of age), the bulk of colostrum antibody will have been depleted from the mare's milk, and the absorptive ability of the foal's gut will have diminished. Withholding milk at this point is of questionable benefit.

Stress should be minimized and exercise restricted. Affected foals have decreased exercise tolerance and can collapse and die if forced to follow their dams. Generalized supportive care should be administered as indicated by clinical parameters. Intravenous fluids are frequently indicated to promote diuresis to minimize the effects of the large hemoglobin load presented to the kidneys. Acid-base balance should be monitored and corrected if indicated.

If the anemia becomes severe (e.g., PCV of 10% to 15%), transfusions that provide RBCs should be considered. Unless the PCV drops below this level, transfusion may not be necessary if rest is enforced. The object of transfusion is to provide the affected foal with RBCs that will not be destroyed by the maternal alloantibodies that were absorbed from colostrum. The foal is immunologically naive and will not have autologous alloantibody directed against any RBCs that would have an immediate effect on transfused RBCs. Thus the key is to select an RBC donor whose cells will not be destroyed by the maternal antibody derived from colostrum. Crossmatching, with particular attention to the reaction of mare sera, colostrum, and foal sera (all contain the same antibody), with the donor RBCs, is important for selecting a cell that will not be destroyed by the maternal antibody.

Washed RBCs from the dam are obviously the perfect choice in terms of cells that will not react with the alloantibodies present in the foal. However, to avoid administering additional harmful antibody to the foal, the mare's sera (containing antibody against the foal's cells) must be removed by washing before administration. Up to 6 to 8 L of blood can be collected from the mare and anticoagulated with acid-citrate-dextrose (ACD) or sodium citrate (3.8% Na citrate solution; 1 part Na citrate/9 parts blood), although 3 to 4 L usually provides sufficient RBCs. The preparation of large volumes of washed cells is aided by a large-volume centrifuge, but the procedure can be accomplished by serial sedimentations. Anticoagulated blood from the mare is allowed to settle for 1 to 2 hours. The plasma is aseptically drawn off; a similar or greater volume of sterile isotonic saline (0.9% Na citrate) is added to the RBCs and mixed; and the RBCs are again allowed to settle. The saline is then drawn off and discarded. At this

point, the RBCs can be resuspended in an equal volume of isotonic saline for administration, or the washing procedure can be repeated. The sedimentation method is less desirable than centrifugation because it is slower and does not remove as much of the offending antibody. The aim is to dilute any harmful antibody to insignificant levels.

If the dam's RBCs cannot be used, alternative donors can be selected. The donor should lack the antigen to which the alloantibody is directed. Because it is generally not possible to blood-type donors on short notice, a previously identified horse that has been determined by blood typing to be Aa⁻, Qa⁻, and free of alloantibody is a good choice for donor, based on most cases of NI being associated with these two antigens. The odds of randomly selecting a donor that lacks the offending type (e.g., Aa⁻, Qa⁻, or both) and would therefore be a suitable donor vary significantly with the breed and would mirror the percentage of the population of mares at risk. For example, the odds of finding an Aa⁻ thoroughbred to serve as an RBC donor would be about 1 in 50 (2%), whereas in quarter horses the odds would be about one in four (25%) (see Table 53-7). The sire of the foal is not the donor of choice. He shares the same RBC antigens as the foal, and his cells would react with the maternal alloantibody present, adding more of a load to the foal's reticuloendothelial system as the cells are destroyed.

With mules the same considerations in the use of washed cells would be necessary if the dam's cells were used. However, because the offending antibody is generally directed against a unique donkey antigen, RBCs from any horse apparently would be satisfactory. Horses do not appear to make naturally occurring antibodies against donkey factor; therefore, in most cases it is not necessary to wash the cells from horses that would not be likely to have been immunized by pregnancy against donkey factor.

Transfusing RBCs that will not react with maternal alloantibody means introducing an obviously incompatible cell into the foal, a cell that will probably not survive long in the circulation. Such transfusions should be considered temporary stopgap measures. Transfused cells may also sensitize the foal to future transfusions, causing reactions (perhaps not within hours or a few days, but potentially within a week). This must be considered when weighing the potential good versus potential harm of such transfusions.

From 1 to 4 L of washed RBCs or whole blood is usually adequate to produce clinical improvement, although some cases may require repeated transfusion if the anemia progresses. Exchange transfusions can be done whereby blood is administered through one jugular vein and withdrawn simultaneously from the opposite jugular vein and discarded, allowing administration of large volumes of blood without overloading the vascular system. There is no good evidence to suggest that this is more effective than simply providing a source of RBCs that are unaffected by the maternal antibody.

Limited transfusion studies in adult horses have suggested that transfused RBCs do not survive long in circulation (e.g., 2 to 4 days), whereas in foals, cells survived slightly longer (e.g., 4 to 6 days).^{253,254} PCVs in foals with NI usually increase after transfusion and then gradually decline. This decline is probably not a concern if it is gradual, because the PCV of the foal generally levels off as the offending maternal antibody is metabolized. However, even short-term survival of cells may be of benefit in severely affected foals and may allow them to survive until the titer of maternal anti-RBC immunoglobulin has declined in the circulation.

The prognosis varies, depending on the quantity of antibody ingested, the rapidity of onset of signs, and the degree of anemia. Foals with peracute NI may die before the problem is recognized, with no chance for administration of therapy. Foals that develop the condition more slowly

may respond to supportive care or transfusion if the PCV continues to fall.

■ **Prevention and Control.** Several strategies are available for prevention of NI.^{255,256} First, identify broodmares at risk for development of NI by testing them for the presence of Aa and Qa. Mares negative for either antigen, which means they could potentially make antibodies against them, should be considered at risk. One subsequent strategy would be to breed at-risk mares to Aa/Qa-negative stallions, thus eliminating the possibility of the foal inheriting the offending antigens. However, in breeds in which a relatively small part of the population is negative for these antigens, identifying a stallion that is negative for these antigens and suitable on the basis of other criteria may be difficult. The percentage of at-risk females based on the presence or absence of Aa or Qa is somewhat balanced by the numbers of males able to transmit the offending antigen. For example, all standardbred mares would be considered at risk based on the absence of Qa; however, because the antigen Qa is not present in the standardbred population, no stallions have the Qa antigen to pass on to foals.

In the circumstance of an unknown or incompatible matings, sera from at-risk mares should be screened for the presence of anti-RBC antibodies within 30 days before foaling. This can be done by submitting a serum sample and an anticoagulated sample to a screening laboratory. A panel of 10 to 12 different RBCs selected to represent all major blood groups is adequate to screen for anti-RBC antibody in the absence of blood from the sire. If results of serum testing are equivocal (e.g., low but positive titer, especially if there is anti-Aa or anti-Qa activity), the test should be repeated closer to the time of parturition because the levels of offending antibody can rise very quickly late in gestation.

If anti-RBC antibody is detected in the mare before parturition, the colostrum should be checked for reactivity against the foal's RBCs before allowing the foal to ingest colostrum. An alternative source of colostrum should be provided to the foal. Most field screening tests of colostrum have not proved to be satisfactory for practical use; however, the jaundiced foal agglutination (JFA) test described in Box 53-2 has been shown to correlate well with the standard hemolytic assay, and it may detect antibody that does not react on the standard agglutination tests.^{257,258}

Horses negative for Ca frequently make anti-Ca antibody; however, this antibody is not known to produce adverse effects in the foal. It has clouded the issue of field screening tests for NI because it causes positive reactions in most screening tests at low dilutions. Because these tests do not differentiate between antibody to Aa, Qa, Ca, or any other blood group, anti-Ca antibody, when present in low dilutions, is responsible for many false-positive reactions. This antibody actually appears to play a protective role in the prevention of sensitization of mares to NI through a mechanism of antibody-mediated immune suppression. Aa⁻/Qa⁻ mares that are also Ca⁻ (and thus often produce anti-Ca antibody) become sensitized to Aa and Qa at a significantly lower rate than mares that are Ca⁺.²⁵⁹ This is attributed to anti-Ca antibody being produced by Ca⁻ mares. The anti-Ca antibody may more rapidly remove potentially sensitizing cells from the circulation before they stimulate production of antibody against Aa or Qa.

Other antigens infrequently have been associated with NI in foals. These include factors Db, Dc, Dg, Ua, Pa, Qc, and Ab.^{226,228,260-263} Two other factors, R and S, have been described to be associated with NI, but they are not detected by routine hemolytic or agglutinating methods and are only detected using an antiglobulin test (direct Coombs' test).²⁴⁸

BOX 53-2

Jaundiced Foal Agglutination (JFA) Test**MATERIALS**

1. Centrifuge capable of spinning 300 to 600 × gravity
2. Test tube rack
3. Test tubes: 13 × 100-mm disposable or blood collection tubes
4. Pasture pipettes and rubber bulbs or other pipette system to deliver 1-mL volumes
5. Isotonic (0.9%) saline at room temperature
6. Serum or colostrum from the mare; RBCs from mare and foal, preferable in EDTA anticoagulant

METHODS

1. Collect colostrum from the mare.
2. Collect an EDTA-anticoagulated blood sample from the foal before nursing.
3. Set up six tubes and add 1 mL of saline to each tube. Label the tubes Control, 1:2, 1:4, 1:8, 1:16, and 1:32.
4. Make serial dilutions of the colostrum at 1:2, 1:4, 1:8, 1:16, and 1:32 in five of the tubes. Add 1 mL of colostrum (or serum) to the tube labeled 1:2 and mix. Then take 1 mL from that tube and add it to the second tube labeled 1:4 and mix. Take 1 mL from that tube and add it to the third tube labeled 1:8, and so on, until all five dilution tubes have been filled. Discard 1 mL from the last tube labeled 1:32.
5. Add 1 drop of the foal's whole blood to each of the six tubes and mix.
6. Centrifuge the tubes for 2 to 3 minutes at a medium speed (300 to 500 × gravity).
7. Invert each tube, pouring out the liquid contents; observe the status of the button of RBCs at the bottom of the tube. *Complete* agglutination causes the cells to remain tightly packed in the button; *strong* agglutination causes the cells to remain in large dumps; for *weaker* agglutination the cells are in smaller dumps as they run down the side of the tube. When there is *no* agglutination, the cells easily flow down the side of the tube. This should be the case in the control tube. If the cells in the control tube are clumped, they may be autoagglutinating, and the results will have questionable validity.

If there is a positive reaction with the foal's cells, the test should be run with the dam's own RBCs to ensure that the conditions of the test and the viscosity of the colostrum are not causing the agglutination.

Positive reactions at 1:16 or greater are considered significant. At levels of 1:16 or greater, this test correlates well with the standard hemolytic assay. At dilutions of less than 1:16, the correlation is not as good, and more false-positive results will be recorded. Also, other factors (e.g., viscosity of colostrum) make less diluted samples more difficult to read.

Data from Bailey E, Conboy HS, McCarthy PF: Neonatal isoerythrolysis of foals: an update on testing, *Proc Am Assoc Equine Pract* 33:341, 1987; and Blackmer JM, Costa LRR, Koch C: The jaundiced foal agglutination test, *Vet Tech* 23:577, 2002.

Because of the difficulty in testing for these antigens, there has never been sufficient agreement between laboratories to allow international designation. These antigens may not be detected using the JFA screening test.²⁴⁹ Estimates are that 1 in 2000 pregnancies may result in sensitization against some other antigen besides Aa or Qa. Because these cases occur so infrequently, it is not practical to consider mares without these antigens to be at risk for NI. A blood type evaluation of mares with a history of production of foals with NI should be done to identify the offending anti-body/antigen.

*Serum or colostrum from the suspect mare is needed to screen for the presence of alloantibody. Acid-citrate-dextrose (ACD)-anticoagulated blood is generally preferred in screening for RBC antigens.

Box 53-3 lists laboratories providing NI screening tests (e.g., Aa, Qa, and Ca typing and screening of sera for alloantibody). Routine agglutinating crossmatch tests using mare serum or colostrum and foal or sire cells can be performed by most veterinary or human hematology laboratories.

Ruminants

Neonatal isoerythrolysis is not a naturally occurring disease in cattle, sheep, or goats. Its occurrence in cattle has been associated with administration of vaccines derived from blood, such as certain anaplasmosis and babesiosis vaccines.²²⁶ When used on breeding females, these vaccines may sensitize the dam to certain blood groups, most often in the A and F systems. Under chance circumstances, if the blood types of the sire and offspring reflect these systems and the dam has produced alloantibodies, an isoimmune hemolytic crisis may appear in the calf associated with successful passive transfer. Hemolytic crises are rare in sheep and are even difficult to induce experimentally.²²⁶

EQUINE NEONATAL ALLOIMMUNE THROMBOCYTOPENIA

■ **Definition and Etiology.** Neonatal alloimmune thrombocytopenia (NAIT) is a condition characterized by the destruction of platelets in the circulation of a foal by alloantibodies of maternal origin absorbed from colostrum.²⁶⁴ The syndrome has been observed in horse and mule

foals.^{251,264,265} The prevalence of NAIT is not known. Some foals may be asymptomatic, and the condition may be self-limiting as alloantibody is metabolized.

■ **Clinical Signs and Differential Diagnoses.** Few clinical signs may appear unless foals are traumatized. Affected foals may have prolonged bleeding from venipuncture sites. Petechial hemorrhages may not be present. Other conditions often associated with thrombocytopenia in neonates include sepsis, disseminated intravascular coagulation, equine infectious anemia, drug-induced thrombocytopenias, and angiopathies. The challenge is to determine whether the thrombocytopenia is primarily caused by allogeneic antibodies or secondary to some other disease process. For differential diagnoses of thrombocytopenia in neonatal foals, see Chapter 19.

■ **Clinical Pathology.** Profound thrombocytopenia in the absence of other hematologic changes typifies uncomplicated NAIT. Evidence of successful passive transfer is present based on quantification of serum IgG. Affected foals are thrombocytopenic. Thrombocyte counts less than 10,000/ μ L have been observed. Prolonged bleeding from venipuncture sites and petechiae may be present.²⁶⁴ Demonstration of significant amounts of antibody in the colostrum (or serum from the mare) that are directed against platelet antigens expressed by the foal provides a definitive diagnosis of NAIT. However, assays for equine platelet-bindable and

platelet-associated immunoglobulins are not routinely available.

■ **Pathophysiology.** The pathophysiology is believed to mirror that of neonatal isoerythrolysis. In mares sensitized to platelet antigens, alloantibodies are concentrated in the colostrum late in gestation. These antibodies are passed to the foal through passive transfer. If the foal's platelets carry the antigen that the antibody recognizes, the platelets become antibody coated. Subsequently, they are removed prematurely by the reticuloendothelial system. Platelet antigens have not been characterized in horses; however, platelet-associated antibodies have been demonstrated in affected foals. Circulating antibody is removed by attachment to platelets and rapid clearance by the reticuloendothelial system.

■ **Treatment and Prognosis.** Circulating antibody is removed relatively quickly, and treatment may not be necessary. Platelet-rich plasma may be indicated in cases of severe thrombocytopenia accompanied by clinical signs of bleeding problems. As offending antibody is removed, however, the problem will tend to be self-limiting.

■ **Prevention and Control.** Currently, there are no screening tests to predict NAIT. After production of an affected foal by a mare, it would be prudent to provide an alternate source of colostrum to foals born in subsequent pregnancies.

Disorders Caused by Toxicants

FRANCIS D. GALEY, *Consulting Editor*

Toxicology cases are not the most common clinical presentation to the veterinarian, but they challenge the clinician because large numbers of animals may be involved, emotions run high, litigation is frequently suggested, and publicity can be intense. This chapter provides tools to approach these potentially complex cases with confidence. After a general discussion of diagnosis and treatment of poisoning in livestock, common toxicoses caused by plants and other natural toxins, metals, inorganic compounds, and organic-synthetic compounds are discussed. Each section contains general comments about a group of poisons, followed by information on specific, commonly recognized toxicants. Each discussion begins with identification of the toxicant, its sources, likely targets, and hazardous situations, then describes the mechanism of toxicosis, signs and lesions, clinical pathology, diagnostic parameters, and approaches to management and prevention, including residue avoidance.

DIAGNOSIS OF POISONING

When toxicosis is suspected, possible sources of the toxicant should be identified and exposure to those sources rapidly eliminated. Diagnosis of poisoning rarely results from a single piece of evidence; rather, historical, clinical, pathologic, and analytical findings all need to be considered.

The investigation begins with tracing of animals, feedstuffs (especially lots and batches), and events that occurred up to the onset of signs to identify likely etiologies. Environmental conditions to check include water sources, surrounding industry or elements, plants, animals, human contact, and availability of these items to the animals. Samples of possible toxic sources should be obtained, labeled, and held for later testing.

Feed (constituents and as-fed) samples should not be pooled among lots or storage bins. Composite samples that are representative of an entire lot should be obtained within each lot. Hay and forage are also sampled in a representative manner and should be examined for weeds. As-fed materials can be tested for many toxicants, and then constituents are tested for any toxicant that is identified to track the original source. Weeds that are abundant in pasture or hay are identified (Table 54-1). Diagnosis of plant toxicity is aided by finding evidence of consumption of a plant from the animal or grazed pasture.

Water and environmental samples should be obtained. Water is sampled at the trough, in transport containers, and at the source. Samples of algal blooms are mixed in 10% neutral-buffered formalin for identification, and with a second 2-liter sample of fresh, thick bloom for toxin identification.

Clinical toxicoses may be *acute* (signs often appear in many animals at once; see causes of sudden death, Chapter 14), *chronic* (e.g., poor weight gain in cattle that graze locoweed),

or *absent* (e.g., food animal residues, antibiotics in milk, organochlorines in fat). Signs may be *specific* (bradycardia from cardiac glycosides) or *vague* (diarrhea caused by many syndromes). Samples of blood, serum, urine, body fluids, and ingesta should be obtained for clinical pathologic and toxicologic analyses (see Table 54-1).

Complete necropsies should be performed on dead animals. The urine should be sampled first, after obtaining samples that might become contaminated during the examination. Appropriate tissues should be fixed for histologic examination. Separate samples of tissue are frozen fresh for toxicologic analyses (see Table 54-1). The ingesta is completely examined for foreign objects and plants and then sampled in representative fashion for chemical analyses.

Pathologic lesions may range from none (residues or biochemical toxicants) to severe. Lesions may be very specific (e.g., nigropallidal encephalomalacia from yellow star thistle poisoning) or nonspecific (e.g., gastroenteritis from infectious, metabolic, and toxicologic causes). Some poisonings can be grouped by the type of lesion produced. For example, white snakeroot (*Eupatorium rugosum*), selenium deficiency, cobalt toxicosis, and monensin toxicosis all can cause white streaking in an animal's heart.

Chemical analysis can be useful as part of the diagnostic puzzle but rarely stands alone. Unless a specific toxicant is suspected, samples are kept frozen or cool (whole blood and some dry feeds) until clinicopathologic, pathologic, microbiologic, and histologic findings are known. Those tests help the diagnostician select the most useful toxicology tests. Environmental samples also must be available for testing because many toxicants, including plants, monensin, other antibiotics, and most mycotoxins, may not be detectable in animal samples.

Another diagnostic tool that may be useful is bioassay. One type of bioassay is assessment of the response of animals to therapy (e.g., animals with carbamate insecticide poisoning respond to atropine therapy). A second type is measurement of a relevant biomarker of toxicant exposure in an animal sample (e.g., cholinesterase assay to indicate exposure to an organophosphorus insecticide). A third type of bioassay, important for new toxicants, is administration of the suspected toxic material (or an extract) to target animals or laboratory animals to determine if a source is toxic.

Analytical results are interpreted in light of the history, epidemiology, signs, and pathology. A poison is determined by the dose received and the animal's response to that compound. The animal's response to a compound is affected by species, age, gender, environment, feed, medication, and other diseases. Species differences stem from varying habits (e.g., foraging), absorption (ruminants, horses, and swine have different digestive systems), and pathways for drug

TABLE 54-1

Sampling Guide for Analytical Toxicology

Sample	Amount	Commonly Requested Tests
Whole blood	5-10 mL (EDTA)	Lead, arsenic, mercury, molybdenum, manganese, selenium, cholinesterase, anticoagulants, cyanide, some insecticides
Serum	5-10 mL (from clot)	Copper, zinc, iron, magnesium, calcium, sodium, potassium, drugs, nitrates, ammonia, alkaloids, tannins, vitamins A and E
Urine	50-100 mL	Drugs, heavy metals, plant alkaloids, tannins, cantharidin, fluoride
Milk	30 mL	Organochlorine insecticides, PCBs, antibiotics
Ingesta	1 kg	Heavy metals, plants, oleander, alkaloids, tannins, insecticides, drugs, nitrates, cyanide, ammonia, other pesticides, cantharidin, avitrol
Liver	300 g	Heavy metals, insecticides, anticoagulant rodenticides, some plant toxins, some drugs, vitamins A and E
Kidney	300 g	Heavy metals, calcium, some plant toxins
Brain	Half of brain	Sodium, organochlorine insecticides, cholinesterase
Fat	100 g	Organochlorine insecticides, PCBs
Ocular fluid	One eye	Nitrate, ammonia, potassium, magnesium
Feeds	1-kg composite	Pesticides, heavy metals, salts, feed additives, antibiotics, ionophores, mycotoxins, growth promoters, nitrates, sulfate, chlorates, cyanide, plant toxins (gossypol, alkaloids, tannins), plants (send weeds for identification), vitamins A, D, E, and K
Plants	Entire plant, press and dry, or freeze	Identification, alkaloids, tannins, glycosides
Water	1 L in preserving jar	Pesticides, heavy metals, salts, nitrate, sulfate, blue-green algae
Environmental	Source material	Variety of organic, inorganic, and natural toxicants

EDTA, Ethylenediamine tetraacetic acid; PCBs, polychlorinated biphenyls.

metabolism. Very young and old animals will respond differently to toxicants than typical adults. Neonatal animals tend to absorb chemicals more readily than adults (e.g., lead), are at risk from compounds in milk (white snake-root), have poorly developed blood-brain barriers (penicillin or ivermectin toxicity), and are inefficient metabolizers of xenobiotics in the liver for up to 30 days after birth (long sleeping times caused by barbiturates). Elderly animals can have deficient liver metabolism, renal function, and immune competency.

TREATMENT OF POISONING

Once poisoning is suspected, the first objective is to minimize exposure of all animals in the herd to a suspected toxicant. Strategies include removal of suspected sources, provision of alternative feeds, changing water sources, and moving the animals.

Once life support (airway, circulation) has been accomplished, animals are decontaminated. Decontamination includes washing or bathing dermally exposed animals. Animals exposed to oral toxicants can be given activated charcoal, with or without a cathartic, to adsorb most organic toxicants. Some treatments can alter absorption of metals (e.g., sodium sulfate to block lead, molybdate for copper) or some organics (changing pH slows ammonia absorption). Nonspecific gastrointestinal damage, such as from nonsteroidal antiinflammatory drugs (NSAIDs), benefit from administration of demulcents (kaolin). Excretion of some organic acidic drugs or toxicants may be enhanced by making the urine more alkaline (ion trapping).

After decontamination, attention centers on maintenance of vital systems (fluid, electrolytes, and acid-base correction), and therapy depends on treating for specific signs (e.g., correction of arrhythmias from oleander) and administration of specific antidotes. Table 54-2 lists common therapies specific for poisoning.

PLANTS AND OTHER NATURAL TOXICANTS

FRANCIS D. GALEY

TOXIC PLANTS

Plant toxicity causes both direct and indirect losses to the livestock industry. Direct losses (deaths) cost producers approximately \$340 million in 1989.¹ More recent estimates suggest annual losses may range 2% to 3% annually.² Indirect losses, not included in that estimate, are likely to be much higher. Estimates of losses in individual animals from locoweed (*Oxytropis*, *Astragalus*) in New Mexico ranged from \$75 to \$282 per head, depending on severity of poisoning, using production and management costs from the mid-1990s.³ In addition to direct losses, indirect losses can result from reduced weight gains, decreased reproductive performance, poor production, fencing and management expenses, and effects on land values.

Plants toxic to herbivores may be in forages (hay, silage), grain (seeds), pastures, and water (blue-green algae). Diagnosis of plant poisoning uses an approach similar to that described in the introduction, except that few chemical assays are available for plant toxins. Thus, diagnosis of a plant poisoning relies heavily on identification of the plant in feed, pasture, or ingesta, along with appropriate clinical and pathologic findings. The presence of a poisonous plant in the environment is insufficient diagnostic evidence of plant poisoning without evidence of consumption by the animal (signs of grazing or presence of the plant or its toxin in ingesta).

Many toxic plants are not palatable and are avoided by livestock unless grazing is forced by other circumstances. Conditions favorable to ingestion of toxic plants include overgrazing, drought, use of some herbicides, and masking the plants in hay, silage, or grain. Environmental and harvesting conditions that can alter toxin levels in plants include soil type and content, herbicide use,⁴ overwatering, drought, fertilizer application, and sunlight.⁵ Conditions

TABLE 54-2

Common Therapeutic Agents for Poisoning

Agent	Action
Activated charcoal	Adsorbs most organic toxicants
Sodium sulfate	Cathartic with charcoal; binds lead; avoid if dehydrated or diarrhea
Magnesium sulfate	Cathartic; binds lead; avoid if dehydrated, diarrhea, or depression
Sorbitol	Cathartic
Atropine	Anticholinergic (extremely dangerous in horse)
2-PAM	Reverses organophosphorus binding
Methylene blue	Treatment for methemoglobinemia
Sodium nitrite	Used with sodium thiosulfate for cyanide poisoning
Sodium thiosulfate	Treatment for cyanide poisoning
Calcium EDTA	Chelation therapy for lead
D-Penicillamine	Chelation therapy for lead, copper
Dimercaprol (BAL)	Chelation therapy for arsenic, lead
DMSA	Chelation therapy for metals (awaiting approval)
Ammonium tetrathiomolybdate	Treatment for copper toxicosis
Barbiturates	Treatment for convulsants
Diazepam	Treatment for convulsants
Sodium bicarbonate	Ion trapping for acids, treatment for acidosis
Calcium, magnesium, fluids	Treatment for hypocalcemia, hypomagnesemia
Saline, lactated Ringer's, dextrose	Treatment for fluid and electrolyte deficits
Doxapram	Respiratory stimulant
DMSO, mannitol, corticosteroids	Treatments for cerebral edema
Mineral oil	Gastrointestinal evacuation
DSS	Treatment for gastrointestinal impactions
Emergency drugs	Drugs for cardiac and respiratory emergencies (e.g., epinephrine, lidocaine, oxygen)
Emergency equipment	Instruments needed to administer drugs, treat respiratory insufficiency (e.g., endotracheal tubes, tracheostomy sets), jars/packages/tubes for analytical samples

2-PAM, 2-Pyridine aldoxime methiodide (pralidoxime); EDTA, ethylenediamine tetraacetic acid; BAL, British antilewisite; DMSO, dimethyl sulfoxide; DMSA, dimercaptosuccinic acid; DSS, dioctyl sodium sulfosuccinate.

related to plant toxicity vary, however, depending on all the listed factors. Although overgrazing and intensive management may increase risk of poisoning from many plants, others such as the larkspurs (*Delphinium* species) are present in pristine conditions.^{6,7} Usually, poisoning occurs when the toxic plants become more palatable than native forages, or when mismanagement has resulted in animals being forced to ingest less desirable forages.

To identify a plant, it should be sampled in its entirety: flower, seed, pod, leaves, and roots. For shipping, the plant should be dried in a newspaper under some heavy books. Plants or leaves found in ingesta should be separated from the ingesta and shipped frozen for identification. In an emergency a plant can be pressed on a high-quality office copier, and the copy can be faxed to a diagnostic toxicologist for identification. Although chemistry analysis for most plant toxins in biologic specimens is not routinely available, recent developmental activity is making that option more available. Tests are currently available for toxins such as cyanide, nitrate, gallotannins, selected alkaloids, and some glycosides (e.g., cardiac glycosides).^{5,8-11}

With a few well-documented exceptions, such as nitrate and cyanide, specific antidotes are rarely available for plant toxins (many have not been characterized). Thus, the primary goals when treating plant poisoning include providing supportive care and eliminating exposure of animals to the suspected feed, plant, or pasture. Curtailing exposure can entail switching feed sources, moving animals, fencing, mowing, and providing supplemental feed. Adsorbents such as activated charcoal may be administered to minimize absorption of organic compounds, including many plant toxins.¹²

Prevention is the most effective cure for plant toxicosis. With a few exceptions, such as larkspur, which is palatable

and grows in pristine pastures,¹³ many toxic plants are unpalatable and grow on overgrazed and disturbed soils. Therefore, plant toxicosis often can be prevented by feeding adequate amounts of feed that is free of toxic plants, managing grazing areas,¹⁴ controlling weeds, and using proper harvest techniques for feeds. Some management schemes use selective spraying of herbicides or biologic control agents to help manage the problem.¹⁵ Conditioned aversion of animals to ingestion of some plants has also been explored using lithium chloride to create persistent aversions to selected plants.^{16,17} Averting lactating cattle to plants using lithium chloride apparently does not result in averting calves to milk contaminated with low levels of the agent.¹⁸ In some cases, animals that are less susceptible to a given plant toxicity might be used to graze infested rangeland.¹⁹ Timing of grazing can be altered to impact toxicity to a variety of plants, such as lupines, locoweeds, and ponderosa pine.²⁰

Some plant toxins may cause potentially hazardous or otherwise noxious residues in milk and meat. For example, tremetone from white snakeroot, selenium, and several alkaloids may be passed in milk.^{21,22} Thus, care should be taken when providing advice about the disposition of animals exposed to plant toxicants, especially about the disposition of milk from lactating animals.

Because a discussion of all toxic plants is beyond the scope of this chapter, this section discusses general aspects of plant toxicology as well as unique aspects of poisoning resulting from select, common classes of poisonous plants. It is assumed that the plants covered here have been identified. Plants can be identified using many resources, including various local agricultural extension agents or bulletins, textbooks,²³ diagnostic laboratories, veterinary schools, herbaria, Internet, and other botany sources. Specific statements

about geographic location of plants are not made, because modern feed and seed transport have blurred the distinction between regions of the United States in which certain plants may be found.

Alkaloids

Alkaloids are compounds that have nitrogen, usually in a heterocyclic ring, and are usually basic chemicals. Alkaloids are the largest class of secondary plant compounds, present in up to 30% of herbaceous species in North America.²⁴ Alkaloids are often quite bitter, and many are toxic.²⁵

■ LOCOWEED

Astragalus spp.: Locoweeds

Oxytropis: Crazyweed

Swainsona: Darling pea

The locoweeds, *Astragalus* and *Oxytropis* species, are found from the Rocky Mountains and Texas to California. Plants of both genera are perennial, herbaceous legumes with opposite, pinnately compound leaves. Flowers are purple to white racemes.²⁵ Seeds are borne in pods. Various species of *Astragalus* have different toxic chemicals and effects. Some species are nontoxic, whereas others have excessive selenium concentrations, 3-nitrocompounds, or swainsonine (the locoweed toxin, also found in *Swainsona*).²⁶⁻²⁸ Swainsonine (locoweed) inhibits cellular α -mannosidases, leading to abnormal glycoprotein metabolism.^{29,30}

Locoweed is unpalatable to livestock and is initially ingested when other feed is lacking (during the winter and spring).³¹ In addition, evidence suggests that cattle may learn to ingest locoweed from one another.³² Once ingestion is initiated, however, animals apparently acquire a taste for the plant.³¹ Locoweed remains toxic when dry,³³ and it affects all classes of livestock. Locoweed ingestion (up to 90% of body weight of plant material) causes gradual onset of signs related to the production, metabolic, central nervous, reproductive, and cardiovascular systems.^{31,33-38} Affected animals become emaciated, lethargic, dull, and ataxic, with an impaired sense of direction.^{33,37} Animals are nervous despite the depression and, especially horses, may react violently to stimulation. Horses do not seem to recover from the tendency to react uncharacteristically to stimuli. Reproductive consequences of "locoism" include abortion, prolonged estrus, altered breeding behavior, decreased libido, inhibition of normal spermatogenesis, weak and docile newborns, and deformed limbs with flexed tendons and joint laxity.^{34,37,38,40,41} Locoweed ingestion predisposes calves to development of right-sided congestive heart failure at high altitudes ("high mountain disease").^{35,36}

Sheep fed locoweed had clinical pathologic evidence of liver and renal (mild) damage, with increased serum concentrations of alkaline phosphatase (ALP), aspartate transaminase (AST), and blood urea nitrogen (BUN).^{39,42} The major postmortem finding in locoweed intoxication is emaciation. Microscopically, locoweed (and swainsonine) causes widespread neurovisceral cytoplasmic vacuolation in animals and the fetus (if present).⁴³⁻⁴⁵ The brain, liver, and kidney are the major affected organs. The vacuoles contain mannose-rich compounds.⁴⁶ Diagnosis of locoweed toxicosis is based on evidence of plant consumption, clinical signs, and lesions. No chemistry test is available for locoism. New tests are under development to stain tissues for mannose accumulation⁴⁶ and measure α -mannosidase activity in serum to indicate exposure to locoweed.⁴⁷

No antidote is available for locoweed poisoning. Exposure to the plant should be stopped and proper nutrition provided. Recovery from emaciation frequently occurs, but

horses that have developed locoism cannot be trusted. Proper grazing management of rangeland, including using range when other, more palatable plants are present, is a recommended strategy to minimize losses caused by the plant.⁴⁸ Milk from animals exposed to locoweed can be toxic, suggesting that swainsonine is passed in milk.⁴⁹ Clearance studies suggest that poisoned animals should be given approximately 28 days to clear swainsonine because of an estimated half-life in livestock of 60 hours.^{47,50}

■ PYRROLIZIDINE ALKALOIDS

Senecio spp.: Tansy ragwort (*S. jacobea*) and groundsels

Crotalaria spp.: Rattlebox

Cynoglossum officinale: Houndstongue

Amsinckia intermedia: Fiddleneck

Heliotropium spp.: Heliotrope

Echium plantagineum: Patterson's curse, Salvation Jane

Losses from pyrrolizidine alkaloids occur throughout the United States, resulting from ingestion of various species (spp.) of plants from the families of Compositae (*Senecio* spp.), Leguminosae (*Crotalaria* spp.), and Boraginaceae (*Cynoglossum* and *A. intermedia*).⁵¹ *S. jacobea* is found in the northwestern United States, *S. vulgaris* (common groundsel) can be found throughout the western United States, *Crotalaria* is present in the Midwest, *Cynoglossum* is primarily in the Rocky Mountain region, and *Amsinckia* is in California. Toxin concentrations are highest in seeds, flowers, and leaves and are lower in stems. The most toxic pyrrolizidine alkaloids are diester rings with a 1,2 double bond and a branched ester group.⁵¹ The compounds are bioactivated in the liver to reactive pyrroles and *trans*-4-hydroxy-2-hexenal.^{52,53} The reactive metabolites bind cell molecules and cross-link deoxyribonucleic acid (DNA), leading to necrosis, alteration of cell division, or carcinogenicity.⁵² The carcinogenicity of these compounds, which is a result of both genotoxic and promoting properties, is a reason for food safety concerns related to the pyrrolizidine alkaloids.^{54,55}

Plants with pyrrolizidine alkaloids are unpalatable. Most poisonings occur when animals are forced to graze the plant, or when the plant is masked in hay (*Senecio* spp. and *A. intermedia*) or grains (*Crotalaria* spp.; a major contaminant before the availability of herbicides for weed control).⁵¹ Toxicity is retained in dry hay and grains. All classes of livestock are affected. Small ruminants such as sheep are more resistant to the alkaloids than are cattle and horses. For example, ingestion of as little as 5% of their body weight of tansy ragwort (*S. jacobea*) in hay may be lethal to a cow or horse. Conversely, more than 100% of their body weight in plant material is needed to cause pyrrolizidine alkaloid poisoning in sheep and goats.⁵² The resistance of sheep to the alkaloids likely results from differences in liver biotransformation patterns.⁵¹ For example, sheep tend to have lower rates of hepatic production of toxic pyrroles plus higher levels of glutathione conjugation of toxic metabolites.⁵⁶ Interestingly, ingestion of pyrrolizidine alkaloids will enhance the toxicity of copper in sheep.⁵⁷ Although cattle and horses tend to have similar sensitivity to *Senecio* species, it is apparent that cattle tend to resist the hepatotoxic effects of *Amsinckia* at levels in hay that would be hazardous to horses (although *Amsinckia* may still cause nitrate toxicity in the cattle instead).

Animals with pyrrolizidine alkaloid toxicosis are usually presented with signs and lesions compatible with liver failure (see Chapter 33 for a complete description of signs and lesions).^{51,52,58} In addition to liver effects, pulmonary disease also has been reported for *Crotalaria* poisoning.⁵¹ Signs may be delayed for months after ingestion of the plant, appearing after the liver damage has had an opportunity to

become chronic.⁵⁹ Emaciation and hepatoencephalopathy often occur, leading to common names for the disease, such as “walking disease,” “walkabout,” and “hard liver disease.”

Diagnosis of pyrrolizidine alkaloid toxicosis depends on a history of exposure to the plants, clinical and pathologic evidence of liver failure, and classic histologic lesions.⁶⁰⁻⁶² Antemortem diagnosis, in the absence of an appropriate history, can be difficult because of the nonspecific nature of signs and the potential for delayed and progressive effects. Diagnosis in these cases benefits from histologic examination of a surgical liver biopsy. Recent studies suggest that a chemistry test for sulfur-bound pyrrolic metabolites of pyrrolizidine alkaloids in unfixed liver tissue may be useful, but is not yet available for diagnostic use.^{63,64}

Treatment for pyrrolizidine alkaloid toxicosis centers on treating the liver failure and eliminating additional exposure to the plant. Although not preventive, evidence suggests that ingestion of sulfur-containing amino acids in high levels can influence pyrrolizidine alkaloid toxicity through maintenance of hepatic glutathione levels.⁶⁵ Note that sheep may be fed added molybdenum to delay accumulation of copper on a chronic basis.⁵¹ Prognosis in advanced cases is poor. Very low levels of pyrrolizidine alkaloids are transferred into the milk, but attempts to transfer toxicity in the milk have not resulted in clinical or pathologic evidence of toxicosis.^{52,66}

■ LARKSPUR ALKALOIDS

Delphinium spp.: Tall and low larkspurs

Aconitum spp.: Monkshood

Larkspur (*Delphinium*) and monkshood (*Aconitum*) have alternating, palmately divided leaves, which in larkspur may cluster at the base. Racemous flowers have a variety of colors, depending on species, and are characterized by a lower spur (larkspur) or an upper hood (monkshood).⁶⁷ Loss of cattle from larkspur is economically important in the western United States. Unlike many toxic plants that prefer disturbed soil, larkspur is found in undisturbed mountain ranges.⁶⁸ Larkspur species are divided into low and tall varieties based on height (low, <76 cm; tall, >76 cm) and elevations (tall larkspurs are found in high mountain altitudes).⁶⁸ Larkspurs contain a variety of complex, diterpenoid alkaloids, such as methylaconitine and deltaline.^{69,70} The larkspur alkaloids cause skeletal muscle paralysis by blocking nicotinic, acetylcholine receptors at the neuromuscular junction and in the brain.^{69,71,72}

Larkspurs are hazardous because they are palatable and appear early in the spring.^{68,73} Although dried plants may be toxic, the diterpenoids are highest and most hazardous in the early-spring leaf growth, after flowering racemes are elongated.^{72,74,75} During that period, cattle will tend to ingest more larkspur during or just after a summer storm.⁷² All animals may be poisoned by larkspur. Cattle are most sensitive to the plant (17 g/kg of body weight of early plant growth may be lethal), whereas sheep are four times less sensitive.⁷⁶ Calves are often affected when they graze with “nurse” cows on the edges of meadows (likely area for larkspur growth) while dams graze steep hillsides. Clinically, larkspur poisoning results in stiffness and weakness, abdominal pain, collapse (often with forelegs first), and death from aspiration of regurgitated ingesta or respiratory paralysis within 3 to 8 hours after exposure.^{69,73,74,76,77} Death may be sudden (see Chapter 14). Recovery may occur in sublethal cases within 1 to 2 days.⁷⁴

Postmortem, animals with larkspur poisoning bloat rapidly.⁷⁴ Clinicopathologic findings are nonspecific. Diagnosis of larkspur toxicosis depends on a history of sudden death with rapid bloating on rangeland in early spring,

evidence of consumption of the plant, and a lack of other diagnostic findings. Chemistry testing is not routinely available for larkspur alkaloids, although testing of urine or serum for the alkaloids may be viable.⁷⁸

Treatment for larkspur poisoning centers on control by pregrazing with sheep (less sensitive), delay of grazing until alkaloid levels drop to less than 3 mg/g in leaves (after seed shatter),⁷⁹ spraying larkspur with nonspecific herbicides such as tebuthiuron,⁸⁰ and attempts to develop in the animals an aversion to grazing the plant.^{74,81} Recently, the ability of the larkspur mirid (*Hoplomachus affiguratus* Uhler) to control larkspur has been suggested as a biocontrol measure.⁸²

■ NICOTINIC-ACTING ALKALOIDS

Nicotiana glauca: Tree tobacco; *N. tabacum*: Tobacco (pyridine alkaloid; e.g., nicotine)

Lupinus spp.: Lupines (quinolizidine alkaloids; e.g., anagyryne, sparteine)

Cytisus scoparius: Scottish broom; *Laburnum anagyroides*: Golden chain; *Thermopsis montana*: Mountain thermopsis (quinolizidine alkaloids)

Lobelia spp.: Indian tobaccos (pyridine alkaloids similar to nicotine)

Conium maculatum: Poison hemlock (piperidine alkaloids; e.g., coniine)

The lupines and thermopsis are found in climax and grassy habitats, whereas poison hemlock and the tree tobacco plants are found in disturbed soils. This group has three classes of nicotinic toxins: pyridine alkaloids, quinolizidine alkaloids, and piperidine alkaloids. Nicotinic alkaloids cause toxicity by ganglionic stimulation, followed by blockade and paralysis.^{83,84} The teratogenic effects of lupines, tree tobacco, and poison hemlock may result from paralysis of the fetus during the period of joint formation (days 40 to 70 of gestation for cattle; days 30 to 60 for swine and sheep).⁸⁵⁻⁸⁹ Thermopsis causes myonecrosis by an unknown mechanism.^{90,91}

The plants are often bitter and are ingested when they are hidden in hay or forage or when animals are forced to do so by drought or hunger. Some lupines may be toxic when incorporated into feed as a supplement, although the toxin and mechanisms remain to be defined.⁹² The plants are toxic when dry except for *Conium*, which has quite volatile toxins that dissipate with time when plants are dry (fresh hay may be toxic).^{84,93} All classes of livestock are affected by the plants, although species variations occur.^{83,84,94,95} For example, acute toxicosis is more common in sheep. Conversely, teratogenesis is more likely in cattle.⁹¹ Despite the lower likelihood of acute toxicity, it does occur. For example, deaths occurred in yearling Holstein dairy cattle pastured on lupine (personal observation). Cattle were more sensitive to the acute effects of coniine (poison hemlock) than were horses or sheep.⁹⁵ Acute toxicosis from nicotinic alkaloids is characterized by ataxia, weakness, tremors, initial stimulation of the central nervous system (CNS) followed by lethargy, increased salivation, respiratory distress, bloating, and death from respiratory paralysis.^{83,84,96,97} Teratogenic signs include cleft palate (earlier in the susceptible period) and if exposed during joint development, classic arthrogryposis (“crooked calf syndrome”) involving the joints of the legs and spine.^{85-89,95,98} Acute *T. montana* toxicosis in cattle leads to tremors, a stilted gait, and recumbency, followed by respiratory paralysis and death. The animal may be found dead (see Chapter 14).⁹⁰

Clinicopathologic changes are nonspecific for most of the nicotinic plants. *Thermopsis* may result in elevations of creatine kinase (CK) and AST, suggesting skeletal muscle damage.⁹⁰ Other than bloat and pulmonary edema, acute nicotinic alkaloid toxicosis results in few specific lesions.^{93,96}

The congenital malformations are usually obvious on post-mortem examination. *Thermopsis* toxicosis is characterized by degeneration and necrosis of skeletal muscles.^{90,91}

Diagnosis of acute nicotinic alkaloid toxicosis depends on identification of the plant and appropriate signs. Additionally, reliable chemical assays have been developed to detect some of the alkaloids in urine and serum of exposed animals, including those of poison hemlock, tree tobacco, and some lupines.^{93,96,99} Diagnosis of the source of crooked calf syndrome requires historical review of plants that may have been grazed during the susceptible period of gestation.

Treatment of acute toxicosis is nonspecific. Exposure should be eliminated. Animals in poor body condition may have higher circulating levels of lupine alkaloids at a given dose, suggesting that disposition of the alkaloids is affected by nutritional condition.¹⁰⁰ Many of the potentially teratogenic alkaloids of these plants, including some from poison hemlock and *Lupinus*, are passed into milk and muscle tissue.^{101,102}

■ STEROIDAL ALKALOIDS

Zigadenus spp.: Deathcamas

Veratrum californicum and *V. viride*: False hellebore, also skunk cabbage

Solanum spp.: Nightshades; *Lycopersicon* spp.: Tomatoes

Deathcamas is a slender, perennial herb (up to 50 cm tall) with grasslike basal leaves that grows from an onionlike bulb and has yellow-white flowers.¹⁰³ False hellebore has short, hairy, stout stems with broad, prominently veined leaves.¹⁰⁴ *Solanum* species range from annual herbs to woody plants. They have four to five lobed, white to purple flowers.¹⁰⁵ The fruit is a berry. The leaves often have two small leaflets at the base or incorporated as small lobes. Deathcamas and *Veratrum* species, both of which are Liliaceae, are found in moist meadows at upper elevations. *Solanum* species are found throughout the United States. Deathcamas (alkaloid is zygacine) and false hellebore contain steroidal alkaloids that cause cardiovascular hypotension.¹⁰³ *Veratrum* alkaloids include the teratogens jervine and cyclopamine.¹⁰⁶ Solanaceous plants such as the nightshades, tomatoes, and potatoes have steroidal alkaloids linked to sugars (glycosides).¹⁰⁷ Those *Solanum* alkaloids may inhibit cholinesterase, cause gastrointestinal (GI) irritation, and induce constipation. Some solanaceous plants accumulate nitrate (tomato vines)¹⁰⁸ or have other toxic factors such as vitamin D, which causes calcinosis (*Solanum malacoxylon*, found in South America and Hawaii).

The steroidal alkaloids are toxic to all classes of livestock. Sheep are most frequently poisoned by *Veratrum* and *Zigadenus*.^{103,109} *Zigadenus* is most hazardous in the early spring because it is among the first plants present.¹⁰³ *Veratrum* is teratogenic when grazed by ewes around days 14 and 30 of gestation.^{110,111} The alkaloids resist drying.¹⁰⁷ Ingestion of as little as 0.6% of body weight of deathcamas can cause ataxia, stiffness, tremors, increased salivation, vomiting, and prostration. Death may occur within 1½ to 8 hours of exposure¹⁰³ (see Chapter 14). *Solanum* species vary in toxicity and effect, causing GI irritation, ileus (in horses), lethargy, increased salivation, dyspnea, tremors, paralysis, diarrhea or constipation, and death.^{103,105,107} Pregnant ewes grazing *Veratrum* during day 14 of gestation produce lambs with craniofacial deformities, including cycloopia, microphthalmia, and cleft palate.^{109,110} Gestation may be prolonged in affected ewes.¹⁰³ Limb and bone shortening in the metacarpal and metatarsal joints can occur in lambs when ewes ingest the plant around day 30 of gestation.¹¹¹

Clinical and pathologic findings are nonspecific, except for the teratogenesis from *Veratrum*. Severe intoxication

from *Solanum* species may lead to congestion of major internal organs.¹⁰⁷ Diagnosis involves accumulated signs with evidence of consumption of the plant. Chemistry testing is not routinely available.

Treatment for poisoning centers on prevention. Deathcamas and false hellebore should be avoided in early spring. The highly variable toxicity of the solanaceous plants makes recommendations about prevention difficult, although feeding large volumes of the plants is ill-advised.

■ TROPANE ALKALOIDS

Datura stramonium, *D. meteloides*: Jimsonweeds

Atropa belladonna: Belladonna

Datura and *Atropa* are also solanaceous plants. Jimsonweeds prefer disturbed soils such as barnyards.¹¹² The plants contain the tropane alkaloids, atropine and scopolamine, which block acetylcholine at muscarinic nerve synapses. Although *Datura* is bitter and unpalatable, herbicide application or overgrazing may encourage consumption. Grain contaminated with *Datura* seeds is toxic.¹¹² *Datura* toxicity results in GI atony, anorexia, rapid heart and respiratory rates, mydriasis, thirst, diarrhea, excess urination, disturbed vision, and delirium.¹¹³⁻¹¹⁵ Death is uncommon, perhaps because gut atony and anorexia may limit plant intake.¹¹² However, gut atony can be fatal in some species, including the horse.^{113,114} Exposure to trace amounts of *Datura* species, such as in the bedding or feed, may result in urinary residues of tropane alkaloids in the horse's urine.¹¹³ Lesions are nonspecific. Tropane alkaloids can be identified in urine, ingesta, and plant material.

■ YEW

Taxus cuspidata: Japanese yew

Taxus baccata: English yew

Yews are evergreen shrubs and small trees with flattened needles. The plants are found throughout the United States in hedges and yards.¹¹⁶ Yews contain alkaloids called *taxines*, which depress myocardial conduction by blocking sodium movement through membranes.¹¹⁷ Some yews also contain antimitotic, diterpenoid taxols, which are of medicinal interest as anticancer agents.¹¹⁸

Yew is extremely toxic; less than 0.1% of body weight of dried leaves may kill a horse.¹¹⁹ Toxicity is retained in dry plants. All species are sensitive to yew toxicity. As with oleander, yew poisoning often results from accidental ingestion of hedge clippings.^{116,120} Clinical toxicosis is usually manifested by collapse and sudden death (Chapter 14) related to heart failure, occasionally preceded by tremors and weakness.^{116,119-121}

Lesions are uncommon, although focal, nonsuppurative myocarditis is possible.¹²⁰ Diagnosis of yew toxicosis requires a history of exposure to yew clippings and sudden death. Finding of leaf parts in the ingesta is diagnostic. The investigator may be confused by needles from *Pinus* and the coastal redwood (*Sequoia sempervirens*). Alkaloids have been suggested by mass spectral chemistry in samples from poisoned animals.¹²²

■ TRYPTAMINE ALKALOIDS

Phalaris spp.: Canary grass

Phalaris species are pasture grasses. Under poorly defined conditions, *Phalaris* accumulates indole and β-carboline alkaloids.^{123,124} Those alkaloids block serotonin in the CNS and may inhibit monoamine oxidases.^{124,125} Cattle and sheep are affected, although sheep are more likely to be poisoned by

Phalaris.¹²⁶ The alkaloids are bitter, resulting in lowered weight gains if present at levels exceeding 0.2% of plant weight.¹²⁴

Clinically, two syndromes can result from canary grass toxicity. Sudden death with cardiac failure is one possible result of poisoning.^{124,126} Chronic lower-level exposures may lead to a staggers syndrome with ataxia, a hopping gait, tremors, excitability, head nodding, convulsions, and eventually paddling and death in sheep and horses.^{124,127-129} Onset of signs may be delayed up to 40 days after ending exposure to canary grass.¹³⁰ (See later discussion and Chapter 35 for grass staggers.)

Postmortem examination of sheep with the staggers syndrome reveals characteristic gray to bluish discoloration of the brainstem.^{130,131} The kidney and liver also may be pigmented. Pigment in the cytoplasm of the nerves apparently destroys those cells.¹³¹ Clinical signs of sudden death or staggers in sheep that have previously grazed canary grass pasture, along with characteristic discoloration of brain tissue, are used for diagnosis. Treatment of clinically affected animals has not been rewarding; however, supplementation with cobalt may help prevent toxicosis.¹³²

Glycosides

Glycosides are ethers that link a sugar to a toxin, called *aglycone*. Either the glycoside or the aglycone alone may be toxic. Most work is based on the properties of the aglycone. Absorption of the aglycone is often enhanced by microbial activity causing release of the aglycone from the sugar.¹³³ The aglycone is frequently released by damage to plant tissue. As with alkaloids, glycosides are often bitter.¹³⁴

■ CARDIAC GLYCOSIDES (CARDENOLIDES, GRAYANOTOXINS)

Nerium oleander: Oleander; *Thevetia peruviana*: Yellow oleander

Digitalis purpurea: Foxglove

Rhododendron spp.: Azaleas

Kalmia spp.: Laurels

Convallaria spp.: Lily-of-the-valley

Pieris japonica: Japanese pieris

Asclepias spp.: Milkweeds

Apocynum spp.: Dogbanes

Bufo marinus: Bufo toads

Many families of plants contain cardiotoxic glycosides. Many of the plants, including azaleas, oleander, and Japanese pieris, are evergreen shrubs and small trees.¹³⁵ In addition to plants, cardiac glycosides may be found in animals such as the bufo toad. The toxic cardiac glycosides, including various cardenolides and bufadenolides, are steroid-like in structure and have a lactone ring.¹³⁶ Common cardiac glycosides include digitoxin and digoxin from foxgloves, oleandrin (aglycone = oleandrogenin) from oleander, and grayanotoxins from rhododendron. Cardiac glycosides block cellular sodium-potassium adenosine triphosphatase (ATPase), leading to sodium accumulation in excitable cells such as nervous tissue and myocardium.¹³⁶⁻¹³⁸ Grayanotoxins block fast sodium inactivation in excitable tissues by binding to sodium channels.¹³⁹ Increased cardiac contraction and altered heart rhythms result from myocardial effects. The plants also are potent GI irritants.

Cardiac glycosides are found in most parts of the toxic plants.¹⁴⁰ Although plants are bitter, dried leaves (oleander) and flowers are readily ingested by all classes of livestock, causing toxicosis.^{10,140,141} Discarded lawn clippings that contain oleander leaves are a common source of livestock poisoning. Some of the plants are extremely toxic, and toxic

effects are cumulative. For example, 0.005% to 0.015% of body weight of oleander (equivalent to a handful of leaves) can be lethal in sheep and cattle, and one leaf may kill a human.^{125,142} Azaleas may be toxic when livestock ingest 0.2% to 0.6% of body weight of plant material.¹⁴² Clinical signs of toxicosis reflect GI irritation and damage to the heart. The onset of toxicosis may be delayed by several hours after ingestion. Although death may be sudden (see Chapter 14), it usually occurs within 36 hours after ingestion but may take up to 14 days.¹⁴³ Signs include abdominal pain, nausea, weakness, anorexia, muscle tremors, rumen atony, increased salivation, bradycardia (or tachycardia later in the syndrome), heart block, and ventricular arrhythmias (including a gallop rhythm for oleander in cattle).^{126,141-147}

Animals with acute cardiac glycoside toxicosis may have hypertension, hypoxemia, acidemia, hemoconcentration, hyperkalemia, hyperchloremia, and elevations of serum creatinine and glucose.¹²⁶ Electrocardiogram (ECG) alterations include widening of the QRS complex, ST segment depression, enlarged P waves, and a variety of ventricular arrhythmias. Lesions associated with cardiac glycoside toxicosis are nonspecific and include hemorrhagic gastroenteritis and pale mottling of the heart with congestion, hemorrhage, and histologic evidence of myocardial degeneration and necrosis.^{125,126,143,144}

Diagnosis of cardiac glycoside toxicosis depends on identification of the plant and evidence of its consumption. Two-dimensional thin-layer chromatography (TLC) and liquid chromatography/mass spectrometry (LC/MS) methods have been developed for assay of oleander in ingesta and body fluids from affected animals.^{10,145,146} LC/MS can be used to assess grayanotoxin exposure in urine and feces of affected animals.¹⁴⁷ A serum radioimmunoassay (RIA) can be used to assess exposure to *Digitalis*; this test may cross-react with oleander glycosides for some diagnostic utility.¹⁴⁸

Treatment of cardiac glycoside toxicosis begins with elimination of exposure to the plant and decontamination using cholestyramine resins or activated charcoal (repeated applications suggested).¹²⁷ Fluids with calcium and potassium should be avoided (unless hyperkalemia is absent). Atropine may be useful if bradycardia or heart block is present (use care in horses; it may cause gut stasis). β -Adrenergic blocking agents and antiarrhythmic drugs can be used for cardiac dysrhythmias; otherwise, β -blockers should be avoided.^{126,127} Use of anticardiac glycoside Fab antibodies is an experimental treatment for digitalis and oleander toxicoses.¹⁴⁸⁻¹⁵⁰ Stress should be avoided in animals exposed to cardiac glycosides. Prevention of cardiac glycoside toxicosis includes keeping hedge clippings away from animals and avoidance of plants when in full flower. *Digitalis* glycosides are widely distributed in the body, including in milk and fetal fluids, and the primary elimination pathway is urinary.¹²⁶ Evidence of oleandrin was identified in the milk of poisoned cows using two-dimensional TLC in the author's laboratory. No oleandrin was found at 5 days after exposure in milk from that dairy.

■ PHOTSENSITIZING SAPONINS

Tribulus terrestris: Puncture vine

Panicum coloratum: Kleingrass

Brachiaria decumbens: Signalgrass

Nolina texana: Sachuista

Agave spp.: Agave

Nartheicum ossifragum: Nartheicum

These grasses and weeds may contain toxic levels of hepatotoxic, steroidal saponinins such as disogenin.¹⁵¹⁻¹⁵⁴ Saponinins are metabolized in animals to glucuronide conjugates of epismilagenin, which crystallize in bile, leading to

biliary blockage, cholangitis, and secondary photosensitization (Chapter 40).¹⁵³⁻¹⁵⁵

Plants are most hazardous when grazed during stages of early, rapid growth when sapogenin levels are highest.¹⁵⁵ Feed refusal can occur because the plants can be bitter. Mature plants are often grazed without incident. All herbivores may be affected. Signs of toxicity involve liver damage with anorexia, weight loss, icterus, hepatoencephalopathy, and secondary photosensitization.^{151,152,156-160}

Serum chemistry alterations reflect liver damage.^{157,158} Postmortem, affected animals are icteric and have evidence of necrosis and sloughing of skin.¹⁵⁹ Lesions in the liver include bridging and fibrosing hepatocyte necrosis, cholangitis, and occlusion of small bile ducts. Bile ducts may have birefringent crystals, probably related to sapogenin accumulation.^{151,153,158,159} (See Chapter 40 for skin lesions.) Lesions also may be present in the kidneys, heart, and adrenals. *Narthecium*, as with other lilies, may cause chronic renal failure in ruminants, most likely from a furanone, not a saponin.¹⁶¹ Animals should be removed from offending pastures (at least until the grass matures).

■ CYANOGENIC GLYCOSIDES

Linum spp.: Flax

Prunus spp.: Cherries, chokecherries, apricots, peaches

Sorghum spp.: Sorghum, Sudan grass

Triglochin spp.: Arrow grass

Trifolium repens: White clover

Zea mays: Corn

Many others; see references.

Many grasses, weeds, and cherry bushes contain cyanogenic glycosides. Damage to the plant causes contact between β -glycosidases and the glycosides, releasing free cyanide. Cyanide blocks a variety of metalloenzymes, most notably the terminal oxidase (cytochrome-*c* oxidase) of oxidative transport.^{162,163} The tight affinity of cyanide for ferric (Fe^{3+}) iron in the cytochrome prevents electron transfer. Sorghums also can cause peripheral neurologic deficits in laboratory animals and horses (from nitriles or cyanide).^{163,164}

Many of the listed plants may be grazed safely; however, cyanide is released when plants are damaged from maceration, drought, frost, wilting, and stunting.¹⁶² Toxicity wanes with drying. All animals are sensitive to cyanide toxicosis. Cyanide toxicosis is very rapid in onset, often resulting in sudden death (see Chapter 14). Clinical signs include dyspnea, excitement, tremors, increased salivation, gasping, clonic convulsions, and death.^{162,163} Chronic exposure to cyanide in rats can cause paralysis, and cattle, horses, and sheep grazing *Sorghum* species have developed ataxia, urinary incontinence, and cystitis.¹⁶³⁻¹⁶⁶

Blood from animals with cyanide toxicosis is cherry red because hemoglobin cannot release oxygen to tissue. Non-specific postmortem findings include cardiac hemorrhage associated with acute death. Chronic exposure to cyanide may lead to patchy encephalomalacia and damage to the spinal cord, along with secondary thickening and necrosis in the bladder associated with cystitis.^{163,164} Diagnosis of cyanide toxicosis is supported by analytical evidence of cyanide in forage and samples from affected animals. Cyanide levels in excess of 200 ppm in plant material and 1 ppm in liver or blood are significant.¹⁶² Samples for cyanide analysis should be frozen immediately and held frozen until analyzed.

Treatment of cyanide toxicosis is based on removal of the cyanide from affected cytochrome *c*. Judicious use of sodium nitrite (16 mg/kg intravenously [IV], to form a small amount of methemoglobin, Fe^{3+}) can help pull cyanide away from

the enzymes. Additional use of sodium thiosulfate (30 to 40 mg/kg IV) will provide substrate for the natural rhodanese enzyme that forms thiocyanate, which is readily excreted in the urine.^{162,167}

■ NITROTOXINS

Astragalus spp.: Milk vetches (*A. miser*: Timber milk vetch; *A. emoryanus*: Emory milk vetch)

Coronalia varia: Crown vetch

Indigofera spicata: Indigo

Some common milk vetches in North America contain glucosides of 3-nitropropanol (NPOH) and 3-nitropropanoic acid (NPA).^{26,168,169} Miserotoxin is a common glucoside of NPOH. The glucosides are relatively nontoxic until hydrolyzed in the rumen to toxic nitrocompounds and nitrite, which is also toxic.¹⁷⁰⁻¹⁷² NPOH is oxidized to the more toxic NPA in the liver.^{170,171} Nevertheless, NPOH may appear more toxic than NPA in ruminants because the NPOH is more thoroughly absorbed from the rumen. Nitrocompound toxicity is distinct from nitrite poisoning (see Nitrates). Less than 33% methemoglobin is usually formed after exposure to nitrocompounds, so nitrite alone does not explain acute nitrocompound toxicity.¹⁷¹ NPA is a powerful inhibitor of succinate dehydrogenase in the Krebs cycle, impairing cellular energy production in the nervous system.¹⁷³

All livestock can be poisoned by nitrocompounds, but cattle and sheep are most at risk. Acute or chronic toxicosis may develop, depending on the amount ingested. Acute nitro-plant toxicosis has a rapid onset of ataxia, distress, dyspnea, cyanosis, weakness, collapse, and death within 4 to 12 hours.¹⁷² Sheep may be found suddenly dead (see Chapter 14). Chronic nitro-plant toxicosis results in respiratory distress, weakness (especially in the pelvic limbs), knuckling of fetlocks, goose stepping, and knocking together of hindfeet when walking ("cracker heels").¹⁷² Increased salivation, constipation, and diarrhea have all been reported. Animals may linger for months, but severely affected individuals seldom recover. Affected cattle may die suddenly if forced to move quickly.

Animals exposed to nitro-containing plants can have up to 33% methemoglobin.¹⁷² Although not lethal at this level, methemoglobin probably contributes to respiratory distress. Lesions of nitrocompound toxicosis include pulmonary edema with fibrosis (in longer-standing cases) and nonspecific cerebral hemorrhages. Histologic alterations in nervous tissue include wallerian degeneration of the spinal cord and peripheral (sciatic) nerves, with variable changes reported in the cerebellum.¹⁷² Other neuronal lesions may include white matter vacuolation, glial edema, and bilateral changes of the thalamus and cerebellum.¹⁷¹

Treatment of nitrocompound poisoning centers on prevention. Cattle native to pastures containing timber milkvetch (*Astragalus miser*) are somewhat tolerant to the plant through rumen microflora adaptation, which may be enhanced by protein supplementation.¹⁷⁴

■ BRACKEN FERN

Pteridium aquilinum: Bracken fern (toxic glycoside + thiaminase)

Cheilanthes humilis: Rock fern (toxic glycosides)

Equisetum arvense: Horsetail (no known glycoside, does have thiaminase)

Bracken is a perennial fern (up to 2 m high) that arises from a black rhizome and is found in disturbed or cleared uplands. The fronds are coarse, triangular, entire at the apex, and lobed toward the stalk. Bracken fern contains a variety of

glycosides, including ptaquiloside (up to 1%), which will alkylate DNA, leading to carcinogenicity and bone marrow suppression in ruminants and laboratory animals.¹⁷⁵⁻¹⁷⁹ Bracken also contains thiaminase activity, which predominates in monogastric animals (horses).^{175,178}

Grazing of fresh, young fronds when other forage is not yet available early in the grazing season is hazardous for cattle and horses, although plowed rhizomes and hay (20% bracken for 1 month in horses) also may be toxic.^{175,180} Signs appear suddenly after animals have grazed approximately their body weight in plant material over several months. Horses develop characteristic thiamine deficiency, with weight loss, ataxia, lethargy, and a braced stance with an arched back, tremors, recumbency (with violent attempts to rise), and death within days to weeks after onset of signs.¹⁸⁰ Cattle with bracken or ptaquiloside toxicosis develop widespread hemorrhages and hematuria ("enzootic hematuria") resulting from severe bone marrow depression and cancer in the bladder and other organs.^{175,178-185} Reduced fertility may occur in chronic cases.

Cattle with bracken toxicosis have a normocytic, normochromic anemia, lymphocytosis, and neutropenia.¹⁸⁶ Severe thrombocytopenia and hemorrhage are also reported, associated with progressive bone marrow failure.^{175,178} Urine from affected animals is hemorrhagic, with high levels of calcium and protein.^{181,186} Lesions in cattle with bracken toxicosis include the hemorrhages, bone marrow hypoplasia, and a variety of tumors in bladders, including hemangiomas, hemangiosarcomas, transitional cell carcinomas, papillomas, fibromas, and adenomas.^{180,181} Other cancers may involve hematopoietic tissues and the GI tract.¹⁸³ Horses with bracken toxicosis have low levels of thiamine.

In addition to prevention, horses that have not reached a terminal state may respond to large doses of parenteral thiamine. No specific treatment is currently recommended for ruminants with bracken poisoning. In terms of safety of food animal products, indirect evidence suggests that bracken ingestion by milking cows may be linked to stomach cancer in people who have chronically ingested that milk.^{187,188}

PHYTOESTROGENS

Medicago sativa: Alfalfa

Trifolium subterraneum: Subterranean clover; *T. pratense*: Red clover

Hyperestrogenism caused by feeds and forages (including clover and alfalfa hays) has been reported in cattle, sheep, and swine. A variety of glycosides in those forages interact with estrogen receptors.^{189,190} Commonly recognized estrogens include coumestrol, formononetin, biochanin A, daidzein, genistein, equol, and many others.^{190,191}

Estrogenic compounds vary in potency. Coumestrol from alfalfa and isoflavones from clovers have the most estrogenic activity, followed by genistein, daidzein, biochanin A, and formononetin.¹⁹² Biochanin A and formononetin are not potent in the laboratory, but ruminants metabolize them to the more estrogenic forms of genistein and daidzein, respectively.^{190,192} Signs of hyperestrogenism from forages include infertility, hyperestrogenism, and anti-estrogenism. Hyperestrogenism includes nymphomania, cystic ovaries, swollen genitalia, and in males development of female characteristics. Antiestrogenic signs include gonadal hypoplasia and anestrus.^{189,190} Diagnosis of forage-induced hyperestrogenism is facilitated by demonstration of estrogens in forages and samples of plasma or urine.¹⁹³⁻¹⁹⁵ Consumption of highly estrogenic forage types should be limited in breeding animals.

OTHER TOXIC GLYCOSIDES

Melilotus alba; *M. offinalis*: White and yellow sweet clovers
The sweet clover forages produce the glycoside melilotoside, which contains coumarin. *Penicillium* species in moldy hay can dimerize the aglycone to dicumarol, which inhibits vitamin K epoxide reductase, leading to failure of vitamin K-dependent clotting factors. Dicumarol can be assayed in feed and animal-related samples. Concentrations of dicumarol in hay as low as 10 ppm may be hazardous to cattle. Moldy sweet clover poisoning in cattle results in widespread, vitamin K-responsive hemorrhage, which is especially hazardous during late-term pregnancy (hemorrhagic abortions).^{196,197}

Xanthium spp.: Cocklebur and spiny cloburs (carboxyatractyloside)
Ingestion of young sprouts, burrs, or adult plant in hay of cocklebur can cause massive centrilobular liver necrosis in swine and cattle. Signs of toxicosis include depression, dyspnea, weakness, convulsions with opisthotonos, and death. Severe hypoglycemia may be observed by the clinician.¹⁹⁸⁻²⁰¹

Ammi majus: Bishop's weed
Cymopterus watsonii: Spring parsley
Thamnosia spp.: Dutchman's breeches (furanocoumarins)
Cooperia pedunculata: (unidentified phototoxin), *Cooperia*
Furanocoumarins such as psoralens are primary photosensitizing agents that lead to severe blistering of light-skinned areas of exposed livestock ingesting the plants and poultry exposed to seeds from Bishop's weed (see Chapter 40).^{196,202}

Cestrum diurnum: Day-blooming jessamine
Solanum malacoxylon
Trisetum flavescens: (calcinogenic glycosides)
These plants contain glycosides of vitamin D (1,25-dihydroxycholecalciferol). Ingestion of the plants causes weight loss, lameness, stiffness, abnormal posturing, and clinicopathologic increases in serum calcium and phosphate in cattle and horses. Lesions include widespread calcification of tissues, including the cardiovascular system, tendons, lungs, and kidney. The vitamin D activity may cross the placenta to affect a developing fetus.²⁰³⁻²⁰⁶

Medicago spp.: Alfalfa
Saponaria spp.: Soapwort, cow cockle
Gutierrezia sarothrae: Broom snakeweed
Sesbania vesicaria: Bladderpod (enterotoxic saponins)
Plant saponins are bitter, foaming, detergent-like glycosides found in a variety of important forage crops and weeds. Midsummer alfalfa cuttings tend to have the highest saponin contents. Saponin toxicosis is characterized by gastroenteritis with diarrhea, poor weight gain, and ill-thrift in cattle. Broom snakeweed has an abortifacient factor with an effect similar to that in *Pinus*.²⁰⁷

Aesculus spp.: Buckeye or horse chestnut
Horse chestnuts are trees with characteristic palmate leaves and a one- to three-seeded, leathery fruit capsule (large seeds with a scar give the tree its name, buckeye). Young growth, sprouts, and seeds contain toxic levels of the glycoside aesculin. Aesculin causes ataxia, twitching, and excitability or sluggishness in livestock. The alcoholic extract from *Aesculus hippocastanum* causes incoordination.

Ranunculus spp.: Buttercups
Ceratocephalus testiculatus: Bur buttercup
Ranunculin is enzymatically converted to the toxic protoanemonin, a potent GI irritant that occurs in bur buttercup, and it becomes nontoxic when the plant is crushed or dried. Thus, bur buttercup in hay is not a hazard. However, grazing of this bitter plant by cattle and sheep, which occurs when animals are forced to do so, results in watery diarrhea, weakness, and dyspnea. Death may occur in

severe cases (nonspecific edema and hemorrhage with fluid in the large cavities).²⁰⁸⁻²¹⁰

Brassica spp.: Turnips, mustards, cabbages

These plants have a variety of glucosinolates and isothiocyanates that cause GI irritation and, for some chemicals, goitrogenic effects in adults as well as neonates.

Cycas spp.: Cycads

Macrozamia spp.: Cycads (azoxyglycosides)

Cycads are palmlike plants found in tropical and subtropical climates. They contain a variety of glycosides, including the hepatogastrointestinal toxin (and carcinogen) cycasin, which is metabolized to the highly toxic methylazoxymethanol, and the neurotoxic amino acid β -methylamino-L-alanine. Ruminants with hepato-GI toxicosis from effects of the cycasin develop depression, anorexia, and weight loss. Necropsy findings reveal a cirrhotic liver, ascites, and hemorrhagic gastroenteritis. Ruminants with the neurologic syndrome develop "Zamia staggers," characterized by weight loss, swaying, weakness, ataxia, and hindlimb ataxia. Post-mortem lesions include demyelination and axonal degeneration of the brain, spinal cord, and dorsal root ganglia. In addition, recent research suggests that cycad toxins may also harm pancreatic β -cells, contributing to development of diabetes mellitus.²¹¹⁻²¹⁴

Alcohols and Acids

■ GOSSYPOL

Gossypium spp.: Cottonseed

Gossypol is a yellow, polyphenolic pigment found in glands of cottonseed (*Gossypium*). It is present in free (toxic) and bound (to protein, perhaps to the epsilon amino of lysine; not directly toxic) forms.^{215,216} Both whole cottonseed and cottonseed meal can be toxic. Extraction of cottonseed using steam and heat will bind gossypol, whereas solvent extraction may leave high levels of free (toxic) pigment. Gossypol binds to cell constituents such as lysine and phospholipids, binds iron, may cause hypokalemia through kidney damage, inhibits a range of dehydrogenases, and uncouples phosphorylation.²¹⁵⁻²¹⁸ Gossypol also adversely affects male reproduction through a variety of mechanisms, including inhibition of lactate dehydrogenase (LDH) in testicular Leydig cells and inhibition of acrosomal plasminogen activator in the sperm.²¹⁸ Cottonseed meal has limitations in protein quality, poor iron availability, and low concentrations of vitamin A.

All species can be poisoned by gossypol. Mature ruminants are more resistant to its effects (probably a result of ruminal degradation) than monogastric animals.²¹⁵⁻²²² The toxicity of free gossypol depends on the quality of the ration and the amount of stress on the animals. For example, although swine may develop toxicity at free gossypol levels in excess of 0.01% in the total ration,^{216,220-223} supplementation of rations with iron and high-quality (lysine) protein will raise the tolerated level to 0.02% to 0.04%.²¹⁶ Although adult ruminants tolerate more than 0.1% to 0.2% of free gossypol in the total ration, some animals may be poisoned at the lower levels if stressed or on a poor ration.^{215,219,220} Adult bulls may develop infertility at these levels. Young adult cattle, under conditions of stress and marginal rations, may be sensitive to as little as 0.05% free gossypol in the total ration (perhaps from binding of protein as well as direct toxicity).²¹⁵

Gossypol effects are cumulative. Low levels of gossypol, if in a ration limited in iron or protein, may cause ill-thrift and poor weight gains in swine, baby calves, and young adult cattle (<1 year of age). Acute gossypol toxicosis results in dyspnea, violent labored respirations ("thumping" in swine), weakness, and

death (see Chapter 14).^{215,216,220,221,223} Signs may appear suddenly after stress, making gossypol toxicosis resemble acute shipping fever.²¹⁵ Adult ruminants may have decreased milk production, anorexia, dyspnea, weakness, gastroenteritis, decreased humoral immune response, and reproductive failure (impaired spermatogenesis in bulls).^{215,219,224,225} Although the level in feed required to cause clinical reproductive failure in cows is not yet known, laboratory evidence suggests that high levels of gossypol may also impair reproductive performance in females.²²⁶ However, these findings must be balanced with the benefits to lactation and milk quality from feeding a moderate level of cottonseed to dairy cows. Lesions of acute gossypol toxicosis include large amounts of yellow proteinaceous fluid in all body cavities, myocardial degeneration and necrosis (pale streaks in the heart), and liver necrosis (centrilobular pattern).

Analysis of feed for free and bound gossypol levels will support a diagnosis of gossypol poisoning. Sperm morphology is adversely affected in bulls, with high levels of proximal droplets observed.²²⁷ In addition, modern high-performance liquid chromatography (HPLC) methods can detect gossypol in some animal-related samples.

There is no specific treatment for acute gossypol toxicosis. Some evidence suggests that feeding of vitamin E may help control some gossypol effects in young animals, although vitamin E will not prevent toxicosis.²²⁸ The total ration for monogastric animals and swine should contain no more than 0.01% of total gossypol.^{215,216,221,223} Slightly higher levels may be fed successfully to swine if dietary protein and iron are adequate.^{215,216,229} Cattle that are less than 1 year of age should have adequate nutrition and minimal stress if being fed more than 0.05% to 0.1% of free gossypol. Adult ruminant cattle should have less than 0.1% to 0.2% of free gossypol in the total ration (avoid cottonseed products in bulls). Lactating dairy cattle should be fed no more than 6 to 8 lb (2.7 to 3.6 kg) of cottonseed per day.^{219,220} Infertility in bulls will take 1 to 2 months on feed that has no gossypol to recover.²²⁷

■ TANNINS

Quercus spp.: Oak

Oaks are trees and bushes that have characteristic multilobed leaves and bear acorns in the autumn. Oaks are common in the United States, especially in Texas and California (60 species in North America).²³⁰ They contain variable amounts of toxic, complex, and hydrolyzable tannins.²³¹⁻²³³ The hydrolyzable tannins are astringents and apparently bind the proteins in plasma and organs, which causes coagulation and necrosis.²³⁴ *Acorn calf syndrome*, a deformity in calves of cows eating oak, may have a nutritional mechanism and is completely different from the syndrome discussed here.²³⁵

The hazard of oak toxicity parallels the tannin content of plant material.²³⁶ Plants tend to have the highest tannin content in the spring during the budding stage, and acorns may have high tannin levels in the fall.²³¹ All livestock may be poisoned by oak tannins. Signs generally appear after 3 days of initial ingestion of the oak. Losses from oak result from gastroenteritis, renal failure, liver damage, death, and deformities of calves.^{230,234,235,237} Clinical effects in cattle include rumen atony, anorexia, constipation with black feces, lethargy, icterus, hematuria, dehydration, and evidence of renal failure.^{230,234} (See Chapter 32 for further discussion of oak toxicosis.)

■ SOLUBLE OXALATES

Halogeton glomeratus: Halogeton or barilla
Sarcobatus vermiculatus: Greasewood

Rumex crispus: Curly dock

Setaria sphacelata: Setaria

Rheum: Rhubarb

Oxalis: Sorrel or soursob

Kochia scoparia: Fireweed, summer cypress (also nitrate, secondary photosensitizing agent, and sulfate)

Many oxalate-bearing plants grow in disturbed or arid soils.²³⁸ Soluble oxalate in acidic plants such as *Oxalis* is present as the potassium salt. Sodium salts of oxalate are present in plants such as halogeton that grow at more neutral pH levels.²³⁹ Proposed mechanisms of acute poisoning from soluble oxalates include hypocalcemia, GI irritation, and inhibition of respiratory enzymes. Subacutely, oxalate is deposited as insoluble, birefringent crystals in kidneys, leading to renal failure. Chronic oxalate poisoning resulting from *Setaria* may lead to calcium deficiency with relative hyperphosphatemia.^{239,240} Insoluble calcium salts of oxalate are present in plants such as *Dieffenbachia* and *Philodendron* species. Those insoluble calcium oxalates are not absorbed, but they do act as potent local membrane irritants.

Oxalate-bearing plants are bitter and not ingested unless grazing is forced. All species are poisoned by oxalate, although historically sheep have been the most frequent victims.²³⁹ Rumen flora adapt to oxalate in forage if animals are gradually acclimated to oxalate over 4 days.²⁴¹ Poisoning occurs when hungry animals that are unaccustomed to oxalate ingest the plants in large quantities.^{236-240,242} Soluble oxalate toxicosis results in labored breathing, ataxia, rumen stasis and bloat, depression, weakness, coma, and death.^{239,241} Horses chronically grazing setaria develop "bighead," which is associated with a low calcium/phosphorus ratio.

Soluble oxalate-related changes in serum parameters reflect hypocalcemia or uremia. Postmortem lesions include hemorrhage and edema of the rumen wall and kidneys. Refractile crystals are found in the kidneys and rumen wall. Renal tubular necrosis and rumenitis are the major lesions, along with the presence of crystals.^{239,240,242} Analytical tests are available for oxalate in plant and animal-related samples.

Treatment of oxalate toxicosis is for gastroenteritis, shock, and renal failure. Gradual acclimation of ruminants to forages containing soluble oxalates and providing adequate levels of clean water may help prevent clinical disease.

■ WHITE SNAKEROOT

Eupatorium rugosum: White snakeroot

Haplopappus wrightii: Desert haplopappus; perhaps also

H. heterophyllus and *H. acradenius*

White snakeroot is a perennial that grows in clumps from clusters of snakelike roots in shady, wooded areas in the midwestern United States. The leaves are opposite and have three characteristic veins on the underside.²⁴³ The plant tends to remain green when other plants have dried. The toxin of white snakeroot has not been identified but is extractable with a ketone and sterol-rich fraction, called collectively *tremetol*.²⁴³ The toxins may require microsomal activation in animals.²⁴⁴

White snakeroot (fresh or dried) is hazardous to all species studied, although lactating animals are resistant because of rapid excretion of the toxins in milk.^{243,245-248} The hazard to grazing animals is highest when other forages have dried during the winter season or conditions force overgrazing. Feeding of 1% and 2% of body weight of the plant to horses resulted in toxicity after 1 to 2 weeks.²⁴⁵ White snakeroot toxicosis causes cardiac and skeletal muscle damage along with ketosis.²⁴³ Clinical signs include weight loss, tremors and stiffness, ataxia, depression, cardiac

arrhythmias (especially ST segment depression), recumbency, and death (within hours of recumbency).^{243,245,247-249} Sudden death is possible (see Chapter 14).

Clinicopathologic alterations include ketosis (many have breath smelling of acetone) and increased serum activities of CK, LDH, ALP, and AST.^{243,245-247} Lesions of white snakeroot toxicosis include pale streaking in the heart with multifocal myocardial degeneration, necrosis, and mineralization.²⁴⁵ Skeletal muscle necrosis also may occur, especially with the *Haplopappus* species. The liver may have centrilobular degeneration and necrosis. Diagnostically, white snakeroot poisoning should be differentiated from selenium deficiency and ionophore toxicosis. Treatment for white snakeroot toxicosis is supportive. Milk from exposed animals is hazardous and should not be fed or consumed.

■ OTHER TOXIC ALCOHOLS AND ACIDS

Agropyron desertorum: Crested wheatgrass; many rapidly growing forages (plant acids such as transaconitic acid)

Lush, early growth of many forages, including crested wheatgrass, can contain acid compounds that sequester magnesium. Ingestion of the plants during this lush stage can lead to hypomagnesemia in cattle, including tetany (see Chapter 41).²⁵⁰

Pinus ponderosa: Ponderosa pine

Pinus radiata: Monterey pine

Juniperus communis: Juniper

Ingestion of pine needles by pregnant cows during late gestation causes abortions or birth of weak calves, with digestive upset and lethargy in cows. The abortions are characterized by retained placentas and metritis. Many cows may die from effects of metritis. The toxins in ponderosa pine include isocupressic acid esters along with a unique class of vasoactive lipids. The major lesion of pine needle abortion is necrosis in the placental trophoblast region, perhaps also resulting from reduced uterine blood flow.²⁵¹⁻²⁵⁸

Cicuta spp.: Water hemlock

Asclepias fascicularis: Whorled milkweed

A. labriformis: Labriform milkweed

A. subverticillata: Narrow-leaved milkweeds

Water hemlock and some of the more toxic narrow-leaved milkweeds contain convulsant resins. Most of the toxicity of water hemlock lies in the resins of the chambered root. Ingestion of less than 0.2% to 0.5% of an animal's body weight of either plant may be lethal. Signs of toxicosis (in all species) may appear within 15 minutes of ingestion and include nervousness, excessive salivation, weakness, tremors, violent convulsions, and death. Postmortem lesions include skeletal muscle and myocardial necrosis, perhaps associated with seizures. Administration of sodium pentobarbital at the onset of signs can result in recovery.²⁵⁹⁻²⁶²

Hypericum perforatum: St. John's wort (hypericin)

Fagopyrum esculentum: Buckwheat (fagopyrin)

The toxins of St. John's wort (a weed of disturbed areas) and buckwheat (an off-season cover crop used for forage) are primary photosensitizing toxins (see Chapter 40).²⁶³

Tetradymia spp.: Horsebrush (tetradymol; requires *Artemisia nova* or *A. tridentata*: Black or big sages to induce toxicosis)

Ingestion of horsebrush by sheep, plus black sage (contains a sesquiterpene lactone), at levels of 1% of body weight, can cause hepatogenous photosensitization (see Chapter 40). The tetradymols are bioactivated in the liver to toxic substances that, among other mechanisms, uncouple oxidative phosphorylation.^{264,265}

Miscellaneous Toxic Plants

■ NITRATES

Sorghum spp.: Sorghum, Sudan grass

Avena spp.: Oat

Amaranthus spp.: Pigweed

Beta spp.: Beets

Solanum spp.: Nightshades

Zea mays: Corn

Various fertilizers, water runoff

Toxic levels of nitrate and nitrite are found in forage, water, and many fertilizers. Sources in water include biologic runoff, industrial effluents (nitrite in water from ponds near oil wells), and fertilizer. Nitrate is reduced to nitrite in the rumen. Nitrite converts hemoglobin (Fe^{2+}) to methemoglobin (Fe^{3+}), which does not bind or transport oxygen, leading to hypoxia.²⁶⁶

Although many of the listed forages are widely used for animals, environmental conditions such as drought, plant stress, rapid growth spurts, some herbicide uses, low light, and fertilization can lead to nitrate accumulation.²⁶⁷ All animals are sensitive to nitrite. Ruminants are 10 times more sensitive to nitrate than monogastric animals because the rumen reduces nitrate to nitrite.^{266,268} Forage containing a nitrate concentration of 1% (dry weight) may be lethal in cattle not acclimated to it.²⁶⁶ Acute toxicosis can result from nitrate in water at levels over 0.12%.²⁶⁶ Levels exceeding 0.5% in forage and 400 ppm in water may be hazardous to pregnant cattle.²⁶⁶ Clinical nitrate toxicosis appears within 4 hours of exposure. Signs include polypnea, dyspnea, weakness, tremors, intolerance to exercise, and terminal convulsions; death is possible within hours (see Chapter 14).^{266,268} Mildly affected cattle may recover spontaneously. Abortion may occur in mild, or apparently nonclinical, cases in cattle within 5 days of exposure (half-life of nitrite in fetus is greater than three times that of adults).^{268,269} Hypoxic stress in the fetus may aggravate other causes of abortion.

Cattle with nitrate poisoning will have chocolate-brown blood (>30% methemoglobin). Postmortem findings are nonspecific. A diagnosis of nitrate toxicosis is supported by finding greater than 45 ppm of nitrate in ocular fluid or serum, along with identification of a toxic level of nitrate in forage or water.

Clinical cases respond well to administration of methylene blue (5 to 15 mL of a 1% solution) by intravenous injection.²⁶⁶ Prevention of nitrate toxicosis requires proper harvest of forage and gradual acclimation of ruminants to potential high-nitrate-type forages.

■ SELENIUM (INDICATORS LISTED)

Stanleya pinnata: Prince's plume

Astragalus bisulcatus: Two-grooved milk vetch

Xylorrhiza spp.: Woody asters

Most common forages under conditions favorable to passive assimilation of selenium

The listed plants are called "selenium indicator plants" because of their requirement for high selenium levels in soil for growth.^{26,270} Although these plants are not palatable because of a garlicky odor, they indicate the presence of selenium. In the presence of arid, alkaline soil, selenium also may be accumulated in toxic levels in a variety of common forage plants and consumable weeds (alfalfa, *Asteraceae*, *Castilleja*, *Atriplex*). Selenium, an essential element (see Chapter 40), can cause both peracute toxicosis from oversupplementation in feed or injection²⁷⁰⁻²⁷³ or chronic toxicosis at lower levels.^{26,270,274} The mechanism of acute selenium toxicity is unknown but may involve direct effects

of organoselenium compounds on cell energy production.²⁷⁴ The mechanism of chronic selenium poisoning is related to its replacing or interacting with sulfur in structural amino acids needed for cross-linking (cysteine or methionine).^{270,274}

All species may be affected by selenium toxicosis. Acute toxicosis is caused by oversupplementation of feeds containing selenium, ingestion of indicator plants (10,000 ppm of selenium), or injection of excessive selenium (0.4 mg/kg of body weight was lethal to lambs). Signs include weakness, dyspnea, bloating, abdominal pain with diarrhea, paresis in some species, and shock and death from respiratory failure.²⁷²⁻²⁷⁶ Animals, especially horses, with chronic alkali disease from selenium in forage (5 to 50 ppm dry weight in forage is toxic) develop ill-thrift, anemia, stiffness, lameness, loss of mane and tail, and deformation and sloughing of hooves.^{26,270,274} Cattle with chronic selenosis may also develop hoof lesions, develop immune incompetence, and if pregnant, may give birth to nonviable calves.^{277,278} Neurologic diseases often reported, such as "blind staggers," are probably not caused by selenosis and may have resulted from ingestion of related locoweeds.²⁷⁷

Lesions of selenium toxicosis vary based on dose and duration of disease. Peracute toxicosis leads to widespread organ congestion, cardiac damage, and severe pulmonary edema.²⁷²⁻²⁷⁴ Chronic selenosis results in articular erosions and deformed, sloughed hooves in horses with loss of longer mane and tail hair.^{26,271,274} Selenium in feed should not exceed 1 to 2 ppm dry weight. Selenium in whole blood should range between 0.08 and 1.0 ppm and, in liver, from 0.25 to 1.0 ppm for most normal animals. After exposure to excessive selenium is terminated, tissue levels may return to normal well before clinical signs dissipate, leading to a false-negative finding (hair testing may be beneficial to diagnose chronic selenosis).

No specific treatment is recommended for chronic selenosis. Reportedly, feeding of proteins that are high in sulfur-containing amino acids may be beneficial.²⁷⁰ Food animals poisoned with selenium may require at least 60 days to clear the excess selenium.²⁷⁹

■ SULFUR-CONTAINING PLANTS

Brassica rapus: Turnip

Kochia scoparia: Fireweed, summer cypress (also nitrate, secondary photosensitization)

Certain plants, feed mixes, and water can contain high levels of sulfur. In general, the total amount of sulfur intake for a ruminant should contain no more than 0.4% of sulfur overall. High levels of sulfur as sulfate may contribute to copper deficiency (see Chapter 32) and can cause polioencephalomalacia in ruminants, as can other forms of sulfur.

In the ruminant and perhaps the horse, ingestion of excess sulfur in water, feed, or from grazing plants such as turnips that can accumulate sulfur, intestinal microbes (rumen or large bowel) may produce excess sulfide. The excess sulfides can cause polioencephalomalacia as they are rapidly absorbed. Clinical signs of polioencephalomalacia include characteristic CNS disease with blindness (see Chapter 35).

Diagnosis of sulfur toxicosis requires testing of all potential sources of sulfur, including feed, pasture, and water, in addition to finding of signs and lesions characteristic for polioencephalomalacia. The differential diagnosis for sulfur toxicosis includes other causes of polio, salt toxicity, water deprivation, lead poisoning, and other infectious causes of neurologic disease in cattle.²⁸⁰

■ PNEUMOTOXIC PLANTS

Perilla frutescens: Perilla mint (perilla ketone)
Rapidly growing forages accumulate tryptophan.

Ipomoea batatas: Moldy sweet potato (4-ipomeanol)

Phaseolus vulgaris: Moldy green beans

Lush forage ("foggage") and possibly feeds that are high in tryptophan, toxic plants (seed and flowering stage of perilla mint), moldy sweet potatoes (infected with *Fusarium solani* mold), and moldy green beans (*Fusarium semitectum*) can cause interstitial pneumonia in animals (see Chapter 31).²⁸¹⁻²⁸⁶ The toxins include the listed pneumotoxic ketones and 3-methyl indole, a rumen metabolite of excessive tryptophan.^{284,287,288} Despite some diversity of structure, the toxins are metabolized by the mixed-function oxidases in pulmonary type I pneumocytes and nonciliated bronchiolar epithelial cells (Clara) to highly cytotoxic free radicals, leading to damage to local alveolar and, perhaps most important, endothelial cells.²⁸¹⁻²⁹³ These oxidant pneumotoxins also deplete cellular antioxidation factors such as glutathione in the liver and lung.²⁸⁹

Ruminants, especially cattle, are at risk of developing 3-methyl indole toxicosis when moved suddenly from dry feed to a lush pasture.²⁸⁴ Unexplained isolated incidents of interstitial pneumonia also occur in feedlot cattle (perhaps from a change in flora or feed tryptophan). Feeding of moldy sweet potatoes or moldy green beans is also hazardous.²⁸¹⁻²⁸³ Perilla mint has pneumotoxic ketones in highest concentrations during the flowering and seed stages.²⁸⁵ Toxicity is retained in dry plant material.²⁸⁵ Clinical effects of these pneumotoxins include sudden onset of increased respiration, severe dyspnea with an expiratory grunt, frothing at the mouth with the head down, and open-mouth breathing.^{284,285} Animals may be found dead (see Chapter 14).

Affected cattle have wet, heavy lungs with variable amounts of emphysema. Histologically, the lungs have severe interstitial edema. Ultrastructural studies reveal degeneration and necrosis of type I pneumocytes, endothelial cells, and Clara cells, with proliferation of type II pneumocytes in longer-standing cases.^{281,282,284,290-295} Perhaps a result of differential bioactivation rates, the major lesion in the horse is bronchiolitis (not alveolitis).²⁹⁶ The extremely short half-life of 3-methyl indole (14 minutes)²⁸⁸ in cattle has hindered development of diagnostic tests. Specific treatment for toxic interstitial pneumonia is not available.

■ OTHER NOTABLE TOXIC PLANTS

Allium spp.: Onions, garlic, chives

Brassica spp.: Kale, beets, rape, cabbage, turnips (hemolytic disulfides)

Acer rubrum: Red maple (unidentified hemolytic toxin)

The onions and brassica plants contain S-methylcysteine sulfoxide, which is metabolized to dimethyl disulfide, which attacks red blood cell (RBC) membranes. Onions and Brassicaceae are toxic to a variety of species, whereas red maple poisoning is reported in horses. Signs in poisoned animals include lethargy, anorexia, dyspnea, coffee-colored urine, icterus, hypoxic abortion, and shock. Death results from respiratory failure secondary to anemia. Affected animals have hemolytic anemia with hemoglobinuria, Heinz bodies, and increased levels of AST, sorbitol dehydrogenase, plasma protein, and bilirubin. Postmortem findings may include icterus, brownish discoloration of blood, centrilobular hepatic degeneration, and hemoglobinemic nephrosis. Note that ruminants such as sheep may adapt to an onion diet because the rumen appears to quickly develop a population of sulfide-reducing bacteria to decrease the hemolytic forms of sulfur.²⁹⁷⁻³⁰⁴

Amaranthus retroflexus: Pigweed (renal toxin)

In addition to the potential to cause high levels of nitrate when in hay, redroot pigweed also can be toxic to kidneys when grazed fresh in the field. Cattle and swine have developed signs of renal failure, including weakness, tremors, ataxia, recumbency, and death after grazing the plant for 5 to 10 days. Serum potassium, BUN, and creatinine concentrations are increased. Lesions include marked perirenal edema (may be bloody), straw-colored fluid in body cavities, and pale kidneys with histologic evidence of degeneration and necrosis of both proximal and distal tubules. Tubules have proteinaceous, cellular casts.³⁰⁵⁻³⁰⁷

Cassia (*Senna*) *occidentalis*, *C. obtusifolia*, *C. roemeriana*: Senna

These annual shrubs of the southeastern United States contain an unknown myotoxin(s) in all plant parts, but the seeds are most hazardous. Signs of toxicosis may occur in all livestock grazing the plant and include anorexia, ataxia, weakness, intense decrease in weight gain, and recumbency. Clinicopathologic abnormalities may include increased serum levels of CK and AST and myoglobinuria. Postmortem findings include degeneration and necrosis of skeletal and cardiac muscle. Goats and cattle given *Cassia roemeriana* may also have hepatocellular damage.³⁰⁸⁻³¹³

Centaurea solstitialis: Yellow star thistle

C. repens: Russian knapweed

These plants contain sesquiterpene lactones such as the cytotoxic repen, along with aspartic and glutamic acids, all of which are potent neurotoxins. Prolonged ingestion of large amounts (>1.8 kg/100 kg body weight daily) of these plants by horses may result in neurotoxicity. The principal sign of toxicity is dysphagia, characterized by dystonia of the lips and tongue. Lethargy and aimless walking are also reported. Lesions include characteristic foci of necrosis in the globus pallidus and substantia nigra (bilateral) of the brain (nigropallidal encephalomalacia). Yellow star thistle is an aggressively growing plant that is difficult to control. Biologic measures, including introduction of rust and insects, have been considered as control measures. Prevention includes providing adequate alternative feeds.³¹⁴⁻³¹⁷

Helenium spp.: Sneezeweed

Hymenoxys richardsonii: Bitter rubberweed (sesquiterpene lactones)

These weeds of the Rocky Mountains and southwestern United States are unpalatable but may be ingested by sheep or goats in the winter when other forage is limited. Sesquiterpene lactones bind with sulfhydryl groups (cysteine), leading to an extreme irritant effect on the nose, eyes, and GI tract. Affected animals develop severe gastroenteritis (sneezeweed toxicosis is called "spewing sickness" because of vomiting), often with secondary aspiration pneumonia. Affected animals may have increases in serum γ -glutamyltransferase (GGT), AST, creatinine, and BUN. Postmortem lesions include gastroenteritis, congestion of liver and kidney, and aspiration pneumonia. Administration of thiol groups (cysteine, protein, methionine) and antioxidants are protective.³¹⁸⁻³²²

Juglans nigra: Black walnut

Horses exposed to fresh black walnut (as little as 5% in shavings used as bedding; possibly also plant) can cause a transient drop in leukocytes, limb edema, and laminitis. The toxin of black walnut is unknown but is not the naphthoquinone juglone, as originally thought. An unknown quinone is suspected. Treatment is removal of offending shavings and traditional therapy for acute laminitis in horses. Rotation of the third phalanx is possible in severe cases.³²³⁻³²⁵

Berteroa incana: Hoary alyssum

Toxicosis with hoary alyssum, a potential weed contaminant of alfalfa hay, is characterized by fever, limb edema, and laminitis in horses.³²⁶ The toxin is unknown.

Karwinskia humboldtiana: Coyotillo

Rhamnus spp.: Buckthorn (neuromuscular toxins)

Coyotillo is a woody shrub from the southwestern United States that may cause toxicosis in cattle, sheep, goats, hogs, and fowl when other forages are scarce. Ingestion of small amounts of the fruit and seeds leads to weakness, incoordination, and eventually paralysis. The onset of signs is delayed for days to weeks after exposure. Lesions include segmental demyelination (wallerian degeneration) of nerve axons. Ingestion of the green parts of the plant may lead to wasting, weakness, and death. Lesions associated with the extraneural syndrome of coyotillo poisoning include necrosis of the myocardium, liver, and kidney, and pulmonary hemorrhage.³²⁷⁻³²⁹

Hypochoeris spp.: Flatweed or smooth catsear

Lathyrus spp.: Pea

Ingestion by horses of plants such as flatweed, especially in conditions of overgrazing, is suspected as causing outbreaks of Australian stringhalt. *Stringhalt* is a distal axonopathy characterized in horses by an unusual gait with hyperflexed hock during movement, reluctance to back up, and in some reports a high incidence of roaring. The etiology is unknown for flatweed. *Lathyrus* neurotoxicity is well described (neurotoxic amino acid derivatives, β -*N*-oxalylalano-L-alanine).³³⁰⁻³³³

Persea americana: Avocado (persin)

Plant matter from avocado trees (primarily the Guatemalan varieties, from most reports) has caused aseptic mastitis, myocardial necrosis, and skeletal muscle lesions with edema. Aseptic mastitis with epithelial necrosis in the mammary gland has been reported in cattle, horses, and goats (an ischemic myotoxin, persin is toxic to the mammary gland). Myocardial necrosis (with widespread edema, including the brisket) has been reported for goats, sheep, horses, and avians including raptites (sudden death with fluid accumulation in avians). Horses develop edema of the lips, tongue, mouth, and neck, along with lethargy and colic. Serum factors increased with avocado toxicosis include CK, AST, and LDH.³³⁴⁻³⁴¹

Ricinus communis: Castor bean

Robinia pseudoacacia: Black locust

Abrus precatorius: Rosary pea (the lectins: ricin, robin, and abrin)

The lectins in the listed plants are glycoprotein dimers, joined by a disulfide bond in ricin and abrin. Seeds, cakes, and foliage are poisonous, but not the oil. A portion of the dimer, the haptomer, binds the cell, allowing the other half to enter and block protein synthesis. All classes of livestock are sensitive to the compounds. Ricin and abrin are among the most potent toxins described. Clinical toxicosis reflects primary damage to the GI tract and includes violent gastroenteritis followed by weakness and death from shock and depression of cardiac function. Other poisonous lectins, although less acutely toxic, are found in legume seeds from a variety of unextracted beans. Those factors interfere with intestinal absorption, inhibit growth, and can inhibit the immune system.^{342,343}

Vicia villosa: Hairy vetch

Cattle and horses grazing hairy vetch when it is green may develop a systemic granulomatous disease. Dried seeds may cause convulsions (apparently unrelated to the immunotoxic syndrome discussed here) in cattle. Prior sensitization may be required for development of clinical signs of systemic granulomatous disease in animals exposed to green vetch. Initially, animals are presented for listlessness and welts on the skin, with alopecia and peeling of skin around the nares. Horses may have lymphadenomegaly and dependent edema. Affected animals may develop wasting, diarrhea, and clinicopathologic changes

of lymphocytosis and hyperproteinemia. Mortality may be high in affected animals. Postmortem, skin is thickened with scaling and alopecia. Other organs that may be pale or may have gross abnormalities include the heart, kidneys, adrenals, and lymphoid tissues. Microscopically, the skin and other organs, including the liver, have cellular infiltrations of monocytes, lymphocytes, plasma cells, eosinophils, and often, multinucleated giant cells. The mechanism of hairy vetch toxicosis is not known but may involve an immunotoxic lectin.³⁴⁴⁻³⁴⁸

Setaria lutescens: Yellow bristlegrass

Other foxtails (mechanical trauma)

Yellow bristlegrass contains sharp, miniature barbs below the seed heads that can cause mucosal trauma, including oral ulcers, in animals ingesting contaminated hay. Horses and young cattle are most frequently affected.

Xanthoparmelia: Lichen

Ingestion of large amounts of lichen growing in the desert during winter has caused paralysis in sheep and Rocky Mountain elk. The paralysis resembles a lower motor neuron failure, but the mechanism of toxicity has not yet been determined. The toxin is not well characterized, although usnic acid has been implicated as causing part of the syndrome.³⁴⁹

■ BLUE-GREEN ALGAE (FRESHWATER)

Microcystis aeruginosa: (microcystin, a hepatotoxic cyclic peptide)

Nodularia spumigena: (nodularin, a hepatotoxic cyclic peptide)

Anabena flos-aquae: (anatoxin-a, a depolarizing neurotoxin; anatoxin-a[s], a cholinesterase inhibitor)

Aphanizomenon flos-aquae: (saxitoxin, neosaxitoxin, blockers of neural transmission)

Potentially toxic blue-green algae (cyanobacteria) may form on stagnant bodies of water under conditions of heat, eutrophication (high nitrogen and nutrients), low flow rates, oxidative stress, and a concentrating wind.³⁵⁰⁻³⁵² The cyclic peptide hepatotoxins cause dissociation of the cytoskeleton of the liver through inhibition of protein phosphatase and induction of apoptosis, leading to disintegration of that organ.³⁵³⁻³⁵⁵ Anatoxin-a is a bicyclic, secondary amine that causes depolarization of nicotinic receptors, leading to muscle and respiratory paralysis.^{351,356} Anatoxin-a(s) is a naturally occurring organophosphorus-like compound that inhibits peripheral cholinesterase.^{351,357} Saxitoxin and neosaxitoxin cause paralysis by blocking neural sodium transport.³⁵¹ A variety of cyanophytes cause skin and GI irritation.

All species are sensitive to the listed algae, which, if ingested in sufficient quantities, may cause sudden death (see Chapter 14). Animals exposed to high doses of the cyclic peptide hepatotoxins may die within 1 hour of exposure from hypovolemia and shock secondary to blood loss into the disintegrated liver and embolism of hepatocytes into the lung.^{350,351,353,354} Lower doses lead to characteristic signs of liver failure. Exposure to a toxic dose of anatoxin-a leads to tremor, collapse, exaggerated breathing efforts, convulsions, and death within minutes.^{351,356} The paralysis is persistent and not responsive to assisted ventilation.³⁵⁶ Anatoxin-a(s) also can kill in minutes after exposure. Characteristic signs of cholinesterase inhibition in the periphery include diarrhea, tremors, hypersalivation, dyspnea, paresis, opisthotonos, cyanosis, convulsions, and death.^{351,357}

Animals with hepatotoxic blue-green algae toxicosis may have elevations in liver-associated serum factors including AST, GGT, ALP, and bilirubin, as well as creatinine, BUN, and LDH. Hepatotoxic lesions include enlarged, red-

blue-colored livers with gallbladder edema. Histologic alterations include severe centrilobular hepatocellular dissociation, degeneration, and necrosis. Only a rim of hepatocytes around the periportal triads may remain.^{350,351,353,354} Hepatocyte emboli may be found in the lung.³⁵⁴ Mild renal tubular degeneration may occur. Animals with anatoxin-a(s) toxicosis will have depression of peripheral cholinesterase, although brain cholinesterase may be normal.³⁵¹ Otherwise, pathologic changes in animals with neurotoxicosis reflect hypoxemia and are nonspecific.

If blue-green algae toxicosis is suspected, samples of ingesta and bloom can be mixed with 10% neutral-buffered formalin for visual identification. Samples should be accompanied by at least 2 L of fresh bloom material (refrigerated) for demonstration of the toxin or toxicity. Liquid chromatography of bloom material or ingesta may be useful to help diagnose poisoning from the *Microcystis* toxins.³⁵⁸

Treatment for blue-green algae poisoning is supportive. Artificial ventilation is required for anatoxin-a toxicosis. Exposed animals might benefit from oral adsorbents such as activated charcoal.³⁵⁰ Exposure of cattle to *Microcystis* toxins does not appear to cause a food safety risk when tested in liver and blood plasma.³⁵⁹

MYCOTOXINS

A mycotoxicosis is a disease caused by a toxin elaborated by a fungus, unlike a mycosis, which is a disease caused by fungal growth (not its toxins). Mycotoxins may be endomycotoxins (mushrooms, not discussed here) or exomycotoxins (this discussion). Mycotoxins are of worldwide veterinary and public health concern. Diseases caused by mycotoxins include acute and chronic poisoning, immunosuppression, loss of production, carcinogenicity, and teratogenicity.

Many genera and species of fungi are toxigenic. A given mycotoxin may be elaborated by more than one fungal species. Some species of fungi may produce more than one toxin. Conversely, a given fungus may not always be toxic (many are ubiquitous), so finding the fungus alone is rarely diagnostic; diagnosis requires chemical identification of the toxins. Colonization and toxin elaboration may occur in the field or in storage. Basic requirements for colonization include substrate with sufficient nutrients (why fruits and seeds are often infested), moisture content in feed greater than 14%, relative humidity over 70%, appropriate temperature (varies with species of fungus), and oxygen. Damage to fruits and plants favors colonization as well. Basic requirements for toxin elaboration may vary from those needed for colonization.

Mycotoxins are found in a variety of matrices, including cereal grains, other crop feeds such as beans, and grass and forage. Mycotoxins cause billions of dollars of losses worldwide from crop losses, animal and human sickness, reduced production, and costs of control measures. Although many toxins have been identified, many more, as yet unidentified, toxins may still exist. For example, moldy hay has been implicated as a cause of many problems, including GI disturbances, liver disease, and photosensitization, but many of those toxins have not been identified. Little testing is possible for mycotoxins in animal samples. Therefore, testing is best performed on suspected source feed. The sampling technique is critical because toxin levels will vary greatly within a lot of feed; samples should be representative of the lot and frozen for storage. Importantly, feed contaminated with mycotoxins may not be visibly moldy. Some mycotoxins are discussed earlier with plants (moldy sweet potatoes and moldy sweet clover hay). Other important mycotoxins of livestock are discussed here.³⁶⁰⁻³⁶³

Aflatoxins

Many fungal species can produce aflatoxins, including *Aspergillus flavus* (A + fla + toxin), *Aspergillus parasiticus*, and various species of *Penicillium*, *Rhizopus*, *Mucor*, and *Streptomyces*. Colonization and toxin production can occur in grains such as corn, cottonseed, and peanuts in all phases from growth through harvest. Aflatoxins are produced in soybeans and other small grains, mainly during storage. Aflatoxin production is encouraged when warm, moist ambient conditions are combined with crop damage (drought or storm). Although many aflatoxins exist, the major toxins of concern include aflatoxins B₁, B₂, G₁, G₂ (B or G = fluorescence color), and the major marker metabolite in milk and meat, aflatoxin M₁.^{361,363} After bioactivation in the liver, aflatoxins act by binding of biologic molecules such as essential enzymes, blockage of ribonucleic acid (RNA) polymerase and ribosomal translocase (inhibiting protein synthesis), and formation of DNA adducts.^{363,364}

Aflatoxin can cause oncogenesis, chronic toxicity, or acute signs, depending on the species and age of animal and the dose and duration of aflatoxin exposure. All animals may be affected by aflatoxins (birds and trout are more sensitive than mammals, possibly because of increased activation of aflatoxin B₁ in the liver and deficient detoxification mechanisms).³⁶⁵ Among mammals, young swine and pregnant sows are most sensitive to aflatoxins, followed by calves (0.2 ppm in feed for 16 weeks caused mild liver damage), horses (0.4 to 0.6 ppm), fat pigs, mature cattle (0.66 ppm in feed caused mild liver damage after 20 weeks), and sheep.^{361,366} Levels over 1 ppm may cause severe organ damage and acute deaths in livestock. As little as 0.15 ppm of aflatoxin in the feed may lead to actionable residues of aflatoxin M₁ in meat and milk (action level is 0.0005 ppm in meat and milk and 0.02 ppm for interstate transport of grains).^{363,367} Aflatoxin in the diet of trout at 0.001 ppm is carcinogenic.³⁶³

Signs of peracute toxicosis include hemorrhage, bloody diarrhea, and rapid death.³⁶³ Lesions of acute toxicosis include hemorrhages and prolonged prothrombin time (PT). Subacute toxicosis may lead to hepatic failure with icterus, anorexia, ataxia, reproductive failure (abortion), weakness and tremors, slowed rumen motility, coma, and death.^{361,363,366,368-373} Impairment of immune function may also occur due to moderate levels of aflatoxin.^{363,372} Animals with aflatoxicosis-induced liver failure may have anemia, ascites, pallor, elevated liver-associated enzymes (ALP, AST, total bilirubin), and decreased albumin levels. Lesions include a pale-yellow liver with centrilobular to portal fatty degeneration and necrosis (species dependent) along with biliary hyperplasia.^{361,363,366,368-371} Chronic toxicity is associated with decreased growth rates, decreased feed efficiency, rough hair coats, ill-thrift, increased incidence of disease, and liver damage (fibrosis with regenerative nodules). Carcinogenesis may occur at low levels. Spermatogenesis may also be disrupted in animals exposed to aflatoxins.³⁷⁴ Experimental studies also suggest that aflatoxins may be present in grain dust in levels that may be bioactivated by pulmonary cytochromes to carcinogenic compounds.³⁷⁵ Testing of feed and liver for aflatoxin will support a diagnosis.

Aflatoxin B₁ is one of the most potent known carcinogens.^{361,363} Aflatoxins are distributed to tissues and milk of food animals, leading to a significant residue concern (aflatoxin M₁ is the marker residue).^{373,376} The highest concentrations of aflatoxin are in liver. Aflatoxin is cleared from the liver over 7 days of withdrawal, during which aflatoxin-free feed is provided.³⁷⁶ Dairy cows can "decontaminate" aflatoxin to below the 0.0005-ppm action level in milk

(United States; may be as much as 10 times lower for some trading partners, such as the European Union [EU]) if the maximum level of aflatoxin in feed is below 0.1 ppm (up to 300:1 dilution in the cow).³⁶³

Beyond providing aflatoxin-free feed and therapy for liver failure, treatment for aflatoxicosis centers on prevention. Feed has been ammoniated to prevent colonization and growth of fungi and to detoxify the aflatoxin. In emergencies, farmers may dilute feeds to nontoxic levels (risky).³⁶¹ Moderate levels of aflatoxins may be fed in combination with hydrated sodium calcium aluminosilicates (clay binders) to prevent aflatoxin absorption, toxicosis, and contamination in milk and meat.³⁷⁷⁻³⁸⁰ Clays should be carefully selected to avoid health risks from untested clays.³⁸⁰ However, experimental studies suggest that a common clay binder can be fed to laboratory animals without toxicity at levels of up to 2% of the diet.³⁸¹

Trichothecenes

The trichothecene mycotoxins are tetracyclic sesquiterpenoid toxins produced in grains (e.g., corn), and some forages, by at least six genera of fungi, the most important of which include various *Fusarium*, *Myrothecium*, *Stachybotrys atra*, and *Trichothecium roseum*. Growth of these fungi and toxin production is favored by undulating, cool temperatures.^{382,383} Trichothecenes may be present in combination with zearalenone. Toxins of major agricultural concern in the United States (in order of importance) include deoxynivalenol (DON or "vomitoxin"), T-2 toxin, stachybotryotoxin (can be in forage), and diacetoxycirpenol (DAS).^{361,382} The trichothecenes are potent inhibitors of protein synthesis, blocking initiation, elongation, and termination of ribosomal translation.³⁸² That mechanism leads to an effect that has been called *radiomimetic*, in which all rapidly dividing cells of the body are attacked, leading to severe gastroenteritis, skin necrosis, immune impairment, and initiation of shock.^{361,382,384}

All species of animals are sensitive to the trichothecenes. The effects of trichothecene mycotoxins depend on the toxin present, its concentration, and species exposed; dairy cows and other ruminants are much less sensitive than monogastric animals. Toxicity in field cases may be greater than that reported for experimental toxicity studies, probably because related trichothecenes are often present in the field along with the toxin being assayed. For example, 10 ppm of pure DON is needed to cause feed refusal in swine experimentally, whereas 0.5 ppm in field-contaminated grain may lead to feed refusal.^{382,383,385}

Dose-dependent signs of trichothecene toxicity include feed refusal, reduced weight gains, severe gastroenteritis with vomiting and diarrhea, coagulopathy and shock, skin necrosis (from direct contact), decreased reproductive performance, and immunosuppression.^{361,382,383,385-387} Clinicopathologic alterations for severe trichothecene toxicosis primarily reflect shock or hemorrhagic gastroenteritis and include decreases in hematocrit, hemoglobin, leukocytes, and serum factors of glucose, calcium, and phosphate.^{387,388} Bilirubin may be increased secondary to feed refusal.³⁸⁷ Transiently increased liver-associated serum factors include AST, LDH, and bromosulphalein (BSP) clearance. DON, the most common trichothecene in field cases, usually causes feed refusal, increased incidence of disease, and associated weight loss.³⁸⁵⁻³⁸⁸ Other trichothecenes are likely to cause more severe, acute signs of hemorrhagic gastroenteritis, shock, and death. Diagnosis of trichothecene mycotoxicosis is facilitated by finding the toxin in feed.

Toxicosis from DON is treated by providing mycotoxin-free feed. In addition to nonspecific therapy for signs, animals with acute trichothecene toxicosis with gastroenteritis

benefit from administration of oral adsorbents such as activated charcoal, along with fluid and steroid therapy for the acute shock.³⁸⁹ Broad-spectrum antibiotic therapy is indicated to minimize complications of skin lesions and gastroenteritis.³⁶¹ The trichothecenes are rapidly metabolized and would not be expected to be a residue hazard 12 to 24 hours postexposure.^{386,390,391}

Fumonisin

Fumonisin is hepatotoxic, neurotoxic, and carcinogenic mycotoxin produced by *Fusarium moniliforme*. These toxins are responsible for the disease known as "moldy corn poisoning" of horses, or equine leukoencephalomalacia.^{392,393} *F. moniliforme* is ubiquitous in the environment, so testing feed for the mold is not diagnostic. Fumonisin (A and B series; fumonisin B₁ most common) act in part by interfering with sphingolipid biosynthesis through inhibition of ceramide synthetase, among other mechanisms, by blocking protein synthesis and by causing apoptosis and oxidative damage in target tissues.³⁹⁴⁻³⁹⁶ Neural tube defects may be caused by fumonisins through blockade of folic acid transport.³⁹⁷ Fumonisin may predispose animals to infectious diseases, such as enhancing colonization of pathogenic *Escherichia coli* in the gut.³⁹⁸ Sphingolipids are critical for cell growth, differentiation, and transformation and are present in brain and liver tissues at high levels.

Fumonisin is produced mainly on corn, especially screenings. Although other species can be affected, horses and swine are most sensitive to fumonisin's effects. Ruminants and poultry are resistant.^{399,400} Fumonisin B₁ at levels of 10 ppm or greater may lead to toxicosis in horses (>40 ppm for swine). Clinical signs in horses appear suddenly after 7 to 90 days of ingesting toxic corn or screenings and may include depression, confusion, ataxia, sweating, apparent blindness, head pressing, recumbency, convulsions, and death within 5 days of onset of signs.^{392,393,401,402} Morbidity is generally low, but mortality rates in affected animals are high.

Clinicopathologic changes include transient increases in serum enzymes associated with liver damage. The pathognomonic lesion of fumonisin toxicosis in horses is *leukoencephalomalacia*, characterized by liquefactive necrosis of white matter of the brain, leaving fluid-filled cavities (often grossly visible).^{392,402} Acutely affected horses may have centrilobular hepatic necrosis, which may be present with or without the brain lesion.^{392,402} Some monogastric species may develop pulmonary edema.^{403,404} Diagnosis of fumonisin toxicosis is aided by finding 10 ppm or more of fumonisin in a corn-based concentrate or screened feed. Elevation of the sphinganine/sphingosine ratio in the urine is a very sensitive indicator of exposure to fumonisins. Assay for sphingolipids in urine may provide a marker for fumonisin exposure.⁴⁰⁵

Avoiding corn in the diet of horses, or at least eliminating corn screenings from the equine diet, will help prevent fumonisin toxicosis. Not much information is available regarding fumonisin as a food-animal residue. The compound is of concern, however, because it is a potent hepatocarcinogen.⁴⁰⁶ From a food safety standpoint, fumonisin is not apparently present in milk from exposed cows in appreciable quantities, possibly because of the low relative absorption of the compound by the rumen.⁴⁰⁷ Although fumonisin B₁ parent compound has a relatively short half-life in most studies (18 minutes), some evidence in swine suggests that accumulation may occur in kidney and liver tissue.⁴⁰⁷ Studies in swine suggest that fumonisins have little toxicologically significant carryover in tissues.⁴⁰⁸

Grassland Stagers

Stagers in livestock is caused by ingestion of forages that contain tremorgenic mycotoxins. Forages causing stagers include perennial ryegrass (*Lolium perenne*) infested with *Neotyphodium* (formerly *Acremonium*) *loliae* in leaf-sheathes, ergotized dallisgrass (*Paspalum dilatatum*; seed fungus is *Claviceps paspali*), Bermuda grass (*Cynodon dactylon*; mold unknown), *Phalaris* species (discussed earlier), moldy walnuts (*Juglans* spp.; walnut mold is *Penicillium* spp.), and although not a forage, *Aspergillus* species in grain.^{361,409-412} The toxins are alkaloidal, indole-based paxallines and include lolitrems (perennial ryegrass), paspalitrems (dallisgrass), tryptamine alkaloids (*Phalaris*), penitrems (moldy walnuts), and aflatrems (*Aspergillus*).^{361,409-413} The mechanism of action of these toxins is incompletely understood but may involve enhanced release of excitatory amino acid neurotransmitters.⁴¹⁴ In addition, annual grasses infested with a nematode that is subsequently infected by the bacterium *Clavibacter toxicus* may also be toxic from production of corynetoxins. Corynetoxins are glycolipids with structures and effects similar to tunicamycin compounds. Affected grasses include annual ryegrass (*Lolium* spp.), blowgrass (*Agrostis* spp.), and *Polyopogon*, especially in moist stubble and floodplains (sometimes called "floodplain stagers").⁴¹⁵

The toxicity of tremorgenic forages depends on grazing habits and climate. Perennial ryegrass tends to be most hazardous late in the grazing season, when grass is grazed low to the ground (lolitrems are found in lower leaf sheaths, so are more of a hazard for sheep).^{409,416,417} Dallisgrass is hazardous when ergotized seed heads are grazed (more of a hazard for cattle).⁴¹² All species exposed to the stagers toxins may be affected. Dried perennial ryegrass and ryegrass seeds may retain toxicity.^{417,418}

Signs of stagers appear within 7 days of initial grazing (within hours for penitrems in walnut).^{361,409} Animals appear normal at rest or may have a fine tremor in the ear and head. When stimulated, affected animals have a characteristic stiff, spastic gait, followed by spasms and tetanic seizures (opisthotonos occurs in severe cases).^{361,409,416,419} Recovery from an episode may be rapid for perennial ryegrass, dallisgrass, and Bermuda grass stagers if animals are not stressed. Losses occur, however, from misadventure (e.g., injuries, drowning, becoming trapped during seizure episodes).⁴⁰⁹ Seizure episodes dissipate within 2 weeks after animals are removed from the toxic forage. Annual ryegrass toxicity cases appear after floods or on grazing pastures with large amounts of stubble from the previous year. CNS signs include ataxia, convulsions, and other signs consistent with grassland stagers. Death often occurs within 24 hours.⁴¹⁵

Lesions of stagers are minimal, although degeneration of cerebellar Purkinje cells has been reported for longer-standing, severe cases of perennial ryegrass stagers.^{420,421} Postmortem, lesions from annual grass stagers from corynetoxins include a fatty liver and cerebellar degeneration.⁴¹⁵ Diagnosis of stagers syndromes is helped by ruling out other tremorgenic syndromes, identification of the fungus (e.g., for perennial ryegrass), and identification of the toxin in the plant (lolitrem B in perennial ryegrass).⁴⁰⁹ If forages are not available for analysis, bioassay using an extract of the forage in the laboratory can be diagnostic.^{409,422}

Alternate forage should be provided for affected animals until new pasture growth is available. Some managers move animals away from the toxic pasture during the sensitive periods. Affected animals are placed in areas where misadventure can be minimized. Mowing the seed heads is suggested to minimize effects of ergotized dallisgrass.

Fescue Toxicosis

Fescue toxicosis is common throughout the United States. Tall fescue grass (*Festuca arundinacea*) infested by *Neotyphodium* (formerly *Acremonium*) *coenophialum* and strains of perennial ryegrass (*Lolium perenne*) infested by *Neotyphodium* (*Acremonium*) *loliae* (also produces stagers toxins) produce ergot-type alkaloids such as ergovaline and pyrrolizidine-type alkaloids (loline).⁴²³⁻⁴²⁵ The ergot alkaloids act by interacting with dopaminergic neurotransmission and blocking prolactin.^{426,427} The presence of endophyte may also be associated with lower copper levels in the fescue grass, contributing to copper deficiency in areas with marginal copper in forages.⁴²⁸

Toxicity of tall fescue depends on the ambient weather and reproductive stage of exposed animals.⁴²⁴ During warm conditions, cattle, sheep, and horses develop "summer syndrome," characterized by increased rectal temperatures, lethargy, ill-thrift, failure to gain weight, and intolerance to ambient heat.⁴²⁹⁻⁴³¹ The breeds of cattle (*Bos indicus* vs. *Bos taurus*) are apparently alike in their sensitivity to ergot alkaloids from fescue.⁴³² This summer syndrome may partly result from alterations of hormonal (plasma cortisol, triiodothyronine [T₃]) and vascular control of body temperature.^{433,434} During cool conditions, cattle may develop typical ergot-type lesions of dry gangrene in the distal extremities.⁴³⁵⁻⁴³⁷ The most devastating aspect of tall fescue toxicosis may be reproductive failure, characterized by agalactia, prolonged gestation, weak offspring, stillbirths, and thickened placentas (horses and cattle).^{424,438,439} Ruminants of both genders may also have decreased fertility.⁴⁴⁰⁻⁴⁴²

Lesions of fescue toxicosis are nonspecific. Serum prolactin, progesterone, and dopamine concentrations are decreased in exposed animals.^{426,427} Postmortem, fat necrosis with foci of hard nodules in the omental region may be present in animals with summer syndrome, and ergotlike gangrene is present in distal extremities of animals with "fescue foot."⁴²⁴ Diagnosis of tall fescue toxicosis is helped by demonstration of the endophyte or toxins in grass.

Pregnant animals should be removed from tall fescue pastures by 30 to 60 days before parturition. Some farms have successfully used herbicides to kill the tall fescue, planted an annual crop the next year, and then followed by planting of endophyte-free tall fescue, which is now available.⁴²⁴ Current work suggests that infesting fescue grass with nonergot alkaloid-producing endophyte may maintain the fescue while eliminating the negative impact of alkaloid exposure.^{443,444} Experimental vaccination and treatments with dopamine antagonists such as dromperidone are being investigated to treat fescue toxicity.^{445,446}

Other Mycotoxins

ERGOT. Classic ergot results from parasitism of developing grass or grain flowers by *Claviceps purpurea*, leading to formation of a dark sclerotium on the seed heads. Several wild grasses and grains such as rye, triticale, wheat, oats, sorghum, and barley may be affected. Affected grains contain a series of alkaloids, including ergotamine, ergonovine, and ergotaxine (also found in fescue; see earlier). Ergotism in livestock may cause ataxia, convulsions, lameness, dyspnea, diarrhea, dry gangrene of the extremities similar to fescue foot, abortion, neonatal mortality, reduced lactation (ergot alkaloids have been used medicinally for uterotrophic effects), poor weight gains, lowered production, and lowered feed intake.^{447,448}

ZEARALENONE. Zearalenone is an estrogenic mycotoxin produced in corn and other grains by various *Fusarium* species (especially *F. roseum*) under similar warm and cold climatic cycles as for trichothecenes (zearalenone is

often found with DON; see earlier). Prepubertal swine and dairy cows are the most sensitive animals to zearalenone. Corn contaminated with zearalenone may cause toxicosis at levels as low as 1 ppm, a level well below the toxicity of pure toxin, suggesting the presence of other estrogenic metabolites in field samples. Zearalenone can be metabolized to the more toxic zearalenol. Species-specific sensitivity to the mycotoxin is related to differential metabolism of the zearalenone to zearalenol and to differential detoxification rates in liver. Zearalenone causes chronic hyperestrogenism, with vulvar swelling, prolapsed rectum, enlarged mammary glands, reduced fertility, and feminization of swine and cattle. Although zearalenone may be distributed to milk and meat, medically significant residues would not be expected in products from animals exposed to grain with natural zearalenone contamination.⁴⁴⁹⁻⁴⁵¹

SLAFRAMINE. Slaframine is an indolizidine alkaloid mycotoxin produced by black batch mold (*Rhizoctonia leguminicola*) contamination in moldy red clover forage (including hay, *Trifolium repens*). Slaframine causes increased salivation, diarrhea, and bloat in affected cattle and horses.^{452,453}

OCHRATOXIN. Ochratoxin is an isocoumarin derivative of phenylalanine. Feeding of more than 0.2 to 4.0 ppm in grain to livestock can cause nephropathy. Monogastric animals such as swine and horses are more sensitive than ruminants, although young ruminants may be susceptible to levels of ochratoxin above 2 to 40 ppm in the grain. Liver damage, enteritis, reduced growth rates, and abortion also have been reported. Citrinin, another nephrotoxic mycotoxin, might be found along with ochratoxin in a contaminated grain sample.⁴⁴⁹

ZOOTOXINS

A variety of lizards, insects, arachnids, ticks, and bees may cause toxicosis in animals.⁴⁵⁴ The incidence of such envenomations (bites) and poisonings (ingestion of toxic animals or insects) is generally rare and requires symptomatic treatment and removal of the toxic source. Two more common toxic and venomous syndromes of livestock are discussed here.

■ VENOMOUS SNAKES

Crotalus spp.: Rattlesnakes

Sistrurus spp.: Pygmy rattlesnakes

Agkistrodon spp.: Copperhead; *A. piscivorus*: Cottonmouth

Micrurus spp.: Coral snakes

The pit vipers *Crotalus* (rattlesnakes) and *Agkistrodon* are responsible for most of the reported envenomations of animals in North America. A pit organ and large, hollow fangs through which venom is passed into the victim characterize pit vipers. Envenomation by Elapidae or the coral snakes is possible in North America, but rarely reported. Coral snakes chew their venom into the victim. Crotalid venom largely consists of toxic proteins (>90% protein).⁴⁵⁴ The toxins include proteolytic and phospholipase enzymes, coagulation and hemorrhagic toxins (affecting clotting cascade), myotoxins, and in the Mojave rattlesnake a potent paralytic neurotoxin.^{455,456} Coral snakes produce neurotoxins. The effects of pit viper envenomation include anaphylactoid reactions with hemolysis and shock in systemically affected animals, with extensive local edema and necrosis near the bite from the proteolytic and myotoxic proteins (local effects are more common in large livestock).⁴⁵⁷

Livestock are usually bitten in the extremities and muzzle by snakes. The severity of effects depends on the size of the snake (larger snake = larger possible envenomation), size of the victim (smaller animal = more severe effects), severity of the strike (one or two punctures, amount of venom injected),

and location of the bite (central vs. extremities).^{454,458} Systemic effects vary depending on the crotalid species. For example, Eastern diamondback rattlesnakes may cause more hemolytic effects, the Mojave rattlesnake may be more neurotoxic, and the Western diamondback may cause more cardiovascular shock and local effects. Systemic signs include weakness, syncope, and hypotension. Mojave rattlesnake envenomations may result in respiratory distress and other signs of neurologic paralysis. Large livestock are more at risk from the local than the systemic effects of rattlesnakes. Signs in the bite region include pitting edema and pain within 20 minutes. Edema progresses rapidly and may involve an entire limb within hours. The skin may have ecchymoses and can become quite turgid. Untreated, local necrosis and effects may not peak until 4 days after envenomation.⁴⁵⁷

Common clinicopathologic abnormalities in animals with systemic envenomation include reduction of erythrocyte numbers (hemolysis), hypofibrinogenemia, echinocytosis, and thrombocytopenia. The presence of echinocytosis may aid in diagnosis of snakebite.⁴⁵⁹ Clotting parameters are prolonged. Serum enzyme alterations reflect local tissue and muscle damage, especially high CK concentrations. The urine may contain protein, glucose, and blood.⁴⁵⁴ Pathologic alterations in large animals include local tissue damage. Severe insect/bee stings, trauma, abscessation, and in the horse, purpura hemorrhagica, should be ruled out in the diagnosis of a snakebite.⁴⁵⁴

Initial treatment of snakebite in horses and large animals bitten near the nose requires maintenance of airway patency. A hose or tube can be placed in a nostril if treatment is initiated promptly. Otherwise, tracheostomy may be indicated. Snakebites are optimal environments for a variety of infectious organisms, requiring treatment with broad-spectrum antibiotics. However, for systemically affected human patients, the use of prophylactic antibiotic therapy for snakebite is becoming controversial.⁴⁶⁰ Horses especially should be given tetanus prophylaxis. Antiinflammatory treatment should be initiated using a nonsteroidal antiinflammatory drug (NSAID) such as phenylbutazone. Local wound care and debridement should be performed. Corticosteroids and fluid therapy are rarely indicated in large animals unless systemic shock develops (unlikely). Expense, marginal efficacy at the local site, and side effects argue against antivenin use in the horse. Systemic treatment of crotalid-induced neurotoxicity has been accomplished in human medicine using a polyspecific Fab antibody.⁴⁶¹ Antihistamine therapy is controversial and is not recommended for horses.

■ BLISTER BEETLE

Epicauta spp.: Blister beetles

Alfalfa and other blooming hays may attract blister beetles. Blister beetles can contain 0.1% to 12% cantharidin (dry weight).⁴⁶² *Cantharidin* is a potent vesicant toxin that causes necrosis of all mucous membranes that it contacts.

Although blister beetles may be found throughout the United States, conditions favoring swarming and toxicity in livestock hay occur in the midwestern United States. Cases have been reported in the region bounded by Florida to Arizona and north to Colorado, Minnesota, and Illinois.⁴⁶² Beetles tend to swarm when alfalfa (or nearby weeds) is in bloom and when conditions favor increases in the grasshopper population.⁴⁶³ Harvest techniques that use a windrower type of machine that cuts, crimps or conditions, and piles hay (unlike classic practices that mow hay, then rake it without crimping) will trap the beetles in the hay, leading to possible toxicity.^{462,463} The beetles retain toxicity in dried hay; 4 to 6 g of dried beetles, or about 100 beetles, may be fatal.⁴⁶²⁻⁴⁶⁵ All classes of herbivorous

livestock may be affected, although most cases have been reported for horses. Animals with blister beetle toxicosis develop colic, gastroenteritis, nonspecific neurologic signs, increased urination, cystitis, shock, and death. Shock and death alone may be reported in severely poisoned horses.

Clinicopathologic alterations reflect dehydration, shock, and renal damage. Hemoconcentration occurs despite decreased levels of protein, calcium, and magnesium in the serum.^{462,464} The serum has increased levels of CK, BUN, and creatinine. Renal damage is also reflected by decreases in urine specific gravity despite dehydration and shock. Hypocalcemia and hypomagnesemia are also likely to occur.⁴⁶⁶ Postmortem lesions include hemorrhagic gastroenteritis (including oral); pale, moist, swollen kidneys; and hemorrhagic damage to the urinary tract. In some cases that involve sudden death, lesions may be absent. Histologic alterations include inflammation and hemorrhage with ulceration of the GI tract, bladder mucosa, ureters, and renal pelvis.^{462,464} Direct myocardial necrosis may occur in severe cases.⁴⁶⁴

Diagnosis of cantharidin toxicosis is facilitated by identification of beetles in hay or ingesta and chemical analysis for cantharidin in beetles, ingesta, blood, and urine (urine may have from 0.0005 to 2.0 ppm of cantharidin).^{462,466}

Blister beetle toxicosis can be prevented through proper harvest of hay by avoiding times when beetles swarm, managing flowering weeds, controlling grasshoppers, avoiding full bloom during cutting, and if possible, avoiding use of crimpers and conditioning equipment during hazardous times.⁴⁶³ Insecticides should be avoided when hay is in full bloom (bees essential for alfalfa crops may be harmed). Livestock with blister beetle toxicosis should have toxic hay removed from the diet (destroy hay; the toxin does not dissipate with time) and treated aggressively for shock and renal failure (fluid replacement).^{462,464}

METALS AND OTHER INORGANIC COMPOUNDS

KONNIE H. PLUMLEE

ARSENIC

Trace levels of arsenic are present in tissues of most animals because arsenic is naturally found in plants and soil.^{467,468} However, arsenic toxicosis can be caused by either inorganic or organic forms. In general, inorganic arsenic compounds are more toxic⁴⁶⁹ and more likely to cause toxicosis than the organic arsenic compounds.⁴⁶⁷

Inorganic arsenic can exist in trivalent (commercial) or pentavalent (natural) forms. The trivalent arsenic compounds (arsenite) are more soluble and thus 5 to 10 times more toxic than pentavalent forms of arsenic (arsenate).^{467,469,470} Inorganic arsenic compounds are used as rodenticides, insecticides, and herbicides.^{469,471} Arsenic pentoxide is a preservative used in salt-treated or pressure-treated wood. However, toxicosis from ingestion of arsenic-treated wood has been reported only when the wood had been burned first, allowing the arsenic to become bioavailable.⁴⁶⁸

Organic arsenic compounds can be either aliphatic or aromatic. *Aliphatic* arsenic compounds are used as herbicides and tonics. *Aromatic* organic arsenic chemicals are trivalent or pentavalent. The trivalent form is used as a treatment for heartworms in dogs. The pentavalent forms (phenylarsonic compounds) are used as feed additives for poultry and swine.⁴⁶⁹

The different types of arsenic have varying mechanisms of action. The phenylarsonic feed additives have an unknown mechanism that causes degeneration of myelin sheaths and axons in monogastric animals. The inorganic and the aliphatic organic compounds directly irritate the gastrointestinal (GI) tract, resulting in necrotic lesions.⁴⁶⁹ Arsenic also acts directly on capillaries, resulting in transudation of plasma and decreased blood volume. The subsequent shock that develops is believed to be responsible for sudden death.^{467,469}

Trivalent inorganic and aliphatic organic arsenic chemicals react with sulfhydryl groups.^{469,470} Two enzyme complexes of the citric acid cycle contain lipoic acid, which has two sulfhydryl groups and thus is sensitive to these forms of arsenic. Pyruvate dehydrogenase complex is inhibited, preventing formation of acetyl coenzyme A (CoA) from pyruvate. Also, α -ketoglutarate is inhibited, thus preventing formation of succinyl-CoA. The liver, kidney, gut, and heart are the organs most susceptible to this metabolic disorder. Arsenic also inhibits the amino acids that contain sulfur and results in fatty infiltration of the liver.⁴⁶⁹

Pentavalent inorganic arsenicals affect a different metabolic pathway. Normally, in the glycolytic pathway, an inorganic phosphate is added to glyceraldehyde 3-phosphate, which is converted to 1,3-diphosphoglycerate. Arsenate can replace the phosphate, resulting in production of 1-arseno-3-phosphoglycerate. This new intermediate can be used in the glycolytic pathway; however, the adenosine triphosphate (ATP) that would be produced during formation of 3-phosphoglycerate is lost. Therefore, arsenate uncouples oxidative phosphorylation.⁴⁶⁹

Clinical signs and lesions are similar except for the phenylarsonic compounds used as feed additives, which cause peripheral nerve degeneration in monogastric animals. All the other arsenic compounds can cause peracute, acute, or subacute conditions. Peracute toxicosis results in cardiovascular collapse and usually presents as sudden death.^{467,469,470} Acute toxicosis is seen 3 to 12 hours after ingestion. The most prominent clinical sign of acute and subacute cases is diarrhea, which frequently is hemorrhagic. Other clinical signs include anorexia, dehydration, weakness, colic, and agalactia.^{467,469-471} The most consistent necropsy lesions are in the GI tract and may be hemorrhagic, edematous, or eroded. The lesions may be confined to one region of, or spread throughout, the GI tract.⁴⁶⁷⁻⁴⁷² In ruminants, the abomasum is often the most severely affected area. The gut lumens are sometimes filled with necrotic material from the sloughed lining of the GI tract. Other lesions include pulmonary edema and hemorrhage of the cardiac serosa and peritoneum.^{467,469,470} Histopathologic examination may reveal multifocal necrosis of the liver and the proximal tubules of the kidney.⁴⁷² Peracute cases often have no abnormal gross findings.

Diagnosis of acute arsenic toxicosis is generally made by finding elevated levels of arsenic in the liver, kidney, and GI contents.^{469,472} In cases of peracute death, the tissues may have normal levels of arsenic, but the GI contents will have toxic levels. In animals with chronic toxicosis, arsenic deposition in hair begins 2 weeks after exposure. Arsenic levels in hair can be used as a retrospective diagnostic tool.⁴⁷⁰ Chronic arsenic toxicosis is rare because arsenic is rapidly excreted in the urine.^{470,471} Urine and whole blood are the best samples to collect from live animals suspected of having acute arsenic toxicosis.

Treatment is dictated by the type and severity of clinical signs. Dimercaprol, also known as BAL (British antilewisite), can be used as a specific antidote if the toxicosis is caused by a trivalent inorganic or an aliphatic organic arsenic. Dimercaprol contains two sulfhydryl groups and can bind to arsenic, forming a chelate that is eliminated by the

kidney.⁴⁶⁹ Galey⁴⁷³ recommends a loading dose of 4 to 5 mg/kg intramuscularly (IM) followed by 2 to 3 mg/kg every 4 hours for 24 hours, then 1 mg/kg every 4 hours for the next 2 days. Stair et al.⁴⁷⁴ recommend a more rigorous protocol of 3 mg/kg IM every 4 hours for the first 2 days, every 6 hours on the third day, and every 12 hours for another 10 days. Dimercaprol has the side effect of potentially inhibiting enzymes that contain metallic coenzymes needed for cellular respiration.⁴⁶⁹ Adverse clinical signs associated with dimercaprol include hypertension, tremors, convulsions, and coma.⁴⁶⁹

Lipoic acid reportedly is a superior chelating agent to dimercaprol when administered to calves in a 20% solution at 50 mg/kg IM (two or three injection sites) every 8 hours.⁴⁷⁴ Sodium thiosulfate has been reported as a safe chelator in large animals at 30 to 40 mg/kg IV or 60 to 80 mg/kg orally (PO) two or three times daily for 3 to 4 days.⁴⁶⁹ Newer chelators for humans and small animals, including 2,3-dimercaptosuccinic acid (DMSA, succimer), have the benefit of chelating toxic metals such as arsenic, lead, and mercury while sparing iron, magnesium, and calcium.⁴⁷⁴ However, DMSA is likely cost-prohibitive for most large animals. D-Penicillamine is an effective arsenic chelator in humans, but also may be too expensive in livestock.⁴⁶⁹ Ethylenediamine tetraacetic acid (EDTA) is not effective for arsenic toxicosis because this chelator removes only extracellular arsenic, not the intracellular arsenic causing the clinical signs.⁴⁶⁸

COPPER

Copper toxicosis can be acute or chronic. Acute toxicosis results from soluble copper salts. Acute copper toxicosis has been reported in adult and juvenile cattle that were given injections of copper disodium edetate as a treatment for copper deficiency.⁴⁷⁵⁻⁴⁷⁷

Chronic copper toxicosis can be categorized as simple, hepatogenous, or phylogenous. *Simple* chronic toxicosis is caused by ingestion of excessive copper relative to the levels of molybdenum or sulfate in the diet. Molybdenum and sulfate can bind to dietary copper and decrease its accumulation in the liver.⁴⁷⁸ Copper accumulates in the liver when the dietary copper/molybdenum ratio is greater than 10:1 for sheep.⁴⁷⁸ Many different sources of excess copper have been reported. Sheep are often poisoned when fed rations intended for cattle or horses,⁴⁷⁹ and llamas have developed copper toxicosis when fed cattle feed.⁴⁸⁰ Cattle develop copper toxicosis when supplemented with excessive copper⁴⁸¹ in their diets or when fields are contaminated with copper from industrial pollution, as with copper smelting units.^{482,483} Cattle have become poisoned when fed litter from chickens that had been fed copper sulfate,⁴⁸⁴ and sheep have developed toxicosis after grazing pastures fertilized with manure from swine that were fed copper sulfate.⁴⁸⁷ Excessive copper in calf milk replacers has been the source of toxicosis in both calves^{486,487} and goat kids.⁴⁸⁸

Hepatogenous copper toxicosis occurs when plant toxins damage the hepatic parenchyma, causing the liver to have an increased avidity for copper. The plants most often associated with hepatogenous copper toxicosis are *Senecio* species and *Heliotropium europaeum*.⁴⁷⁸ *Phylogenous* copper toxicosis occurs when animals graze plants with elevated copper/molybdenum ratios for prolonged periods. In general, mature pastures have higher levels of molybdenum than young, rapidly growing plants.⁴⁷⁸ Subterranean clover (*Trifolium subterraneum*) is especially noted for causing this type of chronic toxicosis.⁴⁷⁸

Copper is absorbed in the intestine, bound to proteins, and transported to the liver. Copper binds with ceruloplasmin, a metalloprotein, in the liver. Copper accumulates in hepatic

lysosomes over several weeks to months during chronic copper poisoning.^{478,485,486} During this accumulation phase, necrosis of hepatic parenchymal cells and swelling of Kupffer's cells occur.⁴⁷⁸ This phase is followed by a sudden release of copper into the bloodstream from the liver, either spontaneously or after some type of stress to the animal.^{478,484,485} This acute hemolytic phase includes an increase in erythrocyte fragility and a decrease in blood glutathione, followed by hemoglobin oxidation and methemoglobin formation.^{478,486} The resulting intravascular hemolysis leads to anemia and hemoglobinuric nephrosis.⁴⁸⁶

The first noticeable clinical signs of chronic copper toxicosis are usually depression, anorexia, and weakness, which often have a sudden onset. Feces may be watery, dark, or blood tinged, especially in cattle. Evidence of a hemolytic crisis is apparent. Animals have anemia, methemoglobinemia, and hemoglobinuria. Mucous membranes are icteric or muddy brown.^{478,481,484,489} Cattle that develop copper toxicosis after injection with copper disodium edetate have dyspnea, head pressing, ataxia, and circling rather than the hemolytic crisis that occurs with chronic copper toxicosis.^{475,477}

Gross necropsy lesions are found in the liver, kidneys, and spleen. The liver is yellow and friable and may be larger or smaller than normal. The kidneys are dark red or blue-black. The spleen may be enlarged and congested. Histopathologic changes in the liver include centrilobular necrosis, pigment-laden Kupffer's cells, hepatic fibrosis, and bile duct hyperplasia.^{478,479,484,485} Granules in the liver will stain positive with rhodamine or rubeanic acid, two histochemical stains that are specific for copper. The degree of staining, however, does not always correlate well with the severity of lesions or with the amount of copper in the liver.⁴⁸⁶

Diagnosis of chronic copper toxicosis is made by measuring copper levels in serum, liver, and kidney.^{485,486} Copper levels in serum are not elevated until just before or during the hemolytic crises.⁴⁷⁸ Animals with toxic levels of copper in their livers can have normal or even deficient levels of copper in their serum. Therefore, measuring serum copper levels is not a reliable method of monitoring animals for excessive copper in the liver.⁴⁸¹

If an animal is suspected to have died from chronic copper toxicosis, copper levels should be measured in both fresh liver and kidney, because after the liver has released its copper load into the bloodstream, liver copper levels may fall into a nontoxic range. In these cases the kidney copper levels will be in a toxic range, so the diagnosis will not be missed. The diagnosis should correlate with histopathologic lesions in formalin-fixed liver and kidney.⁴⁸⁶ Unlike chronic copper toxicosis, acute toxicosis from copper disodium edetate does not necessarily result in elevated copper levels in liver or kidney.⁴⁷⁵

Treatment is often unsuccessful once an animal develops the acute hemolytic crisis. Ammonium molybdate (50 to 500 mg PO once daily) and sodium thiosulfate (300 to 1000 mg PO once daily) for 3 weeks has been used for many years as a treatment.^{478,485} The liver copper levels begin to decrease within 4 days of beginning this therapy.⁴⁸⁵

A newer treatment is ammonium tetrathiomolybdate, 1.7 mg/kg IV or 3.4 mg/kg subcutaneously (SC) on alternate days for three treatments).^{478,490} Either route of administration significantly decreases liver copper levels within 6 days. Thiomolybdates decrease copper absorption and increase copper removal from the liver.⁴⁷⁸ This change is accompanied by an increase of copper in the blood, bile, feces, and urine.⁴⁷⁸ Most of this copper is insoluble in trichloroacetic acid, indicating that it is bound with tetrathiomolybdate and albumin in an inert complex.⁴⁹⁰ Interestingly, one report indicated that when xylazine is given with tetrathiomolybdate, the amount of copper excreted in the urine doubles compared with giving tetrathiomolybdate alone.⁴⁹¹

D-Penicillamine (26 mg/kg PO twice daily for 6 days) results in a 10- to 20-fold increase in urinary copper excretion in sheep.^{478,492} This drug does not seem to increase fecal copper concentration.⁴⁹² Unfortunately, this treatment is often cost prohibitive for many livestock.^{478,485}

Trientine is a cupruric agent used to treat humans. One study reported clinical improvement in sheep given this drug at 0.5 mg PO four times daily.⁴⁷⁸ Another study, however, demonstrated no increase in copper excretion in urine when the dosage was 26 mg/kg PO twice daily for 6 days.⁴⁹²

FLUORIDE

Most cases of fluorosis are caused by animal exposure to industrial emissions. Fluorosis has also occurred after volcanic eruptions, when gaseous fluoride is fixed by foliage.^{493,494} Horses and sheep tolerate higher levels of fluoride than cattle.⁴⁹⁵ Lesions are similar in all species.⁴⁹⁵

Fluoride primarily affects, and is incorporated by, developing and mineralizing teeth and bones.^{495,496} The main clinical signs are weight loss and lameness, especially of the forelimbs. Palpation of the long bones results in intense pain.⁴⁹³ Radiographs of animals with osteofluorosis reveal sclerosis, porosis, periosteal hyperostosis, endosteal hyperostosis, and osteophytosis.⁴⁹⁶

Characteristic lesions occur on incisors, premolars, and molars. Dental hypoplasia, dysplasia, and yellow to brown discoloration of the enamel are common. The enamel is eroded or pitted and may have a chalky appearance.⁴⁹⁶ The molars may become so abraded and painful that animals have difficulty with mastication and drinking cold water.⁴⁹⁵ Dental abrasion is reduced if nonaffected teeth are adjacent to affected teeth.⁴⁹⁶

Gross pathology lesions include abnormal bone formation on the periosteum and thickening of the cortex. The first lesions appear on the ribs, mandible, metatarsus, and metacarpus. Histologic findings include abnormal bone remodeling, abnormal mineralization, coarse collagenous fibers, and increased osteoid.⁴⁹⁶

Only small amounts of fluoride pass the placental barrier. Therefore, teratogenic lesions or congenital malformations have not been observed in offspring of horses, sheep, or cattle with fluorosis.⁴⁹⁶

Fluoride has an intense, dose-dependent osteogenic action, and osteofluorosis is associated with increased bone alkaline phosphatase (ALP) activities.^{493,496} Urine, serum, and bone will have elevated levels of fluoride.^{494,496} These findings, in conjunction with clinical signs, radiography, and lesions, are used to make a diagnosis.

Fluoride toxicosis has no antidote.⁴⁹⁶ Animals should be removed from the source of the excess fluoride and given supportive care. Feeds that are easily masticated should be fed to reduce further abrasion of the teeth.⁴⁹⁵ Affected animals will not completely recover.⁴⁹⁶

IODINE

Iodine is used to prevent infectious diseases and as a treatment for foot rot. Sources of iodine include potassium iodide, sodium iodide, kelp, and ethylenediamine dihydroiodide (EDDI). Oversupplementation can result in toxicosis.

Clinical signs include a nonproductive cough, lacrimation, serous nasal discharge, scaly hair coats, and hyperthermia. Other clinical signs include decreased milk production, decreased rate of gain, and decreased feed conversion. Young animals seem to be more susceptible. Adults may not develop toxicosis unless stress, disease, or other nutritional imbalances also are present.⁴⁹⁷ Excess supplementation in mares has been associated with goiter in foals.

Serum biochemical changes are inconclusive for iodine toxicosis. A diagnosis can be confirmed only with serum or milk analysis. Nonlactating cows have higher serum iodine concentrations than lactating cows because the iodine is eliminated in milk. Iodine levels in milk are directly related to the levels of iodine in the diet.⁴⁹⁷ Iodine-based teat dips can elevate milk iodine levels.

Treatment is restricted to removal of the dietary source of iodine. Clinical signs associated with the respiratory tract disappear 1 to 4 weeks after the iodine source is removed.⁴⁹⁷

IRON

Hemochromatosis can be classified as either primary (idiopathic) or secondary. Primary hemochromatosis is an inherited defect resulting in iron deposition in the liver caused by increased iron absorption.^{498,499} This discussion is limited to iron toxicosis associated with excess oral or parenteral iron supplementation.

Most cases of iron overload have occurred in neonatal foals that were given ferrous fumarate orally before 3 days of age.^{500,501} Adult horses, however, have developed iron toxicosis after oral supplementation with ferrous fumarate or ferrous sulfate.⁵⁰¹ Iron toxicosis has been reported in calves injected with a combination of ferrous gluconate and ferric ammonium citrate.⁵⁰² Young bulls injected with ferric ammonium citrate also developed iron toxicosis.⁵⁰³

Normally, the small intestine absorbs about 3% to 10% of dietary iron and stores the iron as ferritin in the mucosal cells. The iron is transferred to the plasma according to the body's needs. Excess iron is stored in the liver as ferritin and hemosiderin because the body has limited ability to eliminate iron.^{498,500} Foals are born with a high serum iron level and have higher iron absorption than adults. Therefore, foals less than 3 days of age are more susceptible than adults to iron toxicosis.⁵⁰⁴

Clinical signs in neonatal foals include depression, icterus, head pressing, and disorientation.⁵⁰¹ Adult horses develop anorexia, icterus, and sometimes petechial hemorrhages.⁵⁰⁰ Calves with iron toxicosis have trembling, vocalizing, bruxism, colic, and convulsions.⁵⁰²

If clinicopathologic findings are abnormal, they will be related to cholestatic liver failure. Animals often have elevated levels of γ -glutamyltransferase (GGT), ALP, bile acids, and unconjugated bilirubin. Coagulopathies are demonstrated by abnormal coagulation profiles, thrombocytopenia, and elevated fibrinogen and fructose diphosphate (FDP).^{500,501}

Grossly, the liver lesions are variable. Most livers are friable and swollen or shrunken. In general the liver is discolored, pale tan or mottled red-brown. Microscopic lesions include periportal bile ductule proliferation, periportal necrosis, lobular necrosis, and fibrosis. Hemorrhages may be present in the gastric mucosa, intestines, and urinary bladder.⁵⁰¹⁻⁵⁰⁴

Diagnosis of iron toxicosis usually is based on the presence of appropriate clinical signs and a history of recent iron supplementation. Serum levels of free (unbound) iron may or may not be elevated. Liver iron concentrations range from normal to several thousand parts per million. Interpreting iron levels in liver can be complicated because iron may be elevated above normal if the animal had hemolysis or if blood congestion occurred within the liver.

Treatment of iron toxicosis is usually limited to supportive care. Repeated phlebotomy or chelation therapy with deferoxamine is used to treat iron overload in humans and small animals.^{498,500} The success rate of these treatments in large animals has not been well documented.

LEAD

Lead toxicosis is discussed in Chapter 35.

MERCURY

Mercury toxicosis has been associated with ingestion of seed treated with organic mercurial fungicides.⁵⁰⁵⁻⁵⁰⁷ Topical application or ingestion of inorganic mercurials, used as counterirritants (blistering agents), also can result in toxicosis.^{505,507,508} If the blistering agents are used concurrently with dimethyl sulfoxide (DMSO), the absorption of the mercury is enhanced and is more likely to cause toxicosis.⁵⁰⁸

Mercuric ions form covalent bonds with sulfhydryl groups and form mercaptides.⁵⁰⁷ The kidney is the primary target organ, but mercury also localizes in the GI mucosa. Mercury is excreted by the kidneys, partly by exfoliation of renal tubular epithelium.⁵⁰⁸ Metallothionein, a metal-binding protein, is synthesized within 48 hours of exposure to mercury. Metallothionein initially may protect the kidney by sequestering mercury; however, as the sequestered mercury is slowly released from the tubular epithelium, renal damage continues.^{505,508}

Acute signs of mercury toxicosis are caused by the corrosive effect of mercury on mucous membranes. Ulceration of the mouth, esophagus, and rest of the GI tract may be followed by diarrhea and anorexia. If the animal survives, acute toxic nephrosis occurs. Anorexia, gastroenteritis, weight loss, nephritis, and alopecia have been reported in animals exposed to chronic, low doses of mercury.⁵⁰⁷

Clinical pathology testing may reveal elevated creatinine and blood urea nitrogen (BUN), as well as proteinuria, glucosuria, and isosthenuria, depending on the acuteness of the disease. Necropsy findings include an ulcerated and edematous GI tract, with possible intraluminal hemorrhage. The kidneys may be pale and swollen.^{505,508}

Diagnosis of mercury toxicosis is made from history, clinical presentation, and mercury levels within the animal. Mercury concentrations can be measured in liver, kidney, brain, whole blood, and urine. Tissue samples and urine may be frozen after collection.

Chelation therapy can be done using BAL or sodium thiosulfate as for arsenic toxicosis. Remaining topical mercurials should be washed from the animal. Supportive care is necessary for the gastroenteritis and kidney failure. Oliguria indicates a poor prognosis.^{505,508}

MOLYBDENUM

Excess dietary molybdenum (copper deficiency) is discussed in Chapter 32.

SELENIUM

See Toxic Plants.

SODIUM

Sodium (salt) toxicosis is discussed in Chapter 35.

SULFATE

Excess dietary sulfate is discussed with copper deficiency in Chapter 32 and with polioencephalomalacia in Chapter 35.

ZINC

Excess dietary zinc is discussed with osteochondrosis in Chapter 38.

TOXICOLOGY OF ORGANIC COMPOUNDS

KONNIE H. PLUMLEE

INSECTICIDES

Anticholinesterase Insecticides

The anticholinesterase insecticides include the organophosphates and the carbamates. Many organophosphate insecticides are used for insect control in crops. Several organophosphates also have been approved for use as insecticides or anthelmintics in domestic animals. Carbamate insecticides are used primarily for crops and other plants. Livestock are usually exposed to these insecticides as a result of drift, accidental ingestion, or improper treatment by owners.⁵⁰⁹

The mechanism of action of these insecticides is to bind with and inhibit acetylcholinesterase (AChE). As a result, acetylcholine (ACh) accumulates at nerve junctions, and repetitive firing of parasympathetic nerves occurs. Because carbamates bind with ACh on a reversible basis, inhibition of AChE is temporary.^{509,510} Therefore, carbamates have a shorter duration of action than organophosphate insecticides, which bind irreversibly with AChE.⁵⁰⁹

Clinical signs are predominantly described by the acronym *SLUD*: salivation, lacrimation, urination, and defecation. In addition, the animals may have miosis, diarrhea, muscle tremors, seizures, dyspnea, or bloating.⁵⁰⁹ Death can occur within minutes, depending on the toxicity of the specific compound and the amount of toxicant ingested.⁵¹¹ At postmortem examination, lesions may be minor or absent, depending on the acuteness of death. Pulmonary edema is a frequent finding, because death usually results from increased pulmonary secretions, bronchial constriction, and respiratory paralysis.⁵¹⁰

Measuring the cholinesterase activity in brain, retina, or whole blood can be used to make a presumptive diagnosis of toxicosis.⁵¹²⁻⁵¹⁴ Some laboratories use serum rather than whole blood, depending on the testing method used; therefore it is best to check with the laboratory before submission. Whole blood can reliably be used for cholinesterase evaluation for up to 1 week after collection if the sample is refrigerated.⁵¹⁵ Half the brain should be submitted for homogenization because cholinesterase activity varies among regions of the brain.⁵¹² Cholinesterase activity in whole blood or brain that is less than 50% of normal for the species being tested indicates excessive exposure to a cholinesterase inhibitor. Cholinesterase activities less than 25% of normal indicates toxicosis, as long as appropriate clinical signs are present.⁵¹³

An insecticide screen should be performed on GI contents or the liver to identify the insecticide chemical that is involved. These samples should be stored in glass or metal, such as foil, and frozen as soon as possible after collection. If the sample is stored in plastic, the insecticide may leech from the sample into the plastic.

Because carbamates rapidly dissociate from AChE, a diagnosis is often difficult to make based on cholinesterase activity in brain or blood. The activities can be normal or near normal even though the animal has toxicosis.^{509,510} Because carbamates hydrolyze rapidly, parent compounds may be difficult to detect in ingesta and especially in tissue.^{509,510} Therefore, when carbamate toxicosis is suspected, multiple samples should be collected and tested as soon as possible.

Treatment for organophosphate toxicosis includes supportive care, activated charcoal, atropine, and oximes. Activated charcoal (1 to 2 lb [0.45 to 0.90 kg] PO for 500-kg animal) should be given even if the route of exposure is not oral, because these insecticides can act systemically even

when given topically. If the route of exposure is dermal, the animal should be washed with soap and water to decrease absorption through the skin.⁵¹³ Atropine competitively inhibits ACh at muscarinic nerve receptors. Therefore, muscarinic effects, but not nicotinic effects, are reduced. Atropine should be given at a dose of 0.10 to 0.25 mg/kg. One fourth of the initial dose is given by IV injection and the rest SC or IM. The dose can be repeated if the clinical signs reappear.⁵¹³ GI motility should be monitored carefully because atropine can cause ileus, especially in horses. Oximes such as 2-pyridine aldoxime methiodide (2-PAM) can be used as a treatment to release the bond between AChE and an organophosphate. However, oximes are of little benefit after the AChE-organophosphate bond undergoes "aging" meaning that the bond cannot be broken. The amount and time of "aging" that occurs vary among the different organophosphate compounds.^{513,516} Recommended doses for 2-PAM are 20 mg/kg IV twice daily⁵¹⁷ or 10 to 15 mg/kg SC.⁵¹⁸

Treatment of carbamate toxicosis is restricted to atropine, activated charcoal, and supportive care. Oximes such as 2-PAM are contraindicated with carbamate toxicosis because the carbamates bind reversibly, and thus oximes are not needed to release the carbamate from the AChE.⁵⁰⁹

Most anticholinesterase compounds are rapidly metabolized and excreted.⁵¹⁹ Therefore these insecticides do not persist in tissues, and tissue levels are usually low. Animals that survive the toxicosis, however, should be analyzed for residues before consumption.⁵²⁰ Animals that have died from anticholinesterase insecticide toxicosis have been prohibited from being rendered.⁵¹⁹

Chlorpyrifos is a chlorinated organophosphorus insecticide used for lice and fly control in cattle. It is applied as a pour-on caudal to the shoulders. This product causes a delayed toxicosis that occurs primarily in bulls and some exotic breeds of cattle. Toxicosis is associated with the testosterone levels in the animal.⁵²¹ Larger and older bulls are affected more severely. The manufacturer recommends not treating bulls over 8 months old with chlorpyrifos.⁵¹⁷ Clinical signs do not occur until at least 2 to 7 days after exposure and include depression, weakness, muscle fasciculations, anorexia, rumen stasis, and rumen distention.^{517,518,521} The clinical signs typically seen with acute organophosphate toxicosis are usually not present with chlorpyrifos toxicosis.

Animals with chlorpyrifos toxicosis will have depressed cholinesterase activities in brain and blood. After topical application, chlorpyrifos will undergo systemic distribution and may be detected in blood, rumen contents, fat, and hair for weeks. Animals with chlorpyrifos toxicosis should be washed with detergent and water as soon as possible.^{517,518,521} Oral treatment with activated charcoal reduces the signs of toxicosis by adsorption of the chlorpyrifos. The manufacturer recommends atropine as an antidote.⁵¹⁷ Because most cases involve ruminal stasis and few muscarinic signs, however, atropine may be contraindicated.^{517,518} Severity of the rumen stasis often requires removal of rumen contents by a large-bore stomach tube or rumenotomy.⁵¹⁸ Pralidoxime (2-PAM) has decreased clinical signs in some animals when given within 4 days of insecticide exposure.^{517,518}

Haloxon is an anthelmintic and toxicosis was reported in the 1970s in sheep that had a familial absence of a plasma A-esterase.⁵²² This enzyme rapidly hydrolyzes haloxon.⁵²² Clinical signs occur 5 to 90 days after exposure and predominantly include hindlimb ataxia or paresis.⁵²³ Gross lesions are not evident on necropsy. Microscopically, the white matter of the spinal cord was vacuolated, with swollen axons and increased glial cells.⁵²³ Cholinesterase activity can be decreased.⁵²²

Haloxon also has been associated with bilateral laryngeal paralysis in Arabian and part-Arabian foals.⁵²⁴ The foals were

23 to 35 days old and had been treated with haloxon every 2 weeks since 2 days of age. The clinical signs were noticeable only when the foals exercised or were stressed. Rhinolaryngoscopy revealed no abductor movement of the arytenoid cartilages.⁵²⁴ Active wallerian degeneration and loss of nerve fibers were seen in the recurrent laryngeal nerves.⁵²⁴ Tracheotomy relieved the dyspnea, and in foals that survived, function of the right arytenoid cartilage returned before the left.⁵²⁴

Organochlorine Insecticides

Chlorinated hydrocarbons are used to control insects and other pests. Examples include DDT, aldrin, heptachlor, and lindane. Although use of several of these products has been banned or restricted, toxicosis in domestic animals still occurs, either from improper use or from exposure to discarded products.⁵²⁵

The mechanism of actions of organochlorines is not completely understood and seems to vary among compounds. Interference with the kinetics of nerve sodium channels and inhibition of γ -aminobutyric acid (GABA) binding are two proposed mechanisms.

Initial clinical signs may include apprehension, hypersensitivity, and a belligerent attitude. Fasciculations of the face and cervical muscles are followed by spasms of the eyelids, forequarters, and finally hindquarters.⁵²⁵ Ataxia, hypersalivation, and diarrhea also have been reported.⁵²⁶ Intermittent convulsions are the major manifestation in most cases.⁵²⁰ Significant gross lesions usually are not found at necropsy.⁵²⁷

Organochlorines accumulate in fatty tissues. Therefore, diagnostic testing should be performed on samples such as brain, fat, milk, and liver.⁵²⁵ The compounds also may be found in whole blood and GI contents. Collected samples should be put in glass or metal containers⁵²⁵ and frozen, with the exception of blood, which should be refrigerated. As with other insecticides, plastic containers should be avoided if possible.

Treatment is mostly symptomatic because no antidote for organochlorine toxicosis exists.⁵²⁵ The animal should be washed with water and detergent if the exposure was dermal.⁵²⁵ Activated charcoal is beneficial if given immediately after oral exposure.^{525,526} Convulsing animals require treatment with sedatives and muscle relaxants.

Organochlorine residues persist in fat and are excreted in the milk of lactating animals.⁵²⁰ Some of these compounds cross the placental barrier and concentrate in fetal fat.⁵²⁸ Several strategies have been tried to reduce residues as quickly as possible to minimize economic loss. Treatment with compounds such as phenobarbital and butylated hydroxyanisole (BHA) to promote metabolism, cholestyramine to increase excretion, or thyroprotein to increase elimination has not been very successful in livestock.⁵²⁸

At this time, the only successful method of reducing organochlorine residues in livestock is by fat mobilization and removal. One method of accomplishing fat mobilization is by feeding a calorie-restricted diet.⁵²⁶ As the animal loses weight, the fat and organochlorine are mobilized and removed from the body. After removal of the fat, the animal should be fed a high-calorie diet that is free of organochlorine compounds to regain its body fat and decrease the whole-body concentration of the compound. As the body fat decreases, concentration of organochlorine may increase in other tissues as the chemical is mobilized.⁵²⁵ If the diet is too restrictive, the organochlorine mobilization may occur too rapidly, and the animal may develop acute toxicosis.⁵²⁶ The fastest method of reducing organochlorine residues is through milk secretion.⁵²⁸ Residue elimination is fastest during early lactation. Unfortunately, residue reduction may not be economically feasible because of extra costs of feed, labor, and loss of saleable milk.

HERBICIDES

Arsenics

See Metals and Other Inorganic Compounds.

Paraquat

Paraquat is in the class of bipyridyl herbicides, which act as dessicants by altering enzyme systems and reducing photosynthesis.⁵²⁹ Most concerns about this product occur when it is sprayed on foliage that will later be used for animal consumption or when it accidentally drifts from a sprayed field onto animals or their pasture. Paraquat quickly becomes irreversibly inactivated once it comes into contact with soil.^{529,530} It is a concern only when the animal ingests a concentrated form of the herbicide or grazes a field that is still wet from paraquat application.

Paraquat is concentrated against a gradient within type I alveolar pneumocytes. The herbicide accepts electrons to form free radicals.^{529,530} This reaction is catalyzed by nicotinamide adenine dinucleotide phosphate (NADP), reduced from cytochrome P450 reductase (NADPH).⁵²⁹ The result is destruction of cell membranes and subsequent cell death.

Acute signs generally occur 1 to 3 days after ingestion and involve anorexia, depression, and diarrhea. Several days later the animal develops respiratory distress, dyspnea, and pneumomediastinum. Death may be delayed until several weeks after ingestion. Gross and histopathologic lesions primarily consist of progressive lung fibrosis, but may include renal and liver damage.^{529,530}

Treatment should include fuller's earth or bentonite given orally as soon as possible after exposure and certainly within 24 hours of ingestion.^{529,530} These products inactivate the paraquat on contact and thus are more effective than activated charcoal. Oxygen therapy reportedly worsens the lung damage.⁵³¹ Regardless of therapy, the prognosis is poor because of the progressive fibrosis of the lungs.

Chlorophenoxy Acids

Chlorophenoxy acid herbicides includes the compounds 2,4-D; 2,4,5-T; and silvex. These herbicides are plant growth regulators, so the mechanism of action is to alter the metabolism of the plant. Therefore they are relatively nontoxic to mammals unless ingested in a concentrated form.^{529,530} Indirect toxicosis may occur, however, because of the altered metabolism of the sprayed plants. Toxic plants that are normally untouched by grazing animals may become more palatable and result in plant toxicosis after application of some herbicides. In addition, the altered plant metabolism may cause some plants to accumulate higher levels of nitrate or cyanide or increase the level of their inherent toxins.⁵³⁰ Animals should be removed from treated pastures for at least 7 days after application to reduce the occurrence of plant toxicosis.⁵³⁰

Clinical signs of chlorophenoxy acid toxicosis include depression, anorexia, abdominal pain, and diarrhea.⁵²⁹ Weakness is especially profound in the hindlimbs. Gross findings include epicardial hemorrhage and hydropericardium. The liver is swollen and friable. The kidneys may be congested.⁵³²

Chlorophenoxy acid herbicides are quickly absorbed from the GI tract, but dermal absorption is minimal.⁵³³ Treatment consists of activated charcoal and supportive care. The major route of elimination is the urine.⁵³³ Neither parent compounds nor metabolites have been found in the milk from orally dosed cattle.⁵³³

Triazines

Triazine herbicides inhibit photosynthesis by blocking electron transport.⁵³⁴ Products in this group of herbicides

include atrazine, simazine, and propazine. Livestock should be held from pastures treated with simazine for 30 days and off hay for 60 days.⁵³⁰

Sheep have been reported to exhibit signs of generalized muscle tremors, which progressed to mild tetany and collapse of the hindlegs. Other sheep developed a short, prancing gait.⁵³⁵ Cattle have been reported to develop diarrhea after 12 hours, followed by salivation, ataxia, and stiffness.⁵³⁶ Gross lesions include myocardial degeneration, subcutaneous hemorrhages, and liver congestion. Histopathologic examination demonstrated focal degenerative myocardiopathy and mild nonsuppurative encephalitis.^{535,536} Rumen papillae are edematous and the reticulum, rumen, and omasum may contain black pigment.⁵³⁶

Triazine herbicides have no antidote, but treatment with activated charcoal once daily for 4 consecutive days after exposure has reportedly decreased lesions and death loss.⁵³⁶

RODENTICIDES AND OTHER PESTICIDES

Anticoagulant Rodenticides

Toxicosis can result from anticoagulant rodenticides when animals ingest baits made with anticoagulants. These products are often incorporated into grains or pellets that are palatable to livestock. Toxicosis also has been reported in horses that have been overdosed with warfarin, which has been used as a treatment for navicular disease and jugular phlebitis.^{537,538}

First-generation compounds such as warfarin were developed originally, but rodents developed a resistance to these over time. The second-generation compounds, such as brodifacoum and bromadiolone, were created for rats that had developed a resistance to the first-generation compounds.⁵³⁹⁻⁵⁴¹ In general, the second-generation compounds are more toxic and have longer half-lives.

All anticoagulant rodenticides function by interfering with vitamin K-epoxide reductase, the enzyme that converts inactive vitamin K to its active form. This interference results in a depletion of active vitamin K and subsequently the vitamin K-dependent clotting factors (II, VII, IX, and X). Factor IX is in the intrinsic coagulation pathway, factor VII is in the extrinsic pathway, and factors II and X are in the common pathway. Therefore, all three pathways are affected.^{539,540}

Clinical signs may not be noticed until 3 to 5 days after ingestion. Affected animals may exhibit melena, epistaxis, hematuria, or excessive bleeding from a wound or injection site.⁵⁴⁰ Often the hemorrhaging occurs in body cavities, and the animal may show nondescript clinical signs such as depression, weakness, pallor, colic, dyspnea, or fever, depending on the location and extent of hemorrhage.^{539,540} Sometimes the onset is acute, and the animal dies suddenly from extensive hemorrhage and shock.⁵³⁹ Gross and histopathologic lesions primarily consist of unexplained hemorrhage, which may be generalized or localized.

Warfarin is almost completely absorbed from the GI tract of horses and has a biologic half-life of 13.3 hours, similar to that in other species.⁵³⁸ Warfarin is mostly bound to plasma protein, and only the unbound drug is toxic. Therefore, concomitant use of other protein-bound drugs, such as phenylbutazone, can increase the risk of warfarin-induced hemorrhage.^{537,542}

Diagnosis of anticoagulant toxicosis is based on history, clinical signs, clinical pathology, and response to treatment. The degree of anemia resulting from hemorrhage varies with the time since ingestion of the toxicant and severity of disease. A coagulation panel will reveal prolongation of prothrombin time (PT), partial thromboplastin time (PTT), and activated coagulation time (ACT).^{540,543} The

fibrinogen, fibrinogen degradation products, and platelet count are not directly affected by the anticoagulants.

Determining which anticoagulant rodenticide was ingested is difficult in the live animal. Levels are often too low in blood to be detected. Postmortem detection is most promising in the liver. Although GI contents can be tested, the chemical is often completely absorbed before clinical signs appear or death occurs.

Vitamin K₁ is the treatment for all the anticoagulant rodenticides. The duration of treatment, however, depends on the specific compound because the half-life varies considerably. Warfarin has the shortest half-life of the anticoagulants (13.3 hours in the horse).⁵³⁸ The half-lives of the other compounds have not been determined in the horse, but diphacinone has a half-life of 15 to 20 days in humans. Therefore, warfarin toxicosis may require treatment for only a few days, whereas toxicosis from the other compounds may have to be treated for several weeks. Vitamin K₁ treatment for an adult horse has been recommended at a dose of 300 to 500 mg SC every 4 to 6 hours.⁵³⁷ The PT should return to normal within 24 hours. To monitor duration of treatment after the animal has stabilized, vitamin K should be discontinued for 48 hours and the PT retested.⁵³⁹ Intravenous injection of vitamin K has been associated with anaphylactoid reactions, and intramuscular injection can aggravate hemorrhage. Oral treatment is advocated for small animals but may be cost-prohibitive for large animals. Vitamin K₃ is less expensive but not as effective and will cause renal disease in horses.

Clotting factor synthesis requires 6 to 12 hours; therefore animals may need to be transfused with whole blood if anemic, or with fresh plasma if the anemia is not severe enough to warrant blood transfusion.⁵³⁹ Once the packed cell volume (PCV) begins to decrease, it can continue to decrease at a rapid pace, so it should be monitored regularly. Activated charcoal can be given orally to decrease absorption of rodenticides.

Strychnine

Strychnine is used for mammals such as rats, gophers, moles, squirrels, and coyotes. Strychnine is sold as a powder, as pellets, or as treated seeds that are usually dyed bright green or red. Strychnine poisoning was reported in four horses that had eaten milo treated with it. Use of strychnine is restricted in some states to professionals or registered individuals; however, toxicosis in domestic animals still occurs.⁵⁴⁴

Strychnine competitively blocks glycine, the transmitter for inhibitory cells (Renshaw cells) of the spinal cord. This lack of inhibition results in rigidity and tetanic convulsions. Clinical signs include sweating, incoordination, recumbency, and tonic clonic seizures that are inducible by loud sounds, touch, or bright light. Signs appear 10 minutes to 2 hours after ingestion. Gross and histopathologic lesions are limited to those attributable to self-induced trauma.⁵⁴⁴

Diagnosis of strychnine toxicosis is based on clinical signs and detection of the toxicant in urine or serum. Urine is a good diagnostic sample because strychnine is absorbed from the GI tract and excreted in the urine. Stomach contents, liver, kidney, and urine should be collected postmortem and analyzed for strychnine.⁵⁴⁴

A lethal dose of strychnine can be eliminated in 24 to 48 hours. Because strychnine is an alkaloid, it becomes ionized in the acid of the stomach and is not absorbed until it reaches the intestine. Activated charcoal is a good treatment to prevent further absorption of the toxicant. Seizures should be treated with anticonvulsants and rigidity with muscle relaxants. Animals should be protected from excessive light and sound to reduce the incidence of convulsions.

Zinc Phosphide

Zinc phosphide is used to control mice, ground squirrels, rats, and moles. Zinc phosphide is a dark-gray powder that is mixed with grains such as bran, wheat, and oats. Therefore it is palatable to most livestock. The lethal dose for most animals is 20 to 40 mg/kg of body weight.⁵⁴⁵

Zinc phosphide produces phosphine gas under acidic conditions. Therefore, toxicosis occurs when the rodenticide comes into contact with an acidic stomach. Gastric acidity is an important factor in phosphine gas production. Ruminants should be more resistant because the rumen has a higher pH than a monogastric stomach. Studies show a higher survival rate in dogs that are dosed with zinc phosphide on an empty stomach rather than dosed after a meal when the stomach has a lower pH.⁵⁴⁵

Zinc phosphide affects the CNS, and clinical signs are similar to those caused by other toxicants, such as strychnine or the anticholinesterase insecticides.⁵⁴⁵ Gross and histopathologic lesions are not specific, although the GI and pulmonary systems may be red and irritated. Thus, diagnosis is difficult without chemical analysis.

Diagnosis of zinc phosphide toxicosis is based on detecting phosphine gas in the stomach contents. Because the gas dissipates rapidly in air, the collected sample of stomach contents should be placed in an airtight container and frozen immediately.⁵⁴⁵

Treatment is mostly supportive care following activated charcoal therapy. Food should be withheld until the zinc phosphide has been emptied from the stomach. It may be helpful to add an antacid to the activated charcoal therapy to reduce the amount of phosphine gas produced.

Metaldehyde

Metaldehyde is a tasteless ingredient used in slug and snail baits and as a solid fuel for some camp stoves.⁵⁴⁶ Baits may be liquid or dry, but most are dry pellets of metaldehyde mixed with soybeans, rice, oats, sorghum, or apples.^{546,547} Some baits also contain other toxicants, such as arsenate or insecticides, which can cause concurrent disease. Toxicosis occurs mostly in coastal and low-lying areas where there is a high incidence of snails or slugs.⁵⁴⁷

The mechanism of metaldehyde toxicosis is unknown.⁵⁴⁶ It may increase excitatory neurotransmitters or decrease inhibitory neurotransmitters.^{546,547}

Clinical signs can occur immediately or can be delayed for up to 3 hours after ingestion. Affected animals will have convulsions, which may be continuous or intermittent. The animal may have muscle tremors and anxiety and may be hyperesthetic between convulsions. The seizures are not necessarily evoked by external stimuli. Elevated body temperature, up to 43° C (110° F), is a common finding and is probably caused by the excessive muscle activity. Other findings include tachycardia, defective vision, hyperpnea, hypersalivation, ataxia, cyanosis, acidosis, diarrhea, and dehydration. Death usually results from respiratory failure and occurs 4 to 24 hours after ingestion. Gross and histopathologic findings include petechiae and ecchymoses of various organs and subcutaneous edema.⁵⁴⁸⁻⁵⁵⁰

A diagnosis is based on testing for metaldehyde in GI contents or serum.⁵⁵¹ Milk samples taken within 24 hours from two affected cows tested negative for metaldehyde.⁵⁵² No antidote is available.^{552,553} Administration of oral activated charcoal may prevent further absorption from the GI tract. If the animal is convulsing, tranquilizers should be used to control seizures. Tranquilizers should be allowed to wear off periodically and the convulsive condition reevaluated. Horses have been treated successfully with tranquilizers and mineral oil.⁵⁵⁴

INDUSTRIAL TOXICANTS

Petroleum

Animals can become exposed to petroleum hydrocarbons during crude oil spills, pipeline breaks, or careless disposal of automobile or tractor oil. Most cases of petroleum toxicosis occur when the animal's water supply is contaminated.⁵⁵⁵

Clinical signs vary but usually include anorexia, depression, GI stasis, bloat, and diarrhea or constipation. Oil may be seen in the feces within days after ingestion. The most common cause of death is aspiration pneumonia after regurgitation of the hydrocarbons. The petroleum product may be seen around the muzzle of the animal. Oil may be found in the GI tract or the lungs at postmortem examination.

Diagnosis of petroleum toxicosis can be made based on history, clinical findings, and detection of hydrocarbons in tissues. The product may be visible on the animal as well as in the GI contents and lungs. A quick method of checking for oil is to place the GI contents or lung in warm water; the oil should float to the top of the water. Samples also can be checked under a black light because many petroleum products will fluoresce yellow or yellow-green. Liver, kidney, lung, and GI contents can be analyzed for hydrocarbons and matched with available source material.⁵⁵⁵ Collecting suspect source material is especially important because these toxicoses may become legal cases.

The primary aim of treatment is to prevent aspiration pneumonia, which is best achieved by performing a rumenotomy and removing the contaminated ingesta. If surgery is not feasible, activated charcoal should be administered. The charcoal should be followed with a cathartic to enhance removal of the oil. Supportive care is needed for the GI stasis and diarrhea or constipation. Vegetable oil (500 to 1000 mL) may increase the viscosity of the ingested petroleum within the rumen and reduce the occurrence of aspiration pneumonia. The prognosis is generally good unless the animal aspirates or severely bloats.⁵⁵⁵ Some petroleum products may contain heavy metals such as lead, and a concurrent metal toxicosis can occur.

Ethylene Glycol

The most common cause of ethylene glycol toxicosis is ingestion of antifreeze. Although cats and dogs are the species most often affected because of their proximity to available sources, ethylene glycol toxicosis has occurred in cattle and goats.⁵⁵⁶ Some new brands of antifreeze contain propylene glycol rather than ethylene glycol. Although much less toxic than ethylene glycol, propylene glycol can still cause toxicosis.

Ethylene glycol is metabolized in the liver to several metabolic intermediates, especially glycolic acid. This reaction is catalyzed by alcohol dehydrogenase. Glycolic acid results in metabolic acidosis and hyperosmolality in the animal. This metabolite can be excreted or further metabolized into oxalic acid, which combines with ionic calcium and causes hypocalcemia and calcium oxalate formation, especially in kidneys. Ruminants may be more resistant to ethylene glycol toxicosis than monogastrics because the rumen microorganisms can metabolize some ethylene glycol before it is absorbed.^{556,557}

Toxicosis results in an initial inebriation, followed by metabolic acidosis and renal damage.⁵⁵⁷ Clinical signs in ruminants include ataxia, depression, hypersalivation, and absence of a menace response. These signs progressed to recumbency and clonic-tonic seizures in a pygmy goat.⁵⁵⁶ Clinical pathology reveals azotemia, metabolic acidosis, and hyperosmolality. Postmortem findings include swollen

kidneys and pulmonary edema. Dilated capsular spaces and birefringent crystals are found in renal tubules on histologic examination. These crystals may be arranged in sheaves or rosettes and are typical of oxalate crystals.⁵⁵⁶

Rumen or stomach contents can be analyzed for ethylene glycol. It is absorbed within 48 hours after ingestion by monogastrics; however, ethylene glycol has been detected in the rumen contents of a goat 4 days after clinical signs began.⁵ Urine, serum, and ocular fluid can also be analyzed for glycolic acid.

The classic treatment for ethylene glycol toxicosis is 20% ethanol given at 5 ml/kg at 4- to 8-hour intervals. The ethanol binds with the alcohol dehydrogenase so that it is not available to convert ethylene glycol to glycolic acid. This treatment is effective, however, only if initiated within a few hours of ingestion. The effectiveness of ethanol in treating livestock has not been addressed in the literature. Because the ethylene glycol appears to remain in the rumen for several days, treatment with activated charcoal may be beneficial even after the appearance of clinical signs.⁵⁵⁶

Chlorinated Naphthalene

Chlorinated naphthalene has been used in wood preservatives, asphalt roofing, insulating waxes, sealing compounds, and in condensers. Most toxicoses in cattle, however, have been from ingesting lubricating grease used on farm machinery or feed-pelleting machines. Chlorinated naphthalene is no longer used in lubricants, but toxicosis still occurs when animals have access to dumps and salvage yards. The toxic forms are tetra-, penta-, hexa-, hepta-, and octachloronaphthalenes, with the hexa and hepta forms being the most toxic.⁵⁵⁸

Chlorinated naphthalene interferes with the conversion of carotene to vitamin A. Serum vitamin A levels decrease significantly a few days after exposure and remain decreased for at least 4 weeks.⁵⁵⁸

Initial clinical signs include weight loss, anorexia, and depression. Excessive salivation and lacrimation occur because of the formation of papular stomatitis and keratinization of the meibomian glands. Several weeks later, nonpruritic thickening and fissuring of the skin occur. Hyperkeratosis involves the withers, neck, head, trunk, and medial thighs; but usually does not involve the lower legs. Diarrhea may occur late in the disease. Postmortem findings include epithelial hyperplasia or metaplasia of the gallbladder, bile ducts, salivary glands, pancreas, and genital tract.⁵⁵⁸

Diagnosis is based on clinical signs and a low vitamin A level. Suspected source material can be analyzed for chlorinated naphthalene. Treatment with vitamin A may minimize some clinical signs, but treatment of this toxicosis is usually unsuccessful, especially after the appearance of skin lesions.⁵⁵⁸

Pentachlorophenol

Pentachlorophenol (PCP) is used primarily as a wood preservative. Residues have been found in cattle exposed to wood troughs, silos, barns, and fences treated with PCP. Horses have developed toxicosis when bedded on wood shavings that contain PCP.⁵⁵⁹⁻⁵⁶¹

The primary mechanism of action is uncoupling of oxidative phosphorylation.^{559,561} PCP is quickly absorbed from the GI tract and excreted in the urine. It is stored mainly in the liver and kidney and acts as a mild hepatotoxin.⁵¹⁰ The half-life in cattle is 1.5 days.⁵⁵⁹

Acute clinical signs in cattle include weight loss, depression, anorexia, intense thirst, and decreased milk production.^{559,560} Chronic signs in cattle are dyspnea, hyperkeratosis, liver damage, and increased abortion rate.⁵⁵⁹ Horses have anorexia,

dependent edema, weight loss, and alopecia. The skin has cracks and fissures that exude serum. Clinical pathology reveals hepatic changes, anemia, and thrombocytopenia. Horses also may develop colic or recurrent hoof problems.⁵⁶¹

Liver, kidney, and serum can be analyzed for PCP. Because of the rapid rate of excretion, serum PCP concentrations may be useful only during acute toxicosis.⁵⁶¹ No antidote exists, and treatment is usually unsuccessful. Residues may be a concern, especially from dioxin-related contaminants in the "penta"-treated wood.

Phosphatic Fertilizers

Phosphatic fertilizers selectively promote legume instead of grass growth. Therefore these are popular fertilizers for maintaining subterranean clover pastures. The major components of phosphatic or superphosphate fertilizers are calcium pyrophosphate, calcium orthophosphate, calcium sulfate, and sodium fluoride. Toxicosis is believed to be a result of the phosphate and fluoride. It usually occurs after a short pasture has been top-dressed recently.⁵⁶² The fertilizer is not usually palatable, except to ravenous animals.

Sheep have developed ataxia, bruxism, depression, and diarrhea. Animals will be hypocalcemic, probably because of renal failure. Hyperphosphatemia does not occur until oliguria develops and the animal is near death. Gross lesions include hyperemic GI mucosa, pulmonary edema, and bloody intestinal contents. Histopathologic examination reveals acute proximal renal tubular necrosis.⁵⁶²

Diagnosis is based on history, clinical signs, and lesions. Treatment is limited to supportive care, which is generally successful if the disease is diagnosed early.⁵⁶²

Boron Fertilizer

Sodium borate is mildly toxic, and clinical signs may not be seen in ruminants until they consume a near-lethal dose. Toxicosis usually occurs only if animals eat concentrated fertilizer.⁵⁶³ The mechanism of action is unknown, but boron may have a stimulatory effect on serotonergic and dopaminergic neurons.⁵⁶⁴

Reported clinical signs in cattle include weakness, depression, muscle fasciculations, seizures, and a spastic gait. Most animals develop diarrhea and become dehydrated. Gross and microscopic lesions are not seen.⁵⁶³ Goats that were given a sublethal dose of boron developed anorexia and depression. Seizure-like activity consisted mostly of ear flicking and chomping motions; however, tremors, stargazing, head jerking, and extensor rigidity also were noted.⁵⁶⁴

Liver, kidneys, and rumen contents can be analyzed for boron content.⁵⁶³ Treatment is limited to supportive care.

THERAPEUTIC AGENTS

Vitamin K₃

Vitamin K₃ is the synthetic vitamin menadione sodium bisulfite. It has been used as a treatment for anticoagulant rodenticide toxicosis, sweet clover (dicumarol) toxicosis, and exercise-induced pulmonary hemorrhage. Its popularity stemmed from being much less expensive than vitamin K₁. Studies demonstrate, however, that vitamin K₃ is not an effective treatment for sweet clover disease in cattle.⁵⁶⁵ Furthermore, case reports indicate that vitamin K₃ is toxic to horses, even when used at the manufacturer's recommended dose.⁵⁶⁶⁻⁵⁶⁸

The mechanism for the toxicosis is unknown. Within 4 to 48 hours of administration of vitamin K₃, horses become

depressed, anorexic, and weak. They may develop muscle stiffness, laminitis, or colic.⁵⁶⁶ The horses develop renal failure as evidenced by increased BUN and creatinine concentrations. Proteinuria, hematuria, and low specific gravity are found on urinalysis. Serum electrolyte levels are consistent with renal tubular disease: hyponatremia, hypochloremia, and hyperkalemia. Some patients develop hypercalcemia.⁵⁶⁸ Grossly, the kidneys are enlarged.⁵⁶⁶ Microscopically, the kidneys have nephrosis with tubular dilation, epithelial degeneration, and necrosis.⁵⁶⁸ Diagnosis is based on history, clinical signs, and lesions. Treatment should include diuretics and maintenance of serum electrolyte concentrations.⁵⁶⁷

Propylene Glycol

Propylene glycol is used as a vehicle for drugs with poor water solubility, for treatment of bovine ketosis, and in some new antifreeze products.⁵⁶⁹ Toxicosis has been reported when cows are overdosed or when horses are accidentally dosed with propylene glycol.^{569,570}

The median toxic dose of propylene glycol in cattle is 2.6 g/kg body weight.⁵⁷⁰ Ataxia develops in 2 to 4 hours and resolves by 24 hours after dosing. The cattle also become depressed and temporarily recumbent. Serum and cerebrospinal fluid osmolality increase.⁵⁷⁰

A horse mistakenly given propylene glycol rather than mineral oil developed ataxia and depression in 10 to 15 minutes. The horse also developed pain, excessive salivation, and sweating, but these signs disappeared within 5 minutes. The animal developed rapid, shallow breathing and cyanosis and died of respiratory distress the next day.⁵⁶⁹ Gross lesions were not seen. Histopathologic findings included myocardial perivascular edema, pulmonary edema, scattered hepatocyte necrosis, and peracute renal infarcts.⁵⁶⁹

Serum and urine can be analyzed to determine the presence of propylene glycol.^{569,570} Propylene glycol causes lactic acidosis in humans, which is treated with sodium bicarbonate. This treatment was unsuccessfully used in the horse described here⁵⁶⁹; if acidosis occurs, however, sodium bicarbonate may be beneficial if the disease is treated early.

Isopropyl Alcohol

Isopropyl alcohol is used as a topical antibacterial agent. When ingested, it is quickly absorbed from the GI tract and metabolized into acetone by the liver through alcohol dehydrogenase. The majority of the acetone is excreted by the kidney and to a lesser extent by the lungs.⁵⁷¹

Toxicosis in a horse was reported when 2 L of alcohol was mistaken for mineral oil and administered by nasogastric tube. Initially the horse was depressed and reluctant to move before collapsing and becoming semicomatose. A menace response was not detected, and pupillary light reflexes were slow. Treatment consisted of repeated gastric lavage with 2-L aliquots of warm water, followed by activated charcoal and intravenous fluids. Activated charcoal was repeated the following day, and the horse recovered from the incident. However, the odor of acetone could be detected on the horse's breath for about 4 days, and acetone was detectable in the horse's serum during this time.⁵⁷¹

Phenothiazine

This anthelmintic combined with piperazine and carbon disulfide has been used for horses in the past.^{572,573} Phenothiazine currently is being manufactured for horses in combination with piperazine and trichlorfon. Phenothiazine

also has been used in mineral blocks and protein supplements for ruminants.⁵⁷⁴ Phenothiazine is toxic to both horses and ruminants but causes different diseases.

RUMINANTS. Phenothiazine causes primary photosensitization in ruminants. The rumen converts phenothiazine to a phototoxin, phenothiazine sulfoxide. This toxic metabolite can be converted by the liver to a nontoxic metabolite, leukophenothiazine; if the liver is overwhelmed, however, toxicosis can occur. Most cases occur in debilitated or young animals that do not have a fully functional liver.⁵⁷⁴

Clinical signs begin as erythema and edema combined with varying degrees of pruritus, photophobia, and pain. Vesicles and bullae form and progress to oozing, necrosis, and ulceration of the skin. These lesions are usually confined to areas that have white pigmentation or have little hair and are exposed to sunlight. The tail, ears, teats, feet, or ventral surface of the tongue may slough. The skin of black cattle does not usually slough, but these animals can develop epiphora, corneal edema, and blindness because the phototoxin is also secreted in tears and aqueous humor.^{574,575}

Diagnosis is based on the history of phenothiazine consumption and the skin lesions. A skin biopsy may be helpful but usually is not necessary because the lesions are uniquely confined to lightly pigmented skin.

No antidote exists for phenothiazine toxicosis, and treatment is limited to supportive care. Antibiotics may be needed to treat secondary bacterial infections of the skin. Antiinflammatory drugs may be indicated for pain. When prescribing drugs for ruminants with photosensitization, those that can compromise the liver should be avoided. Affected animals should be housed and fed in areas out of direct sunlight to prevent further damage to the skin.

HORSES. Phenothiazine acts as an oxidant to produce hemolytic anemia in horses. Heinz bodies (precipitated denatured hemoglobin) damage the red blood cell membrane, which results primarily in intravascular hemolysis. Toxicosis has been noted primarily in horses that are in poor condition before exposure to the phenothiazine.⁵⁷⁶ Primary clinical signs include anorexia, depression, weakness, icterus, anemia, and hemoglobinuria.^{572,573} Colic, diarrhea, fever, and dependent edema are less frequently reported clinical signs.⁵⁷⁶ Clinical pathology reveals anemia and elevated indirect bilirubin levels.⁵⁷⁶

Diagnosis is based on a history of exposure to phenothiazine and ruling out other causes of hemolytic anemia in the horse. Treatment is basically supportive. A blood transfusion may be necessary if the anemia reaches a critical level.⁵⁷⁶

FEED ADDITIVES

Urea and Nonprotein Nitrogen

Nonprotein nitrogen (NPN) products are converted by ruminal microorganisms to ammonia, which is used to form amino acids. Therefore, ruminants can use the nitrogen from NPN for part of their diet rather than the more expensive natural proteins. Urea is the best known source of NPN, and it is also the most toxic.⁵⁷⁷

Toxicosis can result from overexposure or loss of acclimation to NPN. Too much NPN may be fed to animals because of a miscalculation or by contamination. Urea toxicosis has been reported in cattle that drank from a water source that was contaminated with urea fertilizer.⁵⁷⁸ Ruminants acclimate to NPN in their diets through the ruminal microorganisms. Animals that have been acclimated to a certain level of NPN in their diets and then go without NPN for more than 1 day can develop toxicosis. Ruminants

quickly lose their adaptation to NPN, and toxicosis can occur when urea consumption resumes, even if NPN is fed at the same level as previously.

Ammonia that is not used by the ruminal microorganisms is absorbed from the rumen and detoxified by the liver back into urea for excretion. Toxicosis occurs when the microorganisms and the liver are overwhelmed by the level of ammonia.⁵⁷⁷⁻⁵⁷⁹ As the ammonia level increases in the rumen, the ruminal pH increases and creates a shift from charged ammonium ions to uncharged ammonia. The uncharged ammonia is absorbed readily across the rumen wall and increases the ammonia level in the blood.⁵⁷⁷

Clinical signs begin 30 minutes to 4 hours after ingestion of NPN and include weakness, dyspnea, salivation, bruxism, bloat, and convulsions. Because death can occur in a few hours, some animals may be found dead with no clinical signs observed. The rumen pH will be greater than 8.0 with NPN toxicosis. Rumen pH can decrease with time after death, so the pH should be determined on a recently dead animal.^{577,579}

Diagnosis can be made by analyzing rumen contents, whole blood, or an eye for ammonia. Because ammonia is volatile, the samples should be frozen immediately after collection. Feed material and rumen contents can be analyzed for urea. Urea concentration in the rumen may not be indicative of the amount that was eaten because the microorganisms continue to convert urea to ammonia even after the animal has died. Therefore, a diagnosis should not be based solely on the urea level in the rumen, but in conjunction with the ammonia levels in the animal.

Treatment focuses on decreasing the amount of ammonia absorbed from the rumen. Adult cattle should be given 20 to 30 L of cold water orally to reduce the microorganisms' ability to convert urea to ammonia. These animals also should receive 2 to 6 L of 5% acetic acid (vinegar) to decrease the pH in the rumen so that ammonia absorption is minimized.⁵⁷⁷ Rumenotomies can be used to remove the excess NPN source.

To prevent toxicosis, NPN in feed should not exceed 40% of the total nitrogen requirement, and the animals should be acclimated slowly to NPN. Urea should not be fed at a concentration higher than 3% of the grain ration or 1% of the total ration.⁵⁷⁷

Ammoniated Feed

Molasses, hay, and silage can be treated with aqueous or anhydrous ammonia to increase the dietary quality for ruminants. Under certain conditions, these ammoniated feeds can cause "bovine bonkers," a disease characterized by hyperexcitability. Treatment conditions that predispose to the occurrence of the toxicosis are ammoniating feedstuffs with more than 20% moisture, treating feedstuffs that contain ample soluble sugars, overapplying the ammonia, or treating the forage during high ambient temperatures. High-quality hays, such as wheat, Sudan, alfalfa, orchardgrass, Bermuda grass, fescue, and sorghum, contain high levels of soluble sugars and are more often incriminated in toxicosis than are low-quality hays such as corn stalks, corn silage, and most small grain straws.⁵⁷⁷

The mechanism of bovine bonkers is not completely understood. Pyrazines and imidazoles are the primary byproducts formed during ammoniation. The two major imidazoles that are formed, 2-methylimidazole (2-me-I) and 4-methylimidazole (4-me-I), cause convulsions in mice, with 4-me-I being more potent. Administration of 4-me-I has experimentally reproduced the disease in a nursing cow without affecting the calf.⁵⁷⁷ Nursing calves in field cases have developed the disease,^{580,581} even though

the dams did not. However, when orally dosed with 4-me-I, cows developed the disease but the calves did not, despite the imidazole being detected in the milk and colostrum.⁵⁸² Therefore, more work is needed regarding the mechanism of this disease.

The most striking clinical sign is hyperexcitability, which can occur spontaneously or can be induced by excitement. Animals will suddenly stampede and run in circles or in a straight line while they collide with other animals or with buildings and fences. Other clinical signs include ear twitching, mydriasis, trembling, salivation, increased urination, increased defecation, and bellowing. Gross lesions are not significant other than bruising and broken bones that are self-inflicted.^{577,580,583}

Diagnosis is based on clinical signs and a history of feeding ammoniated feed. Treatment is limited to sedation of animals.⁵⁸¹ Thiamine also has been used as a treatment, with variable results.⁵⁷⁷ It is often not possible to approach an affected animal to treat it without endangering the handler. Most animals recover spontaneously once the ammoniated feed source is removed.

Prevention of ammoniated toxicosis focuses on properly treating the feed. Only poor-quality roughages with low levels of soluble sugars should be ammoniated. The amount of ammonia used should not exceed 3% of the dry weight of the forage. Ammoniate only during cool weather so that the processing temperature of the forage is less than 70° C (158° F).^{577,580}

Ionophores

Ionophore antibiotics are used as coccidiostats and feed additives for poultry and cattle. Ionophores alter the rumen so that a higher level of propionic acid is produced for improved feed efficiency. They also are used to prevent rumen acidosis and emphysema in cattle.⁵⁸⁴⁻⁵⁸⁸ Toxicosis can result from calculation or mixing errors or from use in inappropriate species. Cattle and sheep have been poisoned by ingesting litter from poultry that had been treated with an ionophore.⁵⁸⁹

Ionophores form lipid-soluble complexes with cations to facilitate transport of the cations across lipid membranes. The monovalent ionophores are monensin, salinomycin, and narasin. Monensin preferentially complexes with sodium ions, whereas salinomycin and narasin preferentially bind with potassium ions. Lasalocid is a divalent

ionophore that binds with divalent cations, such as calcium and magnesium ions.^{585,587}

Horses are the most sensitive species to the ionophore antibiotics.^{586,590} The recommended dose of monensin for cattle can be lethal to a horse. Acute clinical signs in horses include colic, anorexia, weakness, and ataxia.⁵⁸⁶ Creatinine phosphokinase (CPK) significantly increases within 24 hours; AST and serum ALP activities are increased to a lesser degree.⁵⁸⁶ Unconjugated serum bilirubin will be slightly but consistently increased. Erythrocyte fragility increases.⁵⁹⁰ Serum enzymes can be used diagnostically but are poor prognostic indicators.⁵⁹¹ If the animal dies peracutely, significant gross lesions may not be present. Acutely affected horses develop degeneration and necrosis of the cardiac muscle and to a lesser degree the skeletal muscles.⁵⁸⁷

If horses survive the acute episode of toxicosis, they often experience delayed toxicosis because of permanent damage to the heart. These animals have marked cardiac myopathy and fibrosis.⁵⁸⁸ The most noticeable clinical sign is exercise intolerance, and affected animals may collapse and die during exercise, making them hazardous to use as riding horses.

Whereas the heart is the most affected organ in horses, ionophores damage the cardiac and skeletal muscles more equally in ruminants.⁵⁸⁷ Clinical signs in feedlot cattle include anorexia, pica, diarrhea, hindlimb ataxia, and dyspnea. These animals have postmortem lesions of hydrothorax, ascites, and pulmonary edema besides hemorrhages and necrosis of the cardiac and skeletal muscles.⁵⁹² Signs of weakness, increased respiratory rate, nasal discharge, and reddened noses have been reported in dairy calves. Postmortem examination revealed pulmonary edema accompanied by pleural and peritoneal effusions. The hearts had myocardial necrosis.⁵⁸⁵ Sheep reportedly develop depression, anorexia, diarrhea, and stiffness. CPK and AST activities are increased. Necrosis of the heart and diaphragm has been reported.⁵⁸⁴

Diagnosis relies on finding appropriate clinical signs and lesions. Currently, analysis for ionophores in tissue or serum is not reliable; however, the feed source can be analyzed for ionophores.⁵⁸⁷

Antidotes for ionophores are not available.^{586,587} Mineral oil or activated charcoal may decrease further absorption of the toxicant. Large volumes of intravenous fluids are needed to treat dehydration and shock.⁵⁸⁶ Serum electrolyte levels should be monitored frequently and fluid electrolytes adjusted accordingly.

- Temperature, elevated, 33
- Temperature, subnormal, 40
- Thorax, splinting, 29
- Treading, 104
- Tremors, intention, 139
- Udder edema, 215
- Ulcerations and erosions, skin, 186
- Ulcers or growths, oral, 112
- Urachal leakage of urine, 177
- Uremia, 177
- Urinary incontinence, 170
- Venous distention or pulsations, 91
- Vesicles, pustules, and papules, skin, 186
- Vocalization, abnormal, 122
- Vomiting, 109
- Weight gain, decreased, 147
- Weight loss, 156

MANIFESTATIONS OF DISEASE IN THE NEONATE

- Anemia, 322(f), 364(r)
- Apgar score, low, 266(f)
- Asphyxia, 253
- Assessment of fetal viability, 250
- Assessment of the mare during late gestation, 243
- Bacterial infection, treatment, 330
- Basic fluid therapy, 326
- Cyanosis, 323(f), 365(r)
- Diarrhea in foals, 315
- Diarrhea in neonatal ruminants, 340
- Distended or painful abdomen, 306(f), 339(r)
- Effects of placental insufficiency, 246
- Failure to thrive—cachexia and weak calf syndrome, 366
- Fever, 322(f), 365(r)
- Fluid and drug therapy, 326
- Heart murmur, 324(f), 366(r)
- High-risk neonatal foal, 243, 262
- Icterus, 322(f), 366(r)
- Induction of parturition, 247(f), 250(r)
- Lameness and reluctance to walk, 319(f), 363(r)
- Management of the high-risk, late-gestation mare, 247
- Nutritional support, 328
- Oliguria and stranguria, 323
- Patent urachus, omphalitis, and other umbilical abnormalities, 321(f), 364(r)
- Perinatal adaptation, 252
- Peripartum ruminant, 248
- Physical examination, 264(f), 275(r)
- Postpartum care, 274(r)
- Prematurity, 247(f), 250(r)
- Prevention of infections, 329
- Respiratory distress, 301(f), 336(r)
- Respiratory support, 330
- Resuscitation, 258
- Seizures, 299(f)
- Sepsis, 282
- Sepsis score, positive, 284
- Supportive care, 325
- Umbilicus abnormal on ultrasound, 270(f)
- Weakness (paresis) and/or depression, 298(f), 366(r)

Normal Values for Erythron Data in Ruminants and the Horse

	Cattle	Sheep	Goats	Horses
PCV (%)	24-46	27-45	22-38	32-53
Erythrocytes ($\times 10^6/L$)	5-10	9-15	8-18	6.7-12.9
Hemoglobin (g/dL)	8-15	9-15	8-12	11-19
MCV (fl)	40-60	28-40	16-25	37-58.5
MCH (pg)	11-17	8-12	5.2-8	12.3-19.7
MCHC* (g/dL)	30-36	31-34	30-36	31-38.6
Reticulocytes	0	<0.5%	0	0
Erythrocyte diameter (m)	4-8	3.2-6	2.5-3.9	5-6
Erythrocyte fragility (percent NaCl)				
Minimum (beginning hemolysis)	0.52-0.66	0.58-0.76	0.74	0.54
Maximum (complete hemolysis)	0.44-0.52	0.40-0.55	0.44	0.34
Erythrocyte sedimentation rate (mm/1 hour)	0	1-2.5	0	50-60
Erythrocyte life span (days)	160	140-150	125	140-150

MCH, Mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; PCV, packed cell volume.

Normal Values for Leukogram Data (Adult Animals)

	Cattle	Sheep	Goats	Horses
White blood cells ($\times 10^3/\mu L$)	4-12	4-12	4-13	5.4-14.3
Neutrophils ($\times 10^3/\mu L$)	0.6-4	0.7-6	1.2-7.2	2.3-8.6
Bands ($\times 10^3/\mu L$)	0-0.12	Rare	Rare	0-1
Lymphocytes ($\times 10^3/\mu L$)	2.5-7.5	2-9	2-9	1.5-7.7
Monocytes ($\times 10^3/\mu L$)	0.025-0.84	0-0.75	0-0.55	0-1
Eosinophils ($\times 10^3/\mu L$)	0-2.4	0-1	0.05-0.65	0-1
Basophils ($\times 10^3/\mu L$)	0-0.2	0-0.3	0-0.12	0-0.29
Neutrophil/lymphocyte (N:L) ratio	0.3-0.6	0.3-0.7	0.6-3.6	0.8-2.8

Normal Values for Hemostatic Data in Ruminants and the Horse

	Cattle	Sheep	Goats	Horses
Platelet count ($\times 10^3/L$)	100-800	250-750	300-600	100-600
Fibrinogen (mg/dL)	200-500	100-500	100-400	200-400
Prothrombin time (s)	22-55	—*	9.5-12.5	7-9
Activated partial thromboplastin time (s)	44-64	—	28-52	37-54
Fibrin/fibrinogen degradation products ($\mu g/mL$)	<8	<8	—	<32
